In a recent issue of *Proc. natn. Acad. Sci. U.S.A.* (**73,** 3428–3432; 1976) Strom and Dorfman offer new data which more directly supports this theory and which suggests a specific mechanism by which such intermediate repetitive sequences in the DNA may control differentiation. They use the chick limb bud system in which chick stage 24 limb bud mesenchymal cells are dissociated and cultured *in vitro* at high density. Once the cell density becomes greater than confluency these cells differentiate into cartilage unless the thymidine analogue 5-bromo-2′-deoxyuridine (BUdR) is present at a concentration of 32 mM during the initial 48 h of culture in which case differentiation is irreversibly inhibited. In this study DNA was prepared from early cultures of these limb bud cells grown in ^{3}H-BUdR. The reassociation rate of this DNA was then measured after shearing and in the presence of a 100-fold excess of DNA prepared from cells at various stages of cartilage differentiation or from liver tissue or from whole chick embryos. These experiments show that sternal cartilage DNA and 8-day cultured limb bud cartilage DNA drive the reassociation reaction about twice as fast as does liver DNA or undifferentiated limb bud DNA or DNA from 8-day limb bud cultures blocked from differentiation by BUdR treatment. Furthermore, by analysing the reassociation kinetics of these reactions Strom and Dorfman determine that the total percentage of the tritium which reannealed in the moderately repetitive fraction was lower in liver DNA (20%) than in sternal cartilage DNA (30%), 8-day limb bud culture DNA (30%), or in total embryonic DNA (33%). These data suggest that in cells differentiated for cartilage production a certain set of intermediately repeated sequences is amplified, whereas in undifferentiated cells or in cells differentiated for other functions, this particular complement of intermediate repetitive sequences is not amplified.

Does this mean that the determinative event in the differentiation of cartilage cells might be the amplification of cartilage-specific sequences initially present in multiple copies? Several facts about this system suggest this to be true. First it must be noted that during the first 48 h of culture during which the differentiation process can be blocked by the presence of BUdR, very little cell division occurs. After 48 h the differentiation process is no longer sensitive to BUdR. Since it is known that the half life of ^{3}H-BUdR in substituted DNA is 11 times shorter than ^{3}H-TdR, it stands to reason that the mechanism of BUdR inhibition of differentiation is that although the amplification of cartilage-specific intermediate repetitive DNA sequences does occur in these cultures during the first 48 h, the amplification is accompanied by and followed by rapid degradation of the sequences (because they contain BUdR) so that the cell does not receive the proper differentiation signal.

Similar BUdR sensitivity is exhibited by differentiation processes in various other chick cell types and in other tissues of diverse eukaryotic organisms. Could it be that this proposed amplification event is a generalised feature of the cell differentiation process and that it is somehow involved in the regulation of genome expression? A positive answer to this question is certainly possible, but regardless of the outcome, further reports of research on this phenomenon are sure to be forthcoming soon and certainly promise to be exciting. ☐

Plasmids and pathogenicity

from David Sherratt

ESCHERICHIA COLI has often been considered a harmless inhabitant both of the large intestine of man and animals and of molecular biology laboratories. However in the past ten years it has become increasingly clear that some strains of *Escherichia coli* can be pathogenic. Enteropathogenic strains in the gut cause diarrhoeal diseases and invasive strains cause bacteraemia and urinary infections. Diarrhoeal disease resulting from enteropathogenic *E. coli* may well be one of the leading causes of death of young children in developing countries (see Sack, *A. Rev. Microbiol.* **39,** 333; 1975), and enteropathogenic *E. coli* cause considerable losses in intensively reared livestock.

Enteropathogenic *E. coli* strains produce either or both of two types of protein exotoxin, one heat stable (ST) the other heat labile (LT). The latter resembles cholera toxin and produces a similar but comparatively short-lived massive salt and water secretion from the mucosal cells of the small intestine —hence the diarrhoea. The similar effects of ST toxin are even more short-lived and the biochemical basis for its action at the cellular level is unknown. H. Williams Smith (*J. gen. Microbiol.* **52,** 319; 1968) was the first to show that toxin production in *E. coli* is transmissible by conjugation, and this led to the finding that the toxins are plasmid specified, often by the same plasmid.

Little is known about the genetic determinants of toxins in other microorganisms, partly because little is known of their molecular biology. The genes for cholera toxin seem to be chromosomally located and the structural genes for diphtheria toxin are known to be located on a lysogenic bacteriophage. In addition, the genes responsible for causing crown gall tumour in plants seem to reside on a plasmid present in the causal microorganism *Agrobacterium tumefaciens.*

positive and negative RNA strands, that hybridise into double-stranded hair-pin forms.

Rabies is another rhabdovirus which, unlike VSV, spontaneously gives rise to persistent infections in cell culture without the addition of DI particles (Wiktor & Clark, *Infect. Immun.* **6**, 983; 1972). However, DI particles are soon found in the infected cultures (Crick & Brown, *J. gen. Virol.* **22**, 147; 1974) and Holland *et al.* show in their paper (*op. cit.*) that even after cloning, rabies virus quickly generates new DI particles. The rate of generation of defective virions may therefore determine whether a particular virus or strain gives rise to acute lytic or persistent infection.

Other virologists (Stanners & Goldberg, *J. gen. Virol.* **29**, 281; 1975; Youngner *et al.*, *J. Virol.* **19**, 90; 1976) have shown that temperature-sensitive VSV mutants can give rise to persistent infections and have emphasised the possible role of conditonal mutants in viral disease. The champions of DI particles point out that TS viruses generate DI particles more readily, but a curious finding is that persistent infections initiated by wild type plus DI particles also generate a high frequency of TS particles among the mature progeny. Furthermore, VSV and many arboviruses replicate in insect cells without cytopathic effects and therefore the wild type readily establishes persistent infections in these cells (which are probably their ancestral as well as present hosts). Yet one finds, as Mudd *et al* (*J. gen. Virol.* **20**, 341; 1973) have shown, that many of the progeny replicated in insect cells become temperature sensitive, and will not grow at 37 °C. Perhaps the virus strains that are virulent in warm-blooded animals represent heat-resistant variants rather than true 'wild types'. Clearly, there is plenty to think about and investigate in persistent viral infections and virus-host interactions without worrying about DNA copies.

Having returned to the question of unusual proviruses, however, it is noteworthy that Zhdanov's and Iinuma's papers indicate that reverse transcriptase was associated with the viruses in their persistent infections, and one wonders whether retroviruses and other viruses might interact genetically in mixed infections. Since many commonly used cell lines are persistently infected with C-type viruses (which can 'persist' as host genes), this question merits investigation. Incidentally, strange transcripts of retrovirus genes themselves have recently come to light. Retroviruses are classified as 'positive strand' RNA viruses as their genomic RNA has the same sense as mRNA. As they replicate by transcription of a DNA provirus one would not expect to find negative strand viral RNA as a replicative intermediate. Recently, however, Stavnezer *et al* (*J Virol.* **20**, 343; 1976) have detected by hybridisation to virion RNA the presence of negative RNA strands in the nuclei and cytoplasm of infected cells, representing up to 30% of the genome in avian sarcoma virus infection, and 45% with murine mammary tumour virus. Previous attempts to detect negative strand RNA may have failed because the RNA is already duplexed with positive strands. The function, if any, of the negative strand RNA is not yet clear. □

Cosmic X- and γ-ray line radiation

from Andrew Fabian

X- and γ-ray astronomers have been observing an increasing number of spectral lines over the past year or so. Most of the X-ray reports have come from two groups. the OSO 8 group at the Goddard Space Flight Center; and the Ariel V group at the Mullard Space Science Laboratory of University College London Line radiation at about 7 keV, presumably due to iron (which is by far the most abundant element emitting at this energy), has been detected to date in one binary X-ray source, Cyg X-3; several supernova remnants (for example, Cas A, Tycho and G287.8-0 5) and several clusters of galaxies (the Perseus cluster for example). All of these results (reported in the *Astrophysical Journal* and the *Monthly Notices of the Royal Astronomical Society*) derive from satellite-borne proportional counters, which have good sensitivity but poor energy resolution. The few high resolution crystal spectrometers carried into orbit are not yet sensitive enough to resolve such features.

The mere detection of line radiation from clusters of galaxies strongly favours a thermal origin for the X-ray emission, and indicates that the hot gas responsible cannot be wholly primordial. Presumably some heavy element enrichment has taken place. Most of the heavy elements are generally considered to be made in supernova explosions, and X-ray spectroscopy of their remnants may offer a direct means of checking that hypothesis. The preliminary results indicate that iron need not be particularly overabundant, but that result is, of course, dependent upon the structure of the remnant, and the proportion of ejecta to swept up material currently radiating X rays. Cyg X-3 is a particularly enigmatic binary source, for it emits throughout the spectrum from radio waves to γ rays. Indeed there is no real proof that it is a binary source, for any companion is only inferred indirectly from the observations. Whereas the iron line radiation from the clusters of galaxies and supernova remnants is probably due to transitions in Fe XXV and Fe XXVI, the feature in Cyg X-3 may be due to fluorescence of 'cold' iron. A slight improvement in sensitivity and resolution should decide this point, since the 'hot' and 'cold' features differ significantly in energy Variations in intensity over the 4.8-h cycle of Cyg X-3, and any future detection of periodic Doppler shifts in the line energy will undoubtedly be important in sorting out the true nature of this system. This work is only in its infancy, and the detection and resolution of more X-ray lines due to iron and the lighter abundant elements will be a worthwhile task.

γ-ray lines observed at energies above 0.511 MeV (the electron–positron annihilation line) are presumably due to nuclear transitions. Such radiation has been predicted to occur due to radio activity in supernovae and the interaction of low energy cosmic rays with interstellar material, and has been observed in intense flares in the Sun. A group at Rice University, Texas, have recently published a detailed account (*Astr. J.* **210**, 631–641; 1976) of their earlier reported detection of nuclear γ-ray lines in Centaurus A. At ~5 Mpc, it is the nearest bright radio galaxy, and contains a nucleus varying at X- and soft γ-ray energies. R. D. Hall, C. A. Meegan, G. D. Walraven, F T. Djuth and R. C. Haymes claim the detection of features at 1.6 MeV and 4.5 MeV, both 3.3σ above the neighbouring continuum. Since they have about 40 energy channels in their balloon-borne scintillation counter, and they could have seen lines in any of these, this result is significant only at the ~2% level. Similar results on the galactic centre region have earlier been reported by the same group. Centaurus A is a reasonable place in which to expect plenty of low energy cosmic rays, and the absorption observed at X-ray wavelengths indicates the presence of a considerable amount of interstellar gas. It will be exciting if the intensity of the γ-ray line activity is found to vary in a similar fashion (but out of phase?) to the X- and γ-ray continuum. The authors note that the total low-energy γ-ray luminosity of Centaurus A is about 10^{44} erg s^{-1}. Since this is about ten times its radio luminosity, perhaps we had all better start referring to it as the nearest γ-ray galaxy. □

Restating the self-thinning rule

from Peter D. Moore

MORTALITY amongst young organisms is one of the basic observations which led Darwin to propound his theory of natural selection. Often this mortality results from the competitive stresses which are derived from a high density of other members of the same species. Among plants the process is often referred to as self thinning. The nature of this process was analysed by Yoda *et al.* (*J. Biol. Osaka City Univ.* **14**, 107; 1963) in pure even-aged populations of plants under density stress. Their most important finding was that if one plots the log of mean individual plant weight against the log of surviving plant density one obtains a straight line with a slope of $-3/2$.

The self-thinning rule which emerges from these observations can be summarised by the formula,

$$W = Kp^{-3/2}$$

where W = mean plant weight and p = density.

The rule was examined by White and Harper (*J. Ecol.* **58**, 467; 1970), who provided new experimental data and who also analysed a body of published data most of which agreed with the observations of Yoda *et al.* Variations in nutrient availability had no influence upon the slope of the line, but did affect its position on the axes. Fertility resulted in a higher degree of thinning. On examining published data concerning light intensity variations and thinning in *Helianthus annuus*, however, they found that decreasing light intensity was correlated with less steep slopes in the log plant weight/log density lines.

Kays and Harper (*J. Ecol.* **62**, 97; 1974) have since experimented with the rye grass, *Lolium perenne* and have tested the effect of light intensity upon both individual (genet) and tiller density and weight. At high light intensities genet weight and density obeyed the 3/2 thinning law, but at the low light levels the slope fell to 1. On this basis they suggested that it is the reduced light intensity within a sward which causes the stress, resulting in mortality.

In this issue of *Nature* (page 330), Westoby re-examines the 3/2 self-thinning law in the context of work on the influence of light on leaf morphology. It is known that leaves produced under low light intensity have a larger area, but not normally a greater weight, than those produced in high light levels. Area : weight ratios are therefore raised at low light. This being so, Westoby has re-examined the original *Helianthus annuus* data analysed by White and Harper, but has plotted mean leaf area on a log scale rather than log mean plant weight. The result is a line with a 3/2 slope which is independent of the light intensity at which the data was obtained. Thus he reformulates the self-thinning rule as

$$L = Kp^{-3/2}$$

where L = leaf area. Not only is this formula of more general application than the original statement of the rule, it also permits one to predict mortality rates given information on the changes in leaf area index (leaf area : ground area) of a population in time. Such information is already available for many crop and forage species, hence one can work from this data to a better understanding of their population dynamics under density stress. □

Persistent infections without proviral DNA

from Robin Weiss

IN 1975, Zhdanov (*Nature* **256**, 471) and Simpson and Iinuma (*Proc. natn. Acad. Sci. U.S.A.* **72**, 3230) claimed to have found integrated DNA copies of RNA viruses such as sindbis, measles and respiratory syncytial viruses in the cells of persistently infected cultures. They suggested that the formation of DNA 'proviruses' might lead to the persistant state. Recently, John Holland and associates (Holland *et al.*, *J. gen. Virol.*, **33**, 193; 1976) have concluded from a series of meticulous experiments on long-term persistent cultures of BHK-21 cells infected with vesicular stomatitis virus (VSV) that there is no evidence for 'proviral' DNA copies of the VSV genome in those cultures. Hybridisation tests capable of detecting 1 viral genome per 40 cells (or 1/40 of a genome per cell) gave no indication of sequences homologous to viral RNA in the DNA of persistently infected cells, and DNA transfection attempts also failed to reveal any biological activity. Transfection with DNA was also negative in a variety of other cultures persistently infected with rabies, influenza, measles, mumps or lymphocytic choriomeningitis viruses. Thus it is clear that the formation of proviral DNA is by no means a prerequisite for the establishment of persistent infections with negative strand RNA viruses.

Holland and Villarreal originally established the persistently infected VSV carrier culture (*Proc. natn. Acad. Sci. U.S.A.* **71**, 2956; 1974) by using a temperature-sensitive mutant (*ts*G31) together with an excess of defective interfering (DI) particles. Nucleocapsids of the DI particles persist in the carrier cultures and presumably interfere with complete particle replication. Nevertheless, most cells in the carrier cultures continue to synthesise viral RNA (Villarreal and Holland, *J. gen. Virol.* **33**, 213; 1976) and proteins even after more than 2 years in culture. Cell cloning can, however, yield 'cured' cell populations lacking all evidence of infection.

Holland's group's studies support the view put forward by Huang and Baltimore in 1970 (*Nature* **226**, 325–327) that defective interfering particles have a role in viral disease processes. Doyle and Holland (*Proc. natn. Acad. Sci. U.S.A.* **70**, 2105; 1973) had previously shown that the addition of excess DI particles to biologically active VSV protected mice against early lethal intracerebral infection. But DI particles might lead to 'slow' persistent infection, as opposed to acute infection, *in vivo* too, and with some viruses (measles, for example) and some hosts (such as man) the consequences to the host may be far more dire than acute infection. Since DI particles depend on non-defective virus for replication, but then replicate to excess and interfere with the non-defective virus, cyclic production of mature and DI virus may ensue, as Palma and Huang (*J. infect. Dis.* **129**, 402; 1974) have shown for VSV when fresh cells are added to infected cultures. The mechanism of interference by DI particles is not clear, but they may compete for polymerase. DI particles typically contain a part of the viral genome as the usual negative strand RNA, although Lazzarini *et al.* (*J. molec. Biol.* **97**, 289; 1975) have described interesting covalently-linked being very brightly marked while the female, presumed to be the fish depicted, is drabber. Such small fish were and are usually cooked whole, and form an essential part of the modern *Zuppa di Pesce*.

(8) Lesser spotted dogfish: *Scyliorhinus canicula*. This is the commonest small shark of the Mediterranean Sea and is taken by net or line on muddy and sandy ground in shallow waters. The flesh is unpleasant when fresh and fishermen often immerse the skinned bodies in seawater to achieve an acceptably flavoured fish (the taint is caused by the presence of a high concentration of urea in the fish's blood).

(9) Sea bream: *Diplodus sargus*. The artist has accurately depicted the dark markings near the tail and under the pectoral fin which distinguish this species from other sea breams.

(10) Red gurnard: *Aspitrigla cuculus*. This is a famous delicately flavoured gourmet fish. The artist has not illustrated the separate 'sensory' rays of the pectoral fin which are usually seen in the gurnards; perhaps they were collapsed or damaged in this specimen.

(11) This is probably a near relative of number 18, *q.v.*

(12) Sea bass: *Dicentrarchus labrax*. This excellent fish may occur in brackish lakes and estuaries as well as in the sea. According to Pliny, the Romans preferred specimens caught in the rivers (*'At in lupis, in amne capti praeferuntur'*), but things are not what they used to be, and nowadays those taken in the sea are better. Bass patrol rocky shores and pounce on shoals of sand-smelt or prawns. They will also maintain an uncanny watch on a SCUBA diver after the style of barracudas in the Caribbean.

(13) Moray eel: *Muraena helena*. This cunning and dangerous fish is highly esteemed by some gourmets, but others deem it worthy only of the *Zuppa di Pesce*. The skin is thick and slimy, but lacks scales. The artist has convincingly depicted the camouflage mottling and the gill opening just behind the mouth.

(14) This is in some ways the most interesting specimen in the mosaic, from the point of view of the marine biologist. It shows a neogastropod whelk having a long grooved siphon, the mark of a hunting snail. The length of this siphon proves the animal to be *Murex brandaris*, one of the snails used by the ancients in the manufacture of the dye Tyrian Purple, used for colouring imperial robes and other garments and furnishings. Whether the specimen illustrated was destined for the table or the dye factory is open to speculation; this species is, under the colloquial name of *murice* (in various parts of Italy) or *sconciglio* (around Naples) still eaten. The modern Neapolitans use the expression 'ugly as a sconciglio' as an insult.

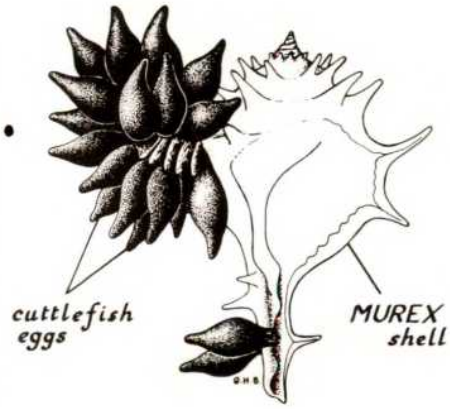

Fig. 2

But this individual is especially interesting because it appears to show around the aperture of the shell a circle of flask-shaped excrescences. These hide the true spines of the shell, which are in any case slender and distinctive in this species, and it appears that they are the eggs of the cuttlefish *Sepia officinalis*. Such eggs are not infrequently found attached to *Murex brandaris* shells, and a drawing of such an association found on the island of Ischia (close to Naples) is reproduced here for comparison (Fig. 2). It seems that the artist may have selected for his sketches just such an individual, perhaps because the unadorned animal was even at that epoch regarded as ugly and uninteresting.

(15) A blenney, of which several species occur in the Mediterranean, in the genus *Blennius*. It is possible but not likely that it is instead a goby. Gobies were not thought highly of as table-fish, although a dissenting Venetian view was recorded by Martial:

> 'At Venice, famed for dainty dishes,
> The Gobies rank the first of fishes.'

(from *Mediterranean Seafood*, Alan Davidson, Penguin Books, 1972)

(16) Striped bream: *Lithognathus mormyrus*. The tail of this species is usually found to be forked (as shown in the bream number 9) but the artist has here illustrated it in a collapsed state.

(17) Smooth hound: *Mustelus mustelus*. This small shark differs from the Mediterranean species of dogfishes (see number 8) by the forward position of the first dorsal fin. In the smooth hound this fin lies above the pectoral fins (more or less), while in the dogfishes it is more to the rear. The artist has shown this feature of shark classification extremely well.

(18) Scorpion fish: *Scorpaena porcus* or *S. scrofa*. There are ten species of scorpion fish in the Mediterranean Sea, and it cannot be certain that the fish portrayed in the mosaic is one of the common ones. They are all bottom-living fish, hunting by twilight, seizing quite large prey with great speed, using the wide powerful mouth. So committed are they to life on the bottom of the sea that the scorpion fishes have lost the swim bladder characteristic of most other bony fish. The dorsal spines can inflict a painful wound if the fish is carelessly handled, and this fact, together with their generally small size, has meant that scorpion fish are utilised chiefly as a flamboyant ingredient in the Neapolitan *Zuppa di Pesce*. The fish in the mosaic was evidently sketched out of water, because the head processes (which normally stand up in water) are not illustrated.

(19) Shrimp: *Crangon vulgaris*. The artist has spread the peraeopods (walking legs) guilefully in order to illustrate all 18, but the chelae (nippers) are not shown so convincingly. This shrimp is usually found on muddy sand in shallow water, and it is drab, small and poor eating. One wonders why the artist chose to include *Crangon*, rather than the more exotic delicate-tasting 'scampi' (*Neophrops norvegicus*) or one of the larger prawns. Perhaps the gear to capture these was at that time nonexistent.

(20) Squid: *Loligo vulgaris*. The diamond shape given to this squid by the position and extent of the gliding 'fins' serves to identify this species, sometimes called the long-finned squid. They usually swim very close to the surface of the sea and can be taken with bony fish in fishing nets. Typical specimens have eight short arms and two long ones, but the artist has shown one whch lacks a short arm. Was this an inaccuracy or had this individual lost one?

(21) Two-banded bream: *Diplodus vulgaris*. The artist has shown the shape of a sea-bream well, but the species must remain a tentative indentification. It is not easy to determine whether certain markings on the mosaic are merely accidental damage.

(22) Octopus: *Octopus vulgaris*. This is the 'Polpo' beloved of modern Italians. The artist has accurately depicted both the restless squirming energy of the octopus and the external features needed for an identification to species. The arms are shown to have two rows of suckers, typical of species of the genus *Octopus* (*Eledone* has single rows), and the proportions are of *O. vulgaris*, not the other Mediterranean octopus, *O. macropus*. Large specimens can reach 25 kg in weight, 3 m across the tentacles; not exactly a kraken, but pretty frightening to meet underwater. □

ings are shown on the dorsal surface, although the number is nearly always five As will be argued below, this represents an error of transcription on the part of the illustrator, and probably occurred between the fishmarket (where he must have made his preliminary sketches) and the execution of the mosaic *in situ* The animals are portrayed in the freshly killed state; they were not observed from life in aquaria. This is evident in a number of cases where fins or other excrescences are illustrated in a collapsed state (as occurs in air but not in water).

No marine biologist could fail to appreciate and admire this extraordinary composition, and one wishes that present-day scientists and their illustrators were always so painstaking and accurate.

(1) Electric ray: *Torpedo torpedo*. This animal is characterised by its possession on the upper surface of several (usually five) dark false 'eyespots' (ring-like markings, not true eyes at all). It is remarkable that the artist has depicted nine such markings and it may be surmised that this represents an error of transcription from the artist's notes and sketches to the mural itself. He has mistakenly depicted the ray's real eyes and spiracles (Fig. 1) (exhalant openings for the respiratory stream) to be four extra false 'eyespots'. This is the only major inaccuracy detectable in the whole mural.

(2) Red mullet. *Mullus surmuletus*. This fish is tantalisingly damaged in the mural and the tendril-like jaw processes characteristic of *Mullus* are not shown, and other features of the snout can only be guessed at. Because of this damage, the possibility cannot be ruled out that this fish belongs to the related variety (or separate species, according to one authority) *Mullus barbatus* Both occur in the Mediterranean Sea. They are among the most highly prized table-fish in the world, and are commonly cooked whole, not gutted. (Naples slang for these fishes is *fragaglie*.)

(3) Grey mullet. *Mugil* sp. A beautiful illustration of a beautiful fish. Grey mullets shoal in coastal waters where they especially favour areas of freshwater inflow, and sometimes enter estuaries and lagoons. There are seven species in the Mediterranean Sea, and only an expert can distinguish them, using whole fresh fish. Highly esteemed for their flavour, grey mullets were in classical times thought to be the most gentle and holy fish because they were herbivorous.

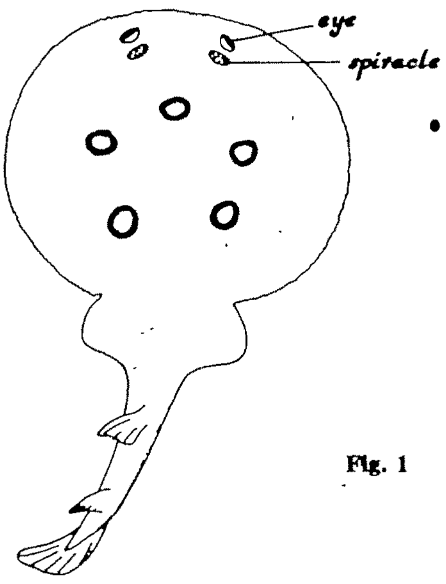

Fig. 1

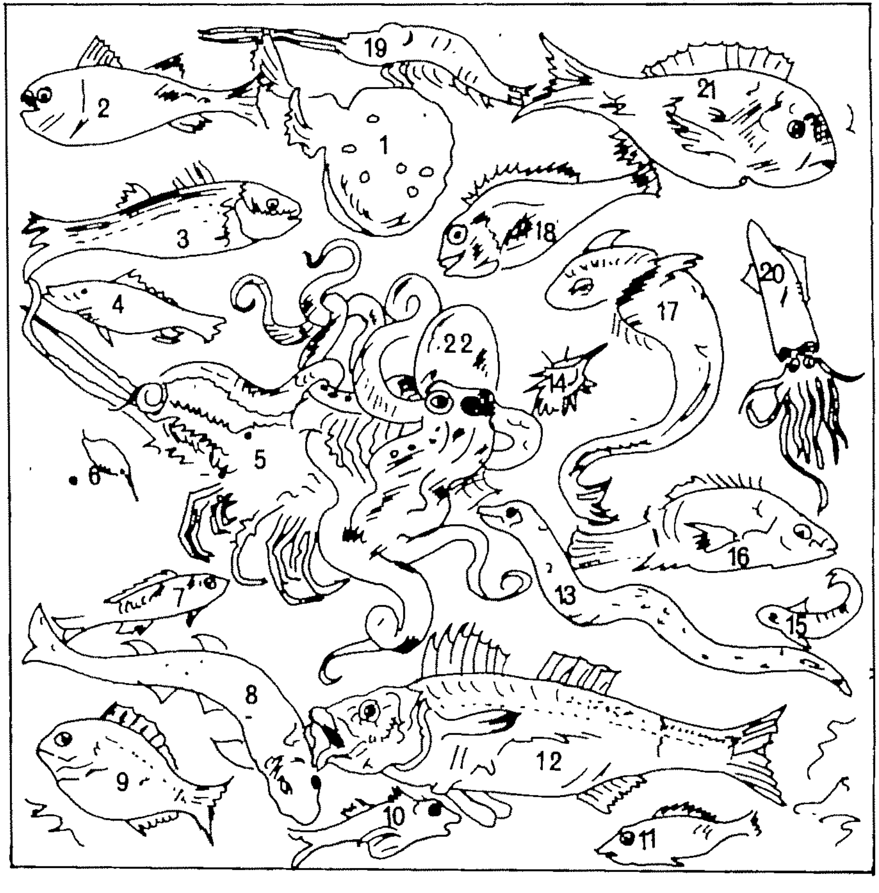
(4) Wrasse. *Labrus* sp. This genus contains a number of well-established species but it is still difficult to identify the fish in the picture down to species. Wrasses include many common and familiar inhabitants of coastal waters in the eastern Atlantic, many of which are flamboyantly patterned. But the patterns vary with the time of the year and males and females are often quite different. Add to this difficulty the fact that many wrasses change sex as they grow up, and the reader will understand that it is difficult to be precise about this fish. *Labrus merula*, the brown wrasse, comes very close.

(5) Crawfish· *Palinurus vulgaris*, shown in combat (more likely to be imagined than real) with an octopus. It is interesting that the European crawfish is depicted and not the African or Green crawfish, which nowadays often finds its way to the fish markets of Italy. According to a cruel legend recounted by Robert Graves the Emperor Tiberius is said to have ordered a fisherman's death (the unfortunate man had startled the Emperor near the cliff-top in Capri) by the unusual means of having his own catch of crawfish (Suetonius writes instead that it was a mullet) rubbed into his face. He was then thrown from the cliff to the sea and rocks far below. Crawfish are nowadays best caught by SCUBA diving, but two thousand years ago they were probably trapped in baited wicker baskets.

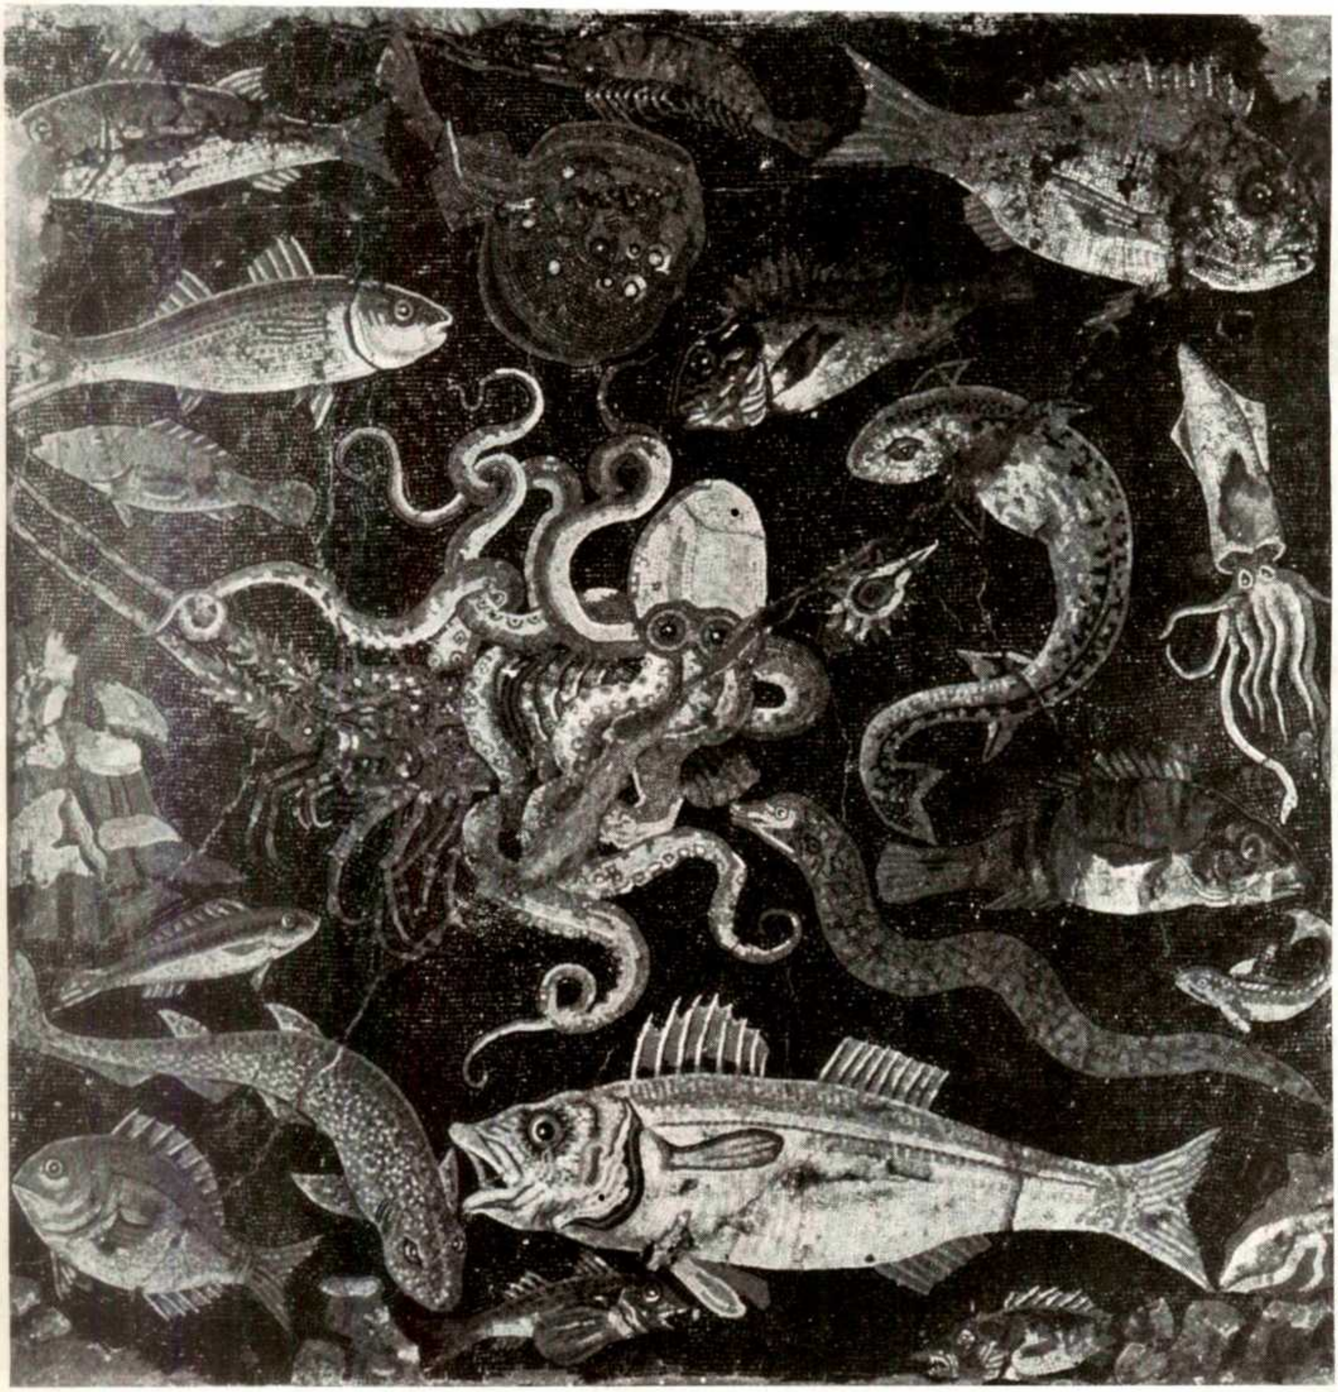
(6) All scientists and illustrators are duffers outside their chosen areas of knowledge, and the author of the mosaic was evidently no ornithologist. This bird is a curious mixture of kingfisher, dunlin and rock pipit. It seems to have been included in the mosaic purely for artistic reasons. Whereas all the marine animals in the composition are represented faithfully and can usually be identified to genus and species, this is a generalised, stylised token bird, Disneyesque in its anonymity.

(7) Rainbow wrasse· *Coris julis*. This is a species which shows pronounced sexual dimorphism, the male



A marine biologist at Pompeii AD 79

from T. E. Thompson



Pompeii Exhibition

THE Pompeii AD 79 exhibition at the Royal Academy contains, in a mural on loan from the Naples Museum (number 120177), a mosaic illustration abut 90 cm square which shows fish and other marine animals of culinary importance from the Bay of Naples. These organisms are portrayed with such vigour and scientific accuracy that marine biologists may well find this mosaic the most interesting and challenging of the exhibits. The artist was a scientific illustrator of rare talent making this composition, originally executed as a domestic decoration, well worth closer inspection.

All the animals shown in the mosaic were primarily edible, with the exceptions of the whelk (number 14 on the diagram) and the curiously artificial bird (6) which was perhaps included simply to fill up a space. The whelk shown belongs to a species of *Murex* which was in classical times the raw material of a great industry surrounding the extraction from its tissues of the dye Tyrian Purple. It does not make good eating, and its modern slang name in Naples (*sconciglio*) is used in an expression of repugnance.

The animals are illustrated with faithful delicacy and accuracy. The only serious error detectable in the mosaic is in the depiction of the electric ray *Torpedo* (number 1 on the diagram), where nine ring-like mark-

news and views

Sea surface temperature and climate

from P. B. Wright

SEA surface temperature (SST) is an important factor in climate. The physical reasons are readily apparent; if relatively cold and unsaturated air blows over the sea, heat and moisture are transferred from the sea into the air, and the rates of transfer depend on the temperature difference. Thus subsequent behaviour of the airstream depends on the temperature of the ocean surface over which it has passed; for example, the latent heat from the additional moisture evaporated into the air may be released into the upper troposphere at some distance downstream, modifying the circulation there. This may in turn influence the circulation even farther afield.

Moreover, SST has high thermal inertia. The sea surface takes a long time to cool down (or warm up) because any change of temperature has to be distributed through the top 100-m layer which is well stirred. Some of the effects of these properties are familiar—maritime climates are more equable and more humid than continental ones, and their seasons are delayed a month or two. It is not surprising therefore to find that SST variations play an important part in causing the climate to differ from year to year. A number of correlations have been discovered over the past few years—between SST near Newfoundland and atmospheric circulation over Europe, SST over the North Pacific and weather over both North America and Europe, and between SST in the Equatorial Pacific and the 'Southern Oscillation', which involves rainfall in Australia and many other regions.

Markham and McLain (see this issue of *Nature*, page 320) have now found a new example, a close relationship between SST in the equatorial Atlantic and rainfall in north-east Brazil. Correlation coefficients reach the remarkably high value of 0.8 in four separate months. It is particularly noteworthy that correlations of 0.7 occur in a predictive formula—between December SST and the following January-to-March rainfall. Moreover they are highly significant, indicating a real physical relationship. The details of the chain of interactions are still far from clear. Warm SST probably favours a modified trade wind pattern, which affects the rainfall. But the physical basis is sufficiently firm, and the relationship sufficiently close (even after allowing for sampling variations), for useful forecasting of the rainfall in this drought-prone region of the globe to be possible. When the physical details become better understood, and the most relevant sea area is pinpointed accurately, improved forecasts should be possible.

The forecasting potential depends essentially on the fact that SSTs in the equatorial Atlantic not only influence the rainfall, but also persist for several months. This is similar to the behaviour of equatorial Pacific SSTs. This raises the following questions. Are there other influences of the Atlantic SST similar to those of the Pacific? Are the two regions in any way coupled? Why do anomalies persist so long, and why do they eventually change? It will be some time before these questions are answered. But another question comes to mind. Are there any other regions where SST anomalies tend to persist for several months or longer? If so, then whatever their cause, we ought to know of their existence, because they would imply a forecasting potential for regions whose climates they influence. This should be simpler to answer; it merely requires a routine statistical analysis of SST data series.

However there are serious problems with data, some of which are mentioned in the paper. It is a tedious and intricate job to transform millions of observations from ships' logs into series of monthly means, checked for errors, for 5° squares over the globe. But the need for reliable homogeneous series cannot be overemphasised. Work is now in progress in the Meteorological Office at Bracknell to devise an objective procedure for identifying errors, which will be a valuable contribution to the task. Nevertheless, as this paper shows, even the data available at present "form a picture that is coherent and of predictive value".

The paper also looks at correlations between equatorial and higher-latitude climates, and suggests a plausible mechanism by which warm South Atlantic sea temperatures could favour a deeper upper-air trough near Newfoundland. This sequence of interactions is the reverse of one put forward by Namias some years ago. The problem of cause and effect is a thorny one. It will not be answered from simple correlation studies like that of Markham and McLain, but these are valuable in providing pointers. Numerical models will have a crucial role; one could impose a persistent SST anomaly and look at the effects in different latitudes. Some such experiments have been made on both the Pacific and the Atlantic, which clearly indicate that equatorial SSTs can greatly influence higher-latitude circulation patterns.

So there is a great deal of further work needed along several parallel lines. The SST data base needs to be improved and made available. The homogeneous series so obtained should be analysed to discover areas where persistence is strongest. These areas should be used in correlation analyses to discover regions for which forecasts are possible, and also in numerical experiments to investigate the physical relationships which underlie the correlations. ☐

IN BRIEF

Scientific freedom

A group of Swedish scientists has recently formed a committee for scientific freedom which is to agitate on behalf of persecuted or harassed scientists in the same way that Amnesty International works for political prisoners. About 100 scientists have so far shown interest in the committee, which is chaired by Professor Ragnar Romanus of Gothenburg. The idea is that physicists will work on behalf of physicists, biologists for biologists, and so on.

The scientists say that their work will not in principle be directed at any particular countries. Several of the committee's members have previously urged the Soviet authorities to grant exit visas to Jewish scientists wanting to emigrate to Israel. They stress however that they do not want to condemn any political system as such, but rather the treatment that various systems mete out to their scientists. At the moment, Argentina is an obvious target for their work.

Hot summer, good news

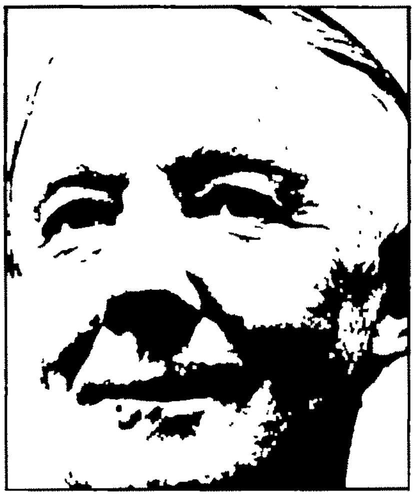
Infant mortality figures for England and Wales in 1976 show a marked improvement on figures for earlier years, and some of this improvement can probably be attributed to the long hot summer. Improvements in obstetric practice and care of newborn infants must also have had an impact, however, in the overall drop in mortality reported by the Office of Population Censuses and Surveys.

Post early neonatal mortality (one week to one year in age) regularly shows a seasonal term, but in 1976 this was exceptionally pronounced, summer deaths being 4.1 per thousand (annual rate) compared with 7.3 for the winter quarter This helped in large part to cause a drop in the whole year's figures by an amount almost equal to the drop for all the previous five years.

Perinatal mortality (28 weeks after cenception to one week after birth) shows a much smaller seasonal term, but there too substantial gains have been recorded. The figure for 1970 was 23.5 per thousand; by 1975 it was down to 19.3 but in 1976 the figure dropped to 17.5.

Infant mortality is now about half the level it was in the early 1950s, but until this past year many people have expressed concern that Britain's performance in reducing the rate did not match that in other developed countries.

Effective science



KENNETH MELLANBY

A FEW years ago politicians were saying that British scientists were about to launch the "white hot technological revolution" which, fanned into flames by the efforts of the civil servants in a newly conceived Ministry of Technology, would revitalise British industry. The revolution, unfortunately, was stifled at birth, and the new Ministry soon disappeared.

Today Britain's scientists are blamed because the growth of industrial productivity is slow or nonexistent. They are castigated because they appear to be unwilling to follow careers in industry, or to direct their research into fields which might ensure economic progress. University courses for undergraduates and graduates are criticised for not imparting the proper skills, and even more for not giving the necessary "motivation". The country's most prestigious committees debate these subjects interminably, but have so far made no suggestions for improvements in education, training or organisation which engender any confidence in academic or commercial circles.

Yet thirty years ago British scientists enjoyed, and may even have deserved, greater prestige. It was generally agreed that they had made many remarkable contributions of a very practical nature to both military and other problems (medicine, public health, transport for instance) during the Second World War. They showed themselves able to tackle and solve difficult and important problems often far removed from those they had previously studied. This they did for the most part with the minimum of expensive and complicated equipment, and often at very little cost to the community. This gave rise to the belief that if Britain increased her scientific establishment many fold, and if its financial support was allowed to grow exponentially (conditions fulfilled during more than twenty post-War years), she would solve many of her social and economic problems.

Unfortunately the results have been disappointing. Today all is not well with both science and industry in Britain and in many other parts of the world, and most attempts to diagnose and cure this malaise have been unsuccessful or have made things worse. Surely the obvious course would be to examine previous successes, and see what can be learned from them. For instance were there any common factors in their education, training and experience which made war-time scientists so adaptable and successful at solving so many of the immediately important problems which faced them and the country?

It is dangerous to generalise, but it is clear that many of those who were most successful in war-time science had previously worked only in university departments or for research councils. Their 'training' had been entirely academic, and, up till then, they had mostly worked in their own way on problems of their own choice. As far as I know, none had ever attended a course in 'management'. In many cases it was the scientists themselves who first became aware of the existence of the problems which they eventually tackled. They often had to convince the authorities, including the expert committee (which existed even then, but fortunately in much smaller numbers than today), that the work was worth doing. And it was often the academic scientists themselves who took the successful initiative in ensuring that their results were put into practice.

In many ways the problems facing the world today are as serious and urgent as those which faced Britain during the war. Can anyone explain why scientists no longer operate as effectively as they did at that time? There are far more trained research workers, and, notwithstanding recent cuts, far more money is spent on science. Surely this is what our committees should be investigating, even if they discover that it is often their own existence which is the barrier to scientific and economic progress?

CANADA

Reorganisation in Ottawa

A long-awaited bill on governmental organisation of scientific activities was finally presented to the Canadian Parliament shortly before Christmas. David Spurgeon reports from Ottawa.

THE bill proposes the reorganisation of the federal granting councils which provide funds for university research, and makes other changes concerning the Science Council of Canada and the Defense Research Board. At the same time Hugh Faulkner, Minister of State for Science and Technology, responded to concerns of the community about falling financial support, and said consideration is being given by the government to providing increases in 1977–78 budgets to cover inflationary increases in the cost of doing research.

The granting council changes were recommended several years ago by the Senate's special committee on science policy (the Lamontagne committee) and changes were promised by the government in February, 1974. According to Mr Faulkner, the bill is "the culmination of a lengthy series of studies, reports, meetings, and debates on the subject of science policy . . .".

The bill creates a Social Sciences and Humanities Research Council, leaving the Canada Council, which has supported both the arts and research in the social sciences and humanities, to deal entirely with the arts. Mr Faulkner said the reorganisation "reflects the growth in size and quality of the social sciences and humanities (in Canada) and the new perception of their importance to the attack on socio-economic problems, to national sovereignty, and to our cultural development". The bill also creates a Natural Sciences and Engineering Research Council, which will remove from the National Research Council of Canada the function of granting funds for university research in these areas. The NRC will henceforth deal with its own laboratories, industrial R&D support programmes, and a national programme of scientific and technical information. Mr Faulkner said the new council "recognises the need for a separate agency to support university research in these disciplines (natural sciences and engineering) and to foster improved dialogue between natural scientists and research engineers."

The Medical Research Council Act is amended under the new legislation to remove the restriction preventing its support of research in public health, but otherwise the council remains unchanged.

In order to advise and co-ordinate the work of all the granting bodies, Mr Faulkner will establish an Intercouncil Co-ordinating Committee, chaired by the Secretary of the Ministry of State for Science and Technology. The committee will include the presidents of the granting councils and will report to Mr Faulkner.

Although the criterion of excellence will continue to be the basis of university research support, additional funds will be provided to the councils for regional balance of scientific capability, national problems and support of inter-disciplinary research.

The Science Council's mandate is also restated in the legislation, to provide it with a greater national and public role. It has actually played such a role for years, but, according to the Minister, "the new mandate . . . will state clearly that the Council is to act as a source of public information and to provide advice on the profound effects developments in science and technology will continue to have on our way of life."

Amendments are also proposed to the NRC Act to give it flexibility to respond to national problems more readily when science and technology have a part to play. Provision has also been made to transfer the responsibility for Canadian Patents and Development Limited from the NRC to the Ministry of Industry, Trade and Commerce. This is supposed to make easier exploitation of inventions from government and university laboratories by industry. Thus the role of NRC is to change somewhat, with "less responsibility for the general development of science in Canada and more for using the demonstrated capability of its laboratories in tackling national problems."

● Towards the end of last year, the Lamontagne committee chairman, Senator Maurice Lamontagne, reported on progress to date in the committee's resurrected hearings, and the group resolved to go on and finish them in 1977. Senator Lamontagne said the current sessions have heard from 31 organisations and have accumulated about 1,300 pages of evidence. Six or seven more meetings are needed to conclude the hearings, which are concentrating on determining how many of the recommendations the committee made in 1972–73 have been followed by the government, and in what way. Mr Lamontagne noted that the current hearings have shown that many recommendations have been carried out, but that failure to follow some "is now producing what has been described to us as an acute crisis, endangering Canada's future capability in the whole field of scientific research, technological development and economic and social innovation." The two recommendations he noted had not been followed concerned the need to transfer older researchers to other jobs in the private and public sectors and the need for greater national expenditure on R&D. If the present situation continues, he warned, "Canada may lose a whole new generation of researchers". ☐

REACTION to the bill was not uncritical. Bill Kempling, Progressive Conservative MP for Halton-Wentworth, asked whether it was the first of several steps to eliminate the science ministry. He noted that MOSST can be cancelled at any time, without reference to Parliament, by an order in council. And he suggested that what the bill really does is increase the number of accounting, auditing and administrative personnel at a time when the government is talking about restraint in spending.

Mr Kempling noted that the intercouncil co-ordinating committee has no budgetary control and called it "another layer of bureaucracy." It would have been better to have set up an overall science foundation reporting to a full minister, with a number of divisions for different disciplines.

Cyril Symes, New Democratic MP from Sault Ste Marie, said it appears to him that whenever the Liberal government gets into trouble and has no real policy answers, "it carries out the old double shuffle: it reorganises parts of its bureaucracy with great fanfare to make it appear that it is doing something, whereas in actuality it is just shuffling the cards . . .". Mr Symes suspected that the bill was a sop to the lobbying of the science community, which had shown concern about funding cutbacks.

Paul Yewchuck, Progressive Conservative MP from Athabacsa, was concerned about the chairmanship of the intercouncil committee: "I can think of no good reason for the minister wanting one of his bureaucrats chairing the . . . committee, unless he thinks he can control the actions of that committee better if one of his underlings is in charge of it . . . I would rather see an active scientist taking this position."

creation of the monsoonal climate. This may in terms of land productivity be regarded as a marginal ecoclimate. The already marginal potential of most of the subcontinent became affected by the arrival of the Aryans with their browsing and grazing animals, their use of fire, and later of iron tools. The ecosystems in South Asia, with which the modern planners of use of arid and semi-arid lands have to cope, have been further reduced in potential in recent and modern times by the great increase in human and livestock populations, the latter due largely to politico-religious factors beyond the control of the land scientist.

In a region where the amount of arable land per person is estimated to have been 0.36 ha in 1950, 0.30 ha in 1965, 0.24 ha in 1975, and to be 0.19 ha in 1985, it is realistic to propose that any major developments in animal husbandry will be limited to marginal land which cannot produce cereal and legume grains for direct human consumption. In terms of the grazing and browsing resources of South Asia alone, the botanical composition of plant covers of the arid and semi-arid lands has deteriorated from a condition in which the superior perennial grasses provided reasonably good feed to livestock in the monsoon and subsequent months to less valuable grass covers of inferior perennials and annuals.

In the East, especially in Japan, Taiwan and China, there are large areas of sloping land, originally under a forest type in conditions between lowland monsoonal and upland temperate, which have been rendered marginal in terms of forest production and agriculture.

Matter of concern

To the conservationist, the ever-increasing area of land being rendered marginal is a matter of profound concern. Idealistic proposals for the total conservation of the environment are difficult to maintain with the population/land position in large parts of Asia. Marginal land *per se* generally represents a continuing and frequently increasing danger in terms of its own conservation, and of the conservation of soil and water on lands lower in the same catchment not yet rendered marginal. A realistic plan for conservation would embrace the preservation of natural biological ecosystems wherever this can be socially and economically justified. It would cover the reclamation of marginal lands either to their original condition or to a new balanced economic ecosystem in which sustained soil fertility and productivity can be maintained by the application of appropriate measures for conservation.

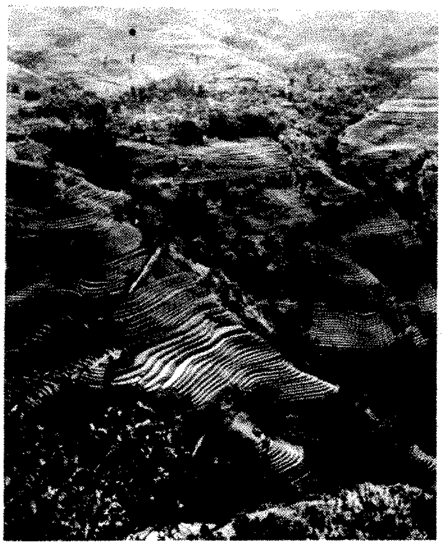
The reclamation of marginal land in either direction has so far been a matter of economics. The rural people responsible for making land marginal have had neither the knowledge nor the financial resources necessary for its correct treatment. Governments of Asian countries in which the return of marginal land from an unproductive to a productive state would be of great economic importance have not approached the problem with the energy it demands.

Again, this is largely because they apply the principles of conservation economics, of return upon capital investment, cost/benefit, input/output ratios and so on. But if most of the countries of Asia are at the age where it is the economics of survival which apply, a different set of criteria will be necessary if measures are to be applied on a sufficient scale.

The administrative structure of most Asian countries does not permit them to emulate the People's Republic of China, where in the winter of 1975–76 130 million rural workers were mobilised for what BBC monitors translated as farmland capital construction projects. These ranged from the reclamation of desert grasslands of Inner Mongolia and Sinkiang and the reforestation and levelling of land for irrigated cultivation in the eastern provinces, to the terracing of mountain slopes in the humid tropical island of Hainan.

Elsewhere some research is in progress. Increased productivity of marginal drylands is an important objective of the Indian government in association with the Canadian government, and at the International Centre for Research in the Semi-arid Tropics (ICRISAT), in Hyderabad. During the past six years the Central Soil Salinity Research Institute at Karnal, Haryana, has evolved economic and speedy methods for the reclamation of alkali soils of the Indo-Gangetic plains.

The essential components are land levelling, the application of gypsum or other additive, the application of fertilisers including micronutrients, the selection of suitable crops and crop varieties, and the adoption of suitable management practices. Semi-dwarf, high-yielding varieties of rice are ideally suited in the *kharif* (rainy) season, to be followed by wheat in the *rabi* (winter) season. Large-scale reclamation programmes based on this research are now being launched to reclaim lands which have been lying uncultivated.



A-CEI

Terraced fields in China

Delaying action

Foresters in the region are conducting a delaying action against rival claims on land for agriculture or for the grazing of livestock. The tropical rain forests present a major problem. Foresters still talk of the promotion after logging of natural regeneration on 100-year cycles, but this is rarely followed in practice. In Java, the relict vegetation on denuded land which might theoretically be reclaimed is used for fuel collection by thousands of people who have few alternative sources of income. Claims are made for the control of *Imperata cylindrica* by deep ploughing (Sumatra), replacement by sown fertilised pastures correctly managed to prevent regeneration (Sabah and the Philippines), or the use of systemic selective weed killers (Malaysia).

The marginal nature of the grazing and browsing resources of arid and semi-arid India are the concern of three research institutes, the Central Arid Zone Research Institute, the Indian Grassland and Fodder Research Institute and the Central Sheep and Wool Research Institute. These compare the relative merits of slow but cheap ecological progression and of reseeding with species of the local climax covers. A substation of the Japanese National Grassland Research Institute at Nishinasuno is developing methods for hill slope utilisation by the cheap method of hoof cultivation for the rearing of Holstein heifers for the dairy industry—a technique that may well be applicable in mainland China, Korea and Taiwan.

The reclamation and planning of future use of marginal land fall between a number of departments and institutes of central or state administrations. If these were to be regarded as a discrete aspect of land use the economic benefit would be great, particularly for the livestock and forest industries. That some type of joint action on a regional basis would be profitable, through ASEAN, the Asian Development Bank or the UN International Consultative Group for Agricultural Research, seems almost indisputable. ☐

Asia's marginal lands

Robert Orr Whyte examines the prospects for reclamation of an important natural resource

> There are no unproductive regions. There are only poor methods for cultivating land; there is no such thing as poor land. Provided only that people manifest in full measure their subjective capacities for action, it is possible to modify natural conditions.
>
> **Mao Tse-tung**

If the countries of monsoonal and equatorial Asia are to act upon the injunctions of United Nations and bilateral agencies and learn to feed themselves, they must utilise all their land and sea resources to the full. At present, there is insufficient knowledge of the real nature and magnitude of the land resources to show whether and to what extent this enormous target can be met. An assessment of land resources on modern lines is essential to confirm or adapt the existing land classes, and to define their relative areas and potential. The classes usually recognised are forests (protective or productive), grazing lands, uncultivable land other than forests, and cultivated land, whether used under systems of shifting cultivation, for plantation agriculture, or for dryland or irrigated crop production. However, one major land class which does not regularly appear in the statistics is marginal land.

Definition of the term depends upon the discipline of the speaker. Most of the uncultivated land, and much of the cultivated land that one sees in flying over the South Asian subcontinent or over the People's Republic of China, is marginal in nature. The agriculturist regards land as marginal when, because of terrain, soil or climatic conditions, the cultivation of arable crops becomes a risky enterprise, involving complete or partial crop failure in two or more years out of ten. The forester regards land as marginal when he cannot apply the appropriate silvicultural techniques to stands of natural vegetation, or when he cannot plant, maintain and harvest the produce from reforested blocks. Grazing land, particularly in arid and semi-arid regions, is marginal when it cannot supply feed of adequate quantity and quality to nomadic and migratory flocks and herds within a radius of daily walking distance, or when resources for stock watering are inadequate.

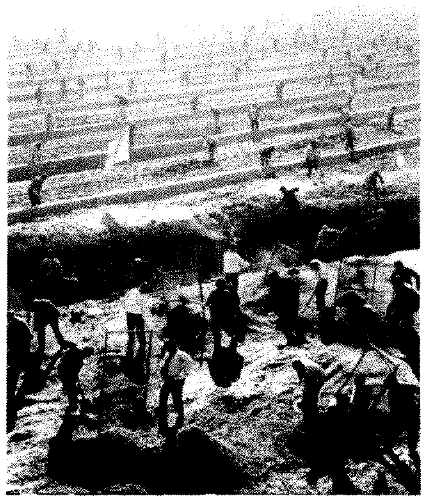
Land may be marginal in its natural state, or may have been rendered marginal due to the activities of man. The total area of marginal land of all types is not known. It is probably at least as large as the area under non-marginal cultivation at present. Only part of the marginal land of the region comes within the scope of the UN Environment Programme's Conference on Desertification, to be held in 1977.

It is debatable whether the greater potential for reclamation and increased production does not lie in the more densely populated countries of humid tropical Asia. The final criterion must be economic—whether the expense involved in bringing land back into economic use or in raising it from one plateau of production to the next above for the benefit of the local population can be justified under present conditions.

Attention to the problem of marginal lands must also be seen in correct perspective. It takes second place to the increase of productivity on existing cultivated land, which remains the great potential. The world average production of cereal grain per hectare is 1,898 kg. If the standards of Japan and other developed countries were to be achieved, the world output of cereals from existing cultivated land would be 3,286 million metric tons, or 859 kg per capita, or 95% of American consumption (see Lincoln Gordon and C. A. Pryor, *Science*, September 19, 1976). Yet we are still losing ground in this respect. In India, net availability per capita per day of cereals and pulses from domestic production was: 1956, 15.2 oz; 1974, 15.97 oz, and 1975, 14.65 oz.

Area increasing

The shifting cultivator has made the largest contribution to the man-made area of marginal land, and the area is still increasing rapidly year by year. Increased pressure of population on existing land resources and the progressive loss of traditionally exploited forest land to settled cultivators and timber extractors cause progressive reduction in the period of bush fallow. Regeneration of vegetation does not occur between successive periods of cultivation, and soil fertility deteriorates. What remains in humid tropical South-East Asia are pure stands of *Imperata cylindrica*, the 'green cogon deserts', much of which may still be reclaimed and can be regarded as marginal.



A-CEI

Turning poor soil to farmland

An estimated 2.5 million hectares of potentially productive land are lying barren, because of high sodicity (alkali or sodic soils), in the west of the region and in the Indian States of Punjab, Haryana and Uttar Pradesh in particular. Inadequate surface drainage and consequent stagnation of water for prolonged periods, and a rise in the ground water table and accompanying physicochemical changes, appear to have resulted in the formation of these soils. These areas are currently grazing grounds for domestic livestock of low productivity or for abandoned bovines which have reverted to a semi-wild condition.

Probably at least comparable in area to the marginal lands created by shifting cultivation are the areas abandoned after deforestation. This happened in historical times in the Himalaya and their associated ranges and in China, and in recent and modern times in the Philippines, Indonesia and East and West Malaysia. Only limited areas have been reforested or transferred to plantation and arable agriculture in new economic ecosystems. These, however, rarely have the same conservation value as the biological ecosystems they have replaced.

The slaughter of the tropical rain forest in South-East Asia is eliminating the last remnants of a unique biological ecosystem, with its relatively unexplored genetic resources of plants and animals. And the areas from which marketable timber have been removed are left in such a condition after the operations of logging and extraction that further deterioration is inevitable, in terms of plant cover, soil erosion, desiccation of the environment and increased carbon dioxide content of the atmosphere—all factors not so far assessed accurately.

South Asia's marginality

The establishment of the drought-resistant plant and animal communities in the South Asian subcontinent, formerly tropical rain forest, followed the

Science as an education

In this shortened version of a talk he gave recently on BBC Radio 3, Professor Sir Hermann Bondi, Chief Scientific Adviser to the Ministry of Defence, argues for a view of science as an education of the mind, rather than as professional training

My thesis is that science should be taught like the classics but has increasingly been taught like medicine. A medical education is a professional training with a practising doctor as end product. A classical education (and I would include more than just the classics here) has no such clearly defined end product, but is widely accepted as a good preparation for demanding tasks in administration and management. The reason is that students are taken through the thinking of some of the finest minds humanity has ever known, discuss and debate the difficult, often undecidable questions that these people discussed, and are trained to express themselves by word of mouth as well as by writing and to give a structure to their ideas, however complex or sophisticated the subject.

This is precisely the ability helpful in any senior task; in such a task one always deals with people and it is through argument and discussion, papers and analysis that one arrives at the kind of conclusion, at the kind of leadership, at the kind of consensus this necessary for achieving anything in administration and management. The only criticism must be that classics courses are very short indeed on numeracy, a skill which is of particular importance to administrators and managers who need to analyse statistics critically.

We have had a lot of trouble in recent years with young people not coming forward in the numbers expected to do science. This limited success of science in the all-important field of marketing an academic education is often ascribed, rightly, to the liking of young people to work with people rather than to deal in facts. This attitude reveals a misconception of what science is like, that to me is simply staggering. Science doesn't deal with facts; indeed, fact is an emotion-loaded word for which there is little place in scientific debate. Science is above all a cooperative enterprise. It is a social activity which is perhaps more successful than any other in enabling people of different religion, politics, race, culture and ideology to work together, and it is thus a particularly human subject.

Science reveals its humanity most in those research issues that are the subject of current debate, discussion and seminar. In these fields there is no certainty, only arguments. These arguments can indeed be supported in an exceptionally important way by experiment, but can also be disproved by a sufficiently careful and ingenious experiment or observation. Science is thus a field in which imagination is of the utmost importance: not, it must be emphasised, untrammelled imagination, but imagination carefully controlled by what can and cannot be tested experimentally.

> 'It ill-becomes scientists to deplore the fact that so few of them are in parliament, the upper reaches of the Civil Service, the banks, the highest positions in industry. For have science courses been aimed to produce such people?'

When we look at science, not so much as a profession but as an intellectual adventure, it is clear that it has had some of the finest minds that mankind ever produced, grappling with problems a little harder to define than some of the philosophical problems of the ancients, but also problems where, through the test of experiment and observation, human imagination has been brought to its highest peak. This aspect of science does not come across anything like well enough to attract young students.

If it is educational for performers of senior and responsible tasks to be taken through the thoughts of a Plato, is it not just as good, perhaps even better, for them to be taken through the thoughts of a Newton or an Einstein? I say better because of the additional demands of numeracy. I claim that if we conceive of science as a group of subjects offering an education in thinking, communication and particularly the evolution of human ideas generated by an unequalled creativity, originality and imagination, then the education that can be provided is unsurpassed.

Hitherto the voracious appetite of government and industry for scientists during the 1950s and much of the 1960s propelled the universities into producing the maximum number of professional 'bench' scientists they could, which was thought, to some extent at least, to involve stuffing as much scientific knowledge into them as was possible. I would not wish it to be thought that I view those efforts—in sime of which I partook—as bad or disadvantageous; only that the emphasis was confined, incorrectly, to the aim of producing professional scientists.

If one had viewed science as an education of the mind rather than as professional training, naturally students emerging with a first degree would have known less science. But they would have known more about the kingdom of scientific ideas, about how to argue, about the evolution of human thinking and about how scientific debate and the interaction of experiment and theory stimulate creativity.

Further, such an orientation of science courses might also produce better scientists, first because such teaching would attract many of the ablest young people now repelled by the supposedly inhuman face of science, and second because in science itself an ability to argue, debate, and understand the other person's ideas, however imperfectly expressed, is at least as important as sheer scientific knowledge.

It ill-becomes scientists to deplore the fact that so few of them are in parliament, the upper reaches of the Civil Service, the banks, the highest positions in industry. For have science courses been aimed to produce such people? There have been a number of efforts in the past ten or fifteen years to improve the balance. They have had most creditable success in establishing novel courses, but these only affect a very small proportion of the science students and therefore do little to alter the prevailing misconception of what science is.

I do not want it to be thought that science as an education is intellectually less demanding than an education in science. Quite the contrary. And I certainly would not wish to propagate a course that was not really demanding, because that would fail in its purpose: attracting the ablest young people to what is the most exciting area of human enterprise. ☐

Ford leaves a healthy legacy

GERALD FORD will no doubt be recorded in the history book as a President who, in his brief term of office, performed an extraordinary act of national healing, pouring a good deal of soothing balm on the political wounds inflicted by his predecessor. He did nothing too flamboyant, pursued few major new initiatives, and left the overall structure and operations of the federal government virtually intact. That pretty well sums up his record in science policy as well.

When he entered the White House two-and-a-half years ago, relations between the federal government and that slice of the population known as the scientific community were at an all-time low. When he handed over the reins to President Carter last week, the management and funding of federal science had been placed on a firmer footing, and the scientific community was, if not satisfied, at least mollified.

Mr Ford's most conspicuous act of healing in science affairs was the reinstatement of a science policy office in the White House, a move which has won much praise even though the new office came into being a scant five months before Mr Ford left Washington. Few of Mr Nixon's acts caused as much bitterness among scientists as his decision in 1973 to abolish the Office of Science and Technology and the President's Science Advisory Committee, bodies which had been providing scientific advice to the White House for more than a decade. Mr Ford's decision to reinstate a science advisory apparatus in the White House, though it took most of his Presidency to accomplish, has laid the basis for more rational scientific planning.

As far as budgets for research and development are concerned, Mr Ford has again placed matters on a relatively sound basis. When he came to power, he inherited a dismal state of affairs. During the previous few years, total federal support for research and development had declined as inflation more than gobbled up the small dollar increases proposed by Mr Nixon. Basic research was especially hard hit, with federal support declining in real terms by more than 20% between 1969 and 1973. And superimposed on the slow downward drift was a debilitating series of abrupt oscillations in funds for some programmes as Mr Nixon attempted to put a hold on public expenditure and to shift funds into priority areas at the expense of less politically favoured programmes. During Mr Ford's brief Presidency, there has been some real growth in funds, and basic research has been given a welcome boost.

The growth was particularly surprising because the three budgets which Mr Ford submitted to Congress all reflected his overriding concern to curb the overall rate of growth in the federal budget; science was given a financial boost while other programmes, particularly those in health and welfare, were held back. And Mr Ford's last budget, delivered to Congress just three days before his departure, continued the trend and even added some long overdue support for new research programmes in agriculture and the earth sciences.

But that does not mean Mr Ford has solved all the problems in federal support of research and development, and that he is handing President Carter a trouble-free scientific enterprise. Far from it.

Energy policy is in a mess, and oil imports are actually higher now than they were before the 1973 embargo. The overall strategy which has marked both the Nixon and Ford energy policies was to throw massive amounts of money into energy research and development, particularly nuclear technologies, in the hope of increasing energy supplies. Little attention has been paid to curbing demand, either through regulation or research on energy-saving technologies, and President Carter has rightly criticised the outgoing Administration for its failure to establish a coherent energy policy. A particular failure has been the Ford Administration's attempts to curb nuclear proliferation, where policies have been thrown together in response to crises rather than developed by careful planning.

In the area of biomedical research, Mr Ford inherited a particularly dismal situation, and though he has made some progress, he is leaving his successor a number of problems. Two chief factors have led to disarray in biomedical research planning. The first was the passage of the National Cancer Act, which has caused funding for cancer to balloon while support for many other areas of research has languished. Although Mr Ford has tried to redress the balance in his budgets, he did not acknowledge, let alone implement, some modest recommendations for reform published last year by a Presidential commission.

The second principal area of irritation has been a continuing struggle between Republican Administrations and the Democratic Congress over the size of the budget for the Department of Health, Education and Welfare. Presidential vetoes and refusals to compromise on both sides have greatly delayed the passage of appropriations bills and caused federal funds to flow into the National Institutes of Health in a series of surges and trickles. Mr Ford's budgets, including his final proposals, have perpetuated the trend.

Nevertheless, on balance, Mr Ford is leaving his successor a surprisingly healthy scientific legacy, and few major changes in the federal science policy should be anticipated from the new Administration, at least in the next year or so. □

announcements

Appointments

Professor C. C. Booth has been appointed by the Medical Research Council to succeed Sir Graham Bull as Director of the Clinical Research Centre, Northwick Park, Harrow.

Awards

The **Paul Martini Award** has been increased to 20.000 DM. The award is for development of scientific methods for evaluation in the clinical, pharmacological and therapeutic fields. Papers should be sent with six copies to the Medizinisch Pharmazeutisch Studiengesellschaft e.V., Humboldtstrasse 94, D 6000 Frankfurt. The competition deadline will be April 30, 1977.

Meetings

March 23–25, **Nuclear Physics,** Surrey (Institute of Physics, 47 Belgrave Square, London SW1).

March 23–25, **The Challenge of Change,** York (Institute of Information Scientists, S. Nichol, 'Rivendell', Southfield Road, Driffield, North Humberside).

March 26–April 5, **Genetics, Evolution and Ecology of Marine Organisms,** Venice (J. A. Beardmore, University College of Swansea; P. Battaglia, University of Padua).

March 28–April 1, **Chemistry in Our Lives,** London (The Chemical Society, Burlington House, London W1).

April 4–7, **Displays for Man-Machine Systems,** Lancaster (Institution of Electrical Engineers, Savoy Place, London WC2).

April 15–16, **Stadler Genetics Symposium,** Columbia, Missouri (117, Curtis Hall, University of Missouri, Columbia Mo 65201).

May 3, **Crop Protection,** Gent, Belgium (Ir. W. Dejonkheere, Agricultural Sciences, University of Gent, Belgium).

May 25–27, **The Testis,** Toronto (I. B. Fritz, University of Toronto, 112 College St, Toronto, Ontario M5G IL6, Canada).

May 31–June 2, **Pharmaceutical Technology,** Paris (Association de Pharmacie Galenique Industrielle, Rue J. B. Clement 92290 Chatenay-Malebry, France).

June 1–3, **Frequency Control,** Atlantic City, New Jersey (J. R. Vig, US Army Electronics Command, Fort Monmouth, New Jersey 07703).

July 5, **Solar Energy Conversion,** London (P. T. Landsberg, The University, Southampton).

July 17–20, **International Metallographic Society,** Houston, Texas (IMSI, Evanston, Illinois 60204).

July 25–28, **Myxobacteria,** Norwich (J. H. Parish, Biochemistry, University of Leeds, UK).

August 15–17, **Endocrine Functions of the Testis,** Austin, Texas (Society for the Study of Reproduction, 113 North Neil St, Champaign, Illinois 61820).

August 21–September 3, **Genome Organisation and Function,** Spetsai, Summer School (H. G. Zachau, Institut für Physiologische Chemie, Physikalische Biochemie und Zellbiologie, Goethestrape 33, D-8000 München 2).

August 23–26, **Chemical Thermodynamics,** Ronneby, Sweden (IUPAC Conference, S. Sunner, Chemical Centre, Lund University, PO Box 740, S-22007, Lund, Sweden).

August 24–26, **High Polymers, Ottawa** (J. Roovers, 19th Canadian High Polymer Forum NRCC, Division of Chemistry, Ottawa, Ontario KIA OR9, Canada).

September 1–2, **Cancer Immunotherapy and Prophylaxis,** Bucharest (Oncological Institute, P.O. Box 5916, Bucharast 12, Romania).

September 5–9, **Precise Electrical Measurement,** London (Institution of Electrical Engineers, Savoy Place, London WC2).

October 2–8, **Physical and Chemical Information Transfer in Regulation of Reproduction and Ageing,** Varna, Bulgaria (J. G. Vassileva-Poppova, Biophysics, Bulgarian Academy of Science, 1113 Sophia, Bulgaria).

October 17–20, **European Society for Radiation Biology,** Liège, Belgium (R. Goutier, 32 Boulevard de la Constitution, B-4020 Liège, Belgium).

October 31–November 4, **Radioimmunassay,** Berlin (E. H. Belcher, Medical Applications Section, IAEA, Kartner Ring 11, PO Box 590, A 1011, Vienna, Austria).

April 4–7, 1978, **Communications Equipment and Systems,** Birmingham (Institution of Electrical Engineers, Savoy Place, London WC2).

Person to Person

Surrey–Minneapolis, St Paul. 4-bedroomed house in Frensham near Farnham, Surrey, offered in exchange for similar sized house in Minneapolis, St Paul, from March 1977 for one year. Frensham is a village in delightful countryside within commuting distance of London by train. The Universities of Surrey and Reading are within 30-min drive. Contact Dr J. N. Gibbs, Dragon Lodge, Millbridge, Frensham, Surrey.

Wanted: copy of *The History of the Study of Landforms,* vol. 1, *Geomorphology Before Davis,* by R. J. Chorley, A. J. Dunn & R. P. Beckinsale (Methuen, London, 1964). Please state condition and price to Dr P. J. Smith, Department of Earth Sciences, Open University, Walton, Milton Keynes, UK.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The **section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.**

Bare outlines of medicine

Molecular and Cellular Mechanisms in Disease. Vol. 1: Pp. xv+1–604+xxvi. Vol. 2: Pp. ix+605–1116+xxvi. By Julian L. Van Lancker. (Springer: Berlin and New York, 1976.) DM362, $148.50.

After some random reading here and there in the two volumes which make up this enormous monograph, I began to experience an extraordinary sensation of *déjà vu*. It was easy to trace this sensation to my memory of an earlier, equally enormous monograph on cellular pathology. The relationship between the two may be likened to that between the very 'with it' grandson of a highly respectable grandfather, with the grandson remaining very much a pillar of the family firm. Every generation of pathologists seems to produce one who cannot resist the temptation of trying to put down in one tome all knowledge that could possibly pertain to the subject, presumably in the hope of making it more comprehensible. This is in the tradition of Virchow and Cohnheim. In their day one man could still know enough facts in all the very different facets of pathology with sufficient accuracy to think about their interrelationship fruitfully. That has long since become impossible.

This book, therefore, demonstrates the case against a multi-topic textbook written by a single person. An almost unbelievable erudition is incapable of preventing errors of fact and distortions in interpretation, usually as a result of oversimplifications, which are serious enough to vitiate any supposed advantage arising from the unity of one man's outlook. In the arts a wide-ranging survey by one percipient mind may be singularly stimulating; thus, the *Outline of History* by H. G. Wells is for many an unforgettable intellectual experience. That this is still possible in the natural sciences is shown by such books as Jacques Monod's *Chance and Necessity* or Richard Dawkin's *The Selfish Gene*. But these are books of ideas, not compendia of information; and therein lies the difference between monographic success and failure.

In the preface the author says: "The book cannot be comprehensive because too little is known about the mechanisms of disease, and no-one could hope to master all available knowledge." So the puzzle is why the attempt was made to do just that. The comprehensiveness of the attempt is shown by the chapter headings: cellular sources of energy; determination of cellular specificity; inborn errors of metabolism; malnutrition; calcium and phosphorus metabolism; iron and bile pigment metabolism; blood coagulation; hormones; alterations of body fluids and electrolyte metabolism; cellular death and degeneration; blood lipids in arteriosclerosis and hyperlipidemia; radiation; inflammation; immunopathology; regeneration, hypertrophy, and wound healing; cancer.

The only way in which someone with much else to do can assess such a book is by reading carefully sections in which his own knowledge is as accurate as possible. Thus, the chapters on blood coagulation, hormones, blood lipids in arteriosclerosis and hyperlipidemia, and inflammation contain much useful, standard information, but any serious student would have to be provided with accurate, up-to-date reviews to correct impressions produced by the book. For example, many of the statements on page 410 are erroneous in fact or interpretation; on page 767 consideration of increased capillary permeability is entirely morphological and non-quantitative, and ignores all physiological and quantitative descriptions; on page 771 there are still discussions of "leukotaxine" and "exudine" which might have been assumed to have been buried long ago; and on page 775 and beyond, the account of the prostaglandins is necessarily already out of date. Indeed, such a book is bound to be out of date by the time it appeared. The references seem to be mainly to the 1960s although some reach as close to the present as 1973 and 1974; and there are references to truly historical papers. There is no harm in that—on the contrary, students nowadays know much too little of the history of their subjects—as long as it does not result in underemphasis of modern developments.

According to the preface, the book is addressed to students of disease whether they are clinicians or researchers. "Hopefully, it will contribute to making medicine more of a science, guide the investigator in unexplored territory, and help the practitioner respond to the request of Macbeth, '. . . find her disease/And purge it to a sound pristinge health'." It seems sad to have to conclude that this book will not achieve what the author hopes of it.

Professor Born is Sheild Professor of Pharmacology at the University of Cambridge, UK.

Contemporary immunology

Manual of Clinical Immunology. Edited by N. R. Rose and H. Friedman. Pp. xxv+932. (American Society for Microbiology: Washington, August 1976.) Hardback $20; paperback $16.

The burgeoning of immunology in the past twenty years has caused alarm to granting bodies and to its increasingly confused protagonists. The grass roots of this monster growth are to be found in methods of vaccination, blood group typing and the various serodiagnostic and classificatory methods of microbiology. Since the last war the successive discoveries of cell-mediated immunity, immunological tolerance, the recirculation of the lymphocyte, a function for the thymus and the fine structure of immunoglobulin molecules have effectively nourished the somewhat desiccated root disciplines and led to the rather top-heavy state of contemporary immunology.

The present volume is a blend of applications of the new immunology with up-to-date versions of some of the older approaches. It is sad that relatively little space is given to epidemiological studies, to vaccination technology and strategy, to the special problems of immunological staging of cancer patients, to the quantitation of lymphocytes by reference to their origins and to parasitic diseases. It may be, however, that some of these topics are already well covered in other large books. The emphasis of the book is avowedly practical, and as a manual it is remarkably useful even if not comprehensive.

The book is split into eleven major sections covering fields such as "Transplantation immunology", "Immunoassays", "Autoimmune diseases" and "Humoral immunity". There is a welcome section on the organisation and development of clinical immunological facilities. Each section consists of a number of papers by specialists in the field. It is claimed that enough information is given about techniques for an experienced technologist to carry out a procedure which was new to him (or her) without further search of the literature. As far as I can judge the chapters are clearly and concisely written with snags and deficiencies exposed to view.

It would be nice to see a book like this with the pages detachable on metal rings and with a visible index if it is really intended as a laboratory manual. The book is, however, good value.

A. J. S. Davies

A. J. S. Davies is Professor of Immunobiology in the University of London, working at the Chester Beatty Research Institute, London, UK.

Drosophila genetics

The Genetics and Biology of Drosophila. Volumes 1a, b, c. Edited by M. Ashburner and E. Novitski. Pp. xv+486, xv+487–954, xii+955–1,427. (Academic: New York, San Francisco and London, 1976.) £16.80 per volume.

THE present three volumes represent a substantial part of an ambitious treatise dealing with the genetics, biology, development, evolution and ecology of *Drosophila* in the form of a series of articles contributed by specialists in the various subdivisions of this extensive field. They deal with the more strictly genetic aspects and display the great variety of analytical techniques which can be applied, especially in *D. melanogaster*. Ever since the early days of *Drosophila* genetics, presided over by the now legendary associates of T. H. Morgan, there has been a progressive development of ingenious ways of exploiting structurally altered chromosomes to investigate the properties of genes and chromosomes, often combined with supporting evidence from the ordered banding of the polytene chromosomes of the salivary gland. This methodology is dealt with in the articles according to their relevance to particular topics, but it is a pity there is no classified account of the principles of analysis and how they may be applied to different kinds of problem. This would have been valuable for newcomers to *Drosophila* and would have reduced the sense of discontinuity created by the rather arbitrary ordering of topics. Is it too much to hope that such an article could be included in a later volume of this series? Might the editors be persuaded to round off their labours with what could well be a *tour de force*?

In the total of some 1,400 pages the articles deal with such topics as chromosome aberration, conditionally expressed mutations, mosaic systems, gene conversion, meiotic mutants, distributive pairing, compound and ring chromosomes, altered segregations including segregation distortion, genetics of the Y chromosome, analysis of simple and complex loci, analysis of the proximal region of the X chromosome and of the fourth chromosome, position effect variation, mitotic recombination, the bobbed locus, radiation genetics, chemical mutagenesis, polytene chromosomes, together with reviews of *D. virilis* and *D. hydei*.

Merely to list these topics, which are generally covered in depth, is sufficient to indicate the wealth of information and conceptual diversity packed into these volumes. Naturally, almost all the theoretical framework has been strictly genetic in origin; ultimately it will have to be reconciled with molecular evidence and interpretation, and a promising start has been made in that direction. Studies of the kinetics of extracted DNA, its appearance under the electronmicroscope, DNA–DNA and DNA–RNA hybridisation, the sequencing of satellites, *in situ* hybridisation to the polytene chromosomes and the characterisation of transfer RNA have already made a notable contribution. The elegant analysis of the bobbed locus described here is an excellent example of how the classic *Drosophila* methodology can be integrated with the analytical methods of nucleic acid biochemistry. Current developments in DNA sequencing will surely guarantee that the *Drosophila* genome will continue to be better known than that of any other eukaryote.

This interest in the use of the analytical tools provided by *Drosophila* is not confined to molecular biologists. In the past decade students of embryonic development and differentiation, cell lineage in organ formation, behaviour, and the biochemistry of gene action have discovered in *Drosophila* strategically significant situations worth investigating.

One of the pleasing features of this work is that the historical aspect is not neglected. There is an introductory chapter by C. P. Oliver, one of the *Drosophila* veterans, which outlines the chronology of the major discoveries. In many of the articles there is comment on the origin of new interpretations or techniques and the reader is often thus reminded of the friendly exchange of stocks and ideas which has been, and remains, a traditional attitude among *Drosophila* workers.

It is obvious from the list of 44 contributors to the first three volumes of this series, that the centre of gravity of *Drosophila* research lies within the confines of North America, not overlooking some important European laboratories. It is a pity there are so few British laboratories in which the *Drosophila* lore flourishes. Perhaps these historic volumes will encourage some of our younger biologists to invade the field, provided they have a chance of reading them, none too certain in these days of dwindling library grants in view of the regrettably formidable price per volume.

It must have required immense effort, patience and tact on the part of the editors to marshall so many authors and ensure that the contributions were sufficiently similar in style and standard. They are to be congratulated on their altruistic devotion which will be gratefully acknowledged for many years to come. **Forbes W. Robertson**

Forbes Robertson is Professor of Genetics at the University of Aberdeen, UK.

Marine pollution

Effects of Pollutants on Aquatic Organisms. (Society for Experimental Biology, Seminar Series 2). Edited by A. P. N. Lockwood. Pp. x+193. (Cambridge University: Cambridge, London and New York, September 1976). Hardcover £8.50; paperback £3.80.

THE overall trend towards physiological effects and turnover is apparent from most of the papers collected in this volume. Heavy metal storage, excretion and tolerance is covered comprehensively by Bryan with considerable experimental data on *Nereis*. The effects of cadmium on fish biochemistry is described by Larsson *et al.* Cautious comparisons are made with published work in the mammalian field.

Fish physiology is taken up further by Lloyd and Swift. Gas exchange and water balance are discussed with some emphasis on the care required in explaining observed abnormalities in fish kept in captivity. A quantitative approach towards histological studies in gills is presented by Hughes along with interesting information on fish respiratory and circulatory mechanisms. Support is expressed for the tentative hypothesis of Lloyd, that increased ventilation rate by the gills increases the toxicity of poisons.

Organochlorine compounds are dealt with in a detailed review by Addison, in which the author makes several helpful suggestions for future work. The effects of hydrocarbons are covered in two papers. Corner *et al.* comprehensively cover zooplankton and fish. Vandermeulen and Ahern appropriately deal with the primary producers, being concerned with algal physiology. Both papers include experimental data on the effects of naphthalene on these organisms. Zooplankton and phytoplankton are discussed again by Reeve *et al.* who describe the first year's results obtained in the ambitious 'Controlled Environment Pollution Experiment'. Interesting comparisons with laboratory-acquired data are presented with particular reference to copper.

The wide coverage of this book, its readability and excellent index, will make it valuable for project hunters and established researchers alike.

G. C. Carney

Dr Carney is a Lecturer in the Department of Science at Bristol Polytechnic, UK.

WILEY
INTERSCIENCE

Water, Wastes and Health in Hot Climates

edited by **R. Feachem,** *Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine;* **M. McGarry,** *International Development Research Center, Ottawa,* and **D. Mara,** *Department of Civil Engineering, University of Dundee.*

This book is a multi-disciplinary approach to the problems associated with water and wastes in hot climates, particularly those of the tropical developing countries. Solutions for these types of problems in hot climates have generally been modelled on practices adopted in industrialized countries with temperate climates which are invariably inappropriate. This book provides a basis for the interdisciplinary activities required to make the best use of the resources available in sanitary engineering in the Third World.

Randon Measures

Olav Kallenberg

1977, 104pp., £6.00/$10.00 0.12.394950.5

Randon measure theory is a new and rapidly developing branch of probability, being of increasing importance both in applications and as a tool in other theoretical fields. Although, historically, most results of the theory were first discovered in the point process case, the more general framework of random measures seems to provide the natural scope of a theory.
The present book gives a concise and systematic account of some basic ideas of the subject, and emphasises questions of uniqueness and convergence in distribution, as well as the notions of infinite divisibility, null-arrays, symmetric distributions, Palm distribution, and mixed Poisson and sample processes.

European Monographs in Social Psychology Number 11
Series editor: H. Tajfel

Linguistic Style and Persuasion

Rolf Sandell

February/March 1977, xiv + 330pp., £10.50/$23.00 0.12.618150.0

In a world where mass communication plays an important part in our attitudes towards people, ideas, events and objects, the wording of a message may well be the most significant factor in persuading us to adopt a particular point of view. How susceptible are we to linguistic style? How profoundly can the impact of a message be enhanced by the manner in which it is written? This stimulating study approaches these questions from an entirely fresh viewpoint. Instead of using a general psychology of language, the author introduces "psychostylistics", the differential psychology of language which outlines a new pathway to the understanding of language as a manipulatory tool.

The Plasma Membrane

Models for Structure and Function

B. D. Gomperts

February/March 1977, xx + 256pp., £11.40/$22.25 0.12.289450.2

In the fast expanding field of membrane science, there now exists a need for specialised monographs at an introductory level devoted to selected aspects. This book brings together a wide experience of the analytical and synthetic approaches to membrane structure with the aim of showing how these may be applied to more general problems of membrane function and mammalian cell biology, and lays great stress on the development and use of model structures in the investigation of membrane structure and function. This monograph is probably the first extensive discussion of this important field to appear at this level; it illustrates how a firm understanding of model systems can be used to unravel complex problems in cell biology, and includes a discussion of work emanating from the author's own laboratory on the mechanism of cellular activation in a secretory system.

The Analysis of Organic Materials An International Series of Monographs Number 9

Aldehydes — Photometric Analysis Volume 4

Eugene Sawicki and Carole R. Sawicki

January/February 1977, x + 288pp., £12.00/$26.25 0.12.620504.3

Here is the fourth in this comprehensive series on the photometric analysis of aldehydes. It discusses the photometric analysis of precursors through their derived aldehydes and also the formation of aldehydes through a variety of reactions. In the future, the latter could be of increased importance in the development of methods of analysis utilizing photometry, gas chromatography, high performance liquid chromatography and mass spectrometry.

Advances in Aquatic Microbiology Volume 1

edited by M. R. Droop and H. W. Jannasch

Autonomic nervous system

Structure of the Autonomic Nervous System. By G. Gabella. Pp. viii+214. (Chapman and Hall: London; Halsted: New York, June 1976.) £9.80.

DR GABELLA has produced an informative account of the structure of the autonomic nervous system. It is given in small compass (160 pages), and the author has also restricted his historical introduction to just over a page. The book then examines the structural anatomy of sympathetic ganglia and peripheral sympathetic nerves, including their development and regeneration. Parasympathetic structures, including the ciliary ganglia and the vagus nerve, are then described. The last chapter is devoted to the innervation of organs, including the eye, salivary glands, skin, adipose tissue, gut, the heart, blood vessels, respiratory tract and the genital tracts. The monograph is well supported by 800 references which are helpfully arranged at the end of the book in alphabetical order .The references quoted are recent, and many have been published in the 1970s up to 1975. The information is based on comparative anatomy and there is frequent mention of the species on which the observations have been made.

Thus the book provides well documented information on the structures described, and will be valuable as a source of reference to anyone who is dealing with the structural anatomy of the autonomic nervous system in animals as well as man. The book has, however, some limitations. On the production side it seems unfortunate that the error in binding—the plates have been incorrectly placed—should not have been corrected, so that the publishers have only noted the error with an erratum slip. It is nevertheless a well produced and attractive volume. There are also some deficiencies in its composition: structure has been interpreted as histology rather than gross anatomy, and the book provides only limited information about the anatomical distribution of nerves. Thus description of the variations in the sympathetic outflow and its links with the sympathetic chain ('prefixing' and 'postfixing') are not included. The autonomic innervation of the eye is restricted to a discussion of two tissues only—the iris and the nictitating membrane—and there is no discussion of the eyelid. On the structural side the information is chiefly relevant to the peripheral autonomic nervous system, and details of the central nervous system are limited. So limited are they, that 'spinal cord' and 'hypothalamus' do not occur in the index and the chapter on the central nervous system (chapter 9) is only 3.5 pages long.

The description of the book explains that it is intended as a basic reference work on the autonomic nervous system for students of, and research workers in, the fields of physiology, pharmacology and neurobiology. As a description of the anatomical structures of the autonomic nervous system at a histological level, it is excellent. But it provides only limited information on the physiological mechanisms involved, and the pharmacology of the system is only briefly discussed, there being no biochemical information throughout the book. Clinical research workers will also find that it does not provide any information on pathology or the clinical relevance of any of the structures described. It may, however, be argued that this was not the intention of the book.

This book can be strongly recommended as a work of reference for any worker engaged in the study of the autonomic nervous system. It should also be available in libraries, but I feel that its information is too restricted for students or most clinical research workers.

R. H. Johnson

Dr Johnson is Senior Lecturer in the Department of Neurology, University of Glasgow, and Consultant Neurologist at the Institute of Neurological Sciences, Glasgow, UK.

Noctilucent clouds

Noctilucent Clouds. By V. A. Bronshten and N. I. Grishin. Pp. v+237. (Israel Program for Scientific Translations: Jerusalem; Wiley: Chichester, February 1976.) £8.25; $16.50.

EVER since the first observations in 1885, noctilucent clouds have been a challenge to atmospheric physicists, in particular to those dealing with problems related to the upper atmosphere. Apart from data on meteors, information on the 80-km region, where the clouds are situated, was almost nonexistent until rocket measurements became available some twenty years ago. Thus, for about seventy years, noctilucent clouds provided a playground for scientists with skill and imagination.

Noctilucent clouds also differ from most other problems in science in the following respect: during ninety years of research an enormous amount of data on various aspects of the problem has been collected and yet the two main problems remain unsolved: how do noctilucent clouds form and what do they consist of?

Since the early 1950s, V. A. Bronshten and N. I. Grishin have contributed much to our knowledge of noctilucent clouds, and their names are well known to colleagues all over the world. In view of their contact with the problem over such a long timespan, they are in the best possible position to undertake such a comprehensive presentation of the history and state of the art of noctilucent clouds.

The book is obviously meant to cover the subject of noctilucent clouds exhaustively, and in large measure the authors have succeeded in their ambitious goal. The huge amount of information on the history of theories, abandoned or still under consideration, and on observational data and techniques, classifies the book as far the most useful and comprehensive source for students at all levels. One may say that there is a bias towards citing the results of Russian scientists. For readers from Western countries, however, this is an advantage rather than a weakness, since it makes available material which is otherwise difficult to obtain.

In the reviewer's opinion the greatest value of the book is to be found in the first four of the book's six chapters: history; range of distribution and frequency of occurrence; morphology and dynamics; and luminosity. All these chapters are very comprehensive and very well presented—not surprising, since this is where the authors have their primary interest and competence. Chapter 5 on the nature of noctilucent clouds is not as complete and up to date as one might wish. The manuscript of the book was, however, finished in June 1969, and much of the information about mesospheric humidity has become available since then. The historical paper by Bates and Nicolet on water vapour in the high atmosphere clearly deserves due reference, and photochemical models with eddy transport, pointing at a humid mesopause, were also available.

This book will be a valuable reference for all those interested in noctilucent clouds.

reviews

Machiavelli with a computer

Eric Ashby

The Humane Technologist. (Science and Engineering Policy Series.) By D. Davies, T. Banfield and R. Sheahan. Pp. ix+180. (Oxford University: Oxford, 1976.) £4.75.

FOR some inscrutable reason the dust cover of this book carries a puff from the co-founders of the Club of Rome. Do not be put off by this. Any apprehension that the book was sponsored by the body which condoned a diet of exponentials for computers is soon dispelled. The authors courteously dissociate themselves from any such nonsense. They are as well equipped as anyone to compose mathematical models of future scenarios; so it is refreshing and reassuring to find them quoting, as a good example of organisational models, the table of contents of Machiavelli's *The Prince*: "and" they add, "the chapters themselves are commendable succinct runs of these models. There are, however, no rules for the construction of such models except the general one of keeping them simple and avoiding the hopeless pursuit of meaningless quantification."

The theme of Davies and his collaborators is that the technologists' honeymoon is over; society will no longer permit man to do all he is capable of doing. But technologists must not lose heart, for they hold the clues to the solution of our present perplexities. They must not lose heart but they must acquire the skills of "human perception and understanding". In brief, an education which equips the technologist to handle ideas and things should equip him, too, to handle people; the immediate threat to industrial societies is not shortage of energy or depletion of resources, it is the risk of disorder due to stresses in human relations, between management and shop floor, between government and citizen.

Drawing on a wealth of examples and the rich background of a great industry, the authors of this intelligent and sophisticated book examine the uses of models by technologists, with special reference to the circumstances of a democratic society. Enriched with historical allusions from Greek tragedy to medieval geopolitics, the book offers facts and opinions on such models as the Boston Experience Curve (which relates the cost of a product to the accumulated experience of making it); the constraints which limit the use of such models in industry and government; and the part played in technological innovation by access to investment capital. It ends by an appeal not to regard people as "inanimate thermodynamic assemblies of customers, clients, operators, and educators". Technologists have been slow to face some of the human problems they have created; yet they have (so the authors claim in their last chapter) the right sort of experience to deal with models of these problems: numeracy, familiarity with the effects of error and uncertainty, patience in reconciling concepts with the realities of everyday systems.

The book is entertaining, but the authors quite rightly want something more from the reader than "polite applause" or "stunned silence". It is a book to provoke discussion and it deserves to, for the issues it raises are critical for modern society. Perhaps the most ominous of these issues is the dilemma of what the authors call "top-down" models. Having persuaded the reader that models are important—indeed essential—to the proper deployment of technology, they then distinguish two kinds of models. On the one hand there are "bottom-up" models (they cite as an example a model for traffic flow in Westminster) which can be assembled with other subsolutions into pragmatic hierarchies to provide data for political and social decision-making; going from the particular to the general. Such models may be too empirical to provide guidance for grand strategy. On the other hand there are "top-down" models (such as the Club of Rome and the Hudson Institute indulge in) which are synoptic, and which adopt doctrinal or dogmatic guidelines. Because "bottom-up" models are liable to be difficult to integrate into a hierarchical whole, there is a temptation to adopt "top-down" models, such as the Soviet Union has used for years. Then comes the authors' warning: "a state based on top-down modelling throughout cannot afford to be democratic and must be authoritarian if it is to be effective. We reject absolute authority in politics, and so we must severely restrict the applicability of top-down modelling." But will society reject absolute authority, if the alternative on the horizon is chaos? To rescue society from having to make this choice is the challenge of this book.

For some years observers of industrial society have stressed the need for innovation in political institutions to match innovation in technology and industry. The only recent political innovation (I use the phrase deliberately) which has emerged in response to this is the multinational corporation. Do we discern in (for example) the oil companies the prototype of international power, if not yet of international government? Such corporations are deeply distrusted by the man-in-the-street; they too, like "top-down" models, are not compatible with democratic government.

The book cleverly leads the reader toward the conclusion the authors intend, namely that there ought to be a "constructive alliance" between technologists and sociologists. But how? Alas, the authors turn to education as the recipe. Education is by its very nature conservative; it is a process analogous to the transfer of genes in heredity: a sort of cultural DNA; not the place to look for such major innovation as is needed. If innovation is to come, its source is more likely to be the political philosophers. The need is for a redefinition of values and a machinery for reconciling conflicts of values. Karl Marx offered one pattern of innovation, but for those who value personal freedom the price to be paid for his pattern is too high. Is some lonely successor to Karl Marx now working in the British Museum on a political philosophy adapted to a post-industrial society? If so, he will find in this book the questions to which democratic societies seek an answer.

One postscript: the Oxford University Press used to be impeccable in its standards of proof reading. The misprints in this book are a disgrace to the Press. □

Eric Ashby (Lord Ashby of Brandon) recently retired from the Mastership of Clare College, Cambridge. He was chairman, from 1970 to 1973, of the UK Royal Commission on Environmental Pollution.

Brings into focus recent research on the septal nuclei, and provides a clear understanding of the role played by this area of the limbic system in brain processes. Volume 20 in the Advances in Behavioral Biology series. *539 pages, $47.40/£24.89*

Basic Limbic System Anatomy of the Rat

by **Leonard W. Hamilton**
Rutgers University

Conducts the reader in logical fashion through the structures and interconnections of the rat limbic system, utilizing a battery of models, stained sections, and line drawings, and enabling students to fully understand the anatomy of the rat limbic system and to make serious use of known anatomical connections in the design of their research projects.
150 pages, $17.94/£9.42

Attachment Behavior

edited by **Thomas Alloway, Patricia Pliner,** and
Lester Krames
University of Toronto

Draws enlightening parallels between animal and human behavior through investigations of the factors responsible for the development of social attachment between parents and their offspring. Volume 3 in the Advances in the Study of Communication and Affect series. *229 pages, $27.00/£14.18*

Psychopathology of Human Adaptation

edited by **George Serban**
New York University Medical Center

Integrating the latest neurophysiological and clinical data on stress with comprehensive coverage of the general adaptation syndrome, eminent investigators examine the diversity of normal and abnormal reactions to stress—both biological and psychological.
382 pages, $29.40/£15.44

Human Sleep and Its Disorders

by **Wallace B. Mendelson, J. Christian Gillin,** and
Richard Jed Wyatt
National Institutes of Health

Synthesizes current knowledge on the mechanisms of human sleep and demonstrates their relation to a variety of disorders, including the more traditional problems of insomnia and narcolepsy, as well as schizophrenia, depressive illness and alcoholism.
approx. 255 pages, $23.40/£12.29

Pain Mechanisms
A Physiologic Interpretation of Causalgia and Its Related States

by **W. K. Livingston**
with a new foreword by **Ronald Melzack**
McGill University

First published in 1943, this book still stands as a landmark critique of the traditional specificity theory of pain. It reveals and illuminates every major pain problem that concerns us today.
253 pages, $17.94/£9.42

SCIENCE&SOCIETY

This week The Times Higher Education Supplement presents the second in a series of 8-page features covering developments in science and their social implications; the series is published quarterly in collaboration with the British Association.

This week's articles include: Professor Sir Hermann Bondi on the social responsibilities of the defence scientist; Sir Alistair Pilkington on the development of the float-glass principle; Dr B. J. Mason and Professor Hubert Lamb on climatic changes.

To anyone concerned about the role and responsibilities of the contemporary scientist, this feature makes vitally important reading. Don't miss it – in this week's

observed in the Dead Sea region[2,3]. A continuous layer 1–2 mm thick represents a deposition of up to a million tons of dry material[3,5] (nearly pure aragonite), the derivation of which from springs would require many billions of cubic metres of water, even if very high concentrations are assumed. Such a gargantuan influx and a corresponding rise in lake levels (1 m per influx of 10^9 m^3) could not have passed unnoticed[3]. Likewise, no mud or gas volcanoes supplying CO_2 which would induce precipitation of carbonates were ever reported. For this reason, clearly stated in the previous works[2,3], the hypothesis of springs whitening the Dead Sea waters was abandoned in favour of earthquake-triggered landslides[3,4] or an aseismic chemical process[5].

Recent study of the Dead Sea[7] established that 'whitening' occurs when late summer high temperatures trigger a massive precipitation of aragonite from the hypersaline lake waters oversaturated, through evaporation, with HCO_3 and SO_4. The high temperature origin of the aragonite laminae is confirmed by their isotope composition[8]. Also the whitenings of sea waters in other parts of the world has been attributed to biogenic or chemical processes unrelated to seismicity[9,10].

(2) 15–20 White laminae were deposited[7] between 1890 and 1960. Neither these laminae, nor the conspicuous whitening of August 1959, investigated in great detail[7], can be matched with earthquake records.

(3) Composition, colour and thickness of sediments are controlled by fluctuating patterns of sediments supply, transport and deposition[11]. The pronounced lateral and vertical variations in layering and thicknesses of the dark, detrital sediments of the Dead Sea are determined by discharge, distance from river inlets, water depths and local patterns of circulation and currents[12]. In such conditions, thickness is not a unique function of time and should not be used as a yardstick in estimating time intervals.

(4) The sediment core analysed by Ben Menahem was taken in the proximal part of the Jordan delta (rough co-ordinate 199/129), where rates of deposition range up to 20 mm yr^{-1} (ref. 12), in contrast to the distal parts where values of ~ 1 mm yr^{-1} were reported[7,12]. It is very unlikely therefore, that the 170-cm long core represents the full record of 2,000 yr of deposition. Assuming the present rate of formation of white laminae, 15–20 laminae in 70 yr, it would seem that the core with its 50 white layers represents up to 300 and not 2,000 yr. Incidentally, dating and counts of laminae in the Lisan Marl, a lacustrine formation deposited in the precursor of the Dead Sea[13] between 65,000 and 15,000 yr BP indicate annual formation of white layers, implying according to Ben Menahem's supposition, a yearly occurrence of strong earthquakes . . .

(5) Last, but not least, of the objections to Ben Menahem's correlations, is the fact that the uppermost part of the discussed core is missing, having been lost in the process of coring[2]. Thus it is not clear how and why the two uppermost white layers in the core were identified as the imprints of the 1903–06 and 1834 earthquakes.

These arguments amplify and vindicate the reservations clearly stated in studies in which the possible correlation between the white laminae and earthquakes was originally discussed[2,3,5,6]. These doubts, which led to an early rejection of the hypothesis, are not mentioned in Ben Menahem's paper, which seems to rely solely on a correlation between a sequence of historic earthquakes and an undated sequence of layers in a single and incomplete, random sediment core.

BEN MENAHEM REPLIES—Karcz, Neev and Zak have unearthed some counter-arguments[1,2], but their quoted figures for core dating, sedimentation rates, lacustrine formation dates, summer high temperatures and Lisan Marl laminae counts are of such obscure origin that all my efforts to trace their sources were fruitless.

The main issues centre, however, on "new facts" which the above authors have marshalled against my "assertions" and "assumptions". The first "fact" is the speculation[1] that "whitening" of the Dead Sea is caused by an alleged high temperature triggering of aragonite precipitation—a process that has never been duplicated elsewhere. Now, according to the statistics of Karcz *et al.*, a 'whitening' should occur every 5 yr, which renders about fifteen such events in the twentieth century alone. Unfortunately, only a single true grand-scale "whitening" was documented during this century[1], close to the occurrence of a magnitude 5 earthquake. The reported[1] "whitening" of August 1959 was much weaker and probably caused by a microtremor that passed unnoticed by the low-magnification JER station.

A second 'fact' which is mentioned twice by Karcz *et al.*, is based on the desultory observation[1]: ". . . 15 to 20 laminae were found on shore exposures and on trees which are known to have been drowned in the Dead Sea ~70 yr ago." Besides the question of relevance of this novel 'tree-meter' to our mud-core deposits, this observation[1] implies a repetition of 'whitening' on the average every 3 yr since 1890. Ashbel[5] on the other hand, counted 2,000 annual grey layers in the mud core of Elazari Volcani[6].

Another "fact" presented by Karcz *et al.*, which contradicts the published reports of Amiran[7] and Ashbel[5], is their dubious statement : "No pre-earthquake emergence of new springs was observed in the Dead Sea region". It has, however, been recently established[8] that the Dead Sea is sitting on a huge active fault, some 60-km long, with an estimated area of 1,500 km^2. Its motion, whether abrupt or slow, can and should affect the regular flow of the many springs inside and on the shores of the eastern side of the lake. It may, in addition, cause massive landslides and other topographical changes at the flanks and bottom of the Dead Sea, as already suggested by Shalem[9].

The exact mechanism by which the fault slip or pre-earthquake creep is coupled to the outbreak of turbidity is immaterial to the correlation under discussion.

There is nothing therefore in the objections of Karcz *et al.* that has bearing on the remarkable correlation[10] of past seismic events to the mud-core white layers. Karcz *et al.* have not added new data or information to the already known reports[3-7,9] while their use of the "drowned-tree timescale"[1] and the "whitening" speculation[1] leads them to predict an almost everlasting snow-white colour for the Dead Sea.

matters arising

Brain tryptophan in rats on a high fat diet

Inasmuch as the article by Hutson *et al.*[1] constitutes a serious criticism of the data reported from our laboratories over the past three years[2–6], we would like to make the following reply:

- In 1974, some of us[4] examined the validity of the various methods then available for measuring free tryptophan in blood. We described fully that the equilibrium dialysis method, performed at 37 or at 0 °C, gave identical results for serum-free tryptophan and for serum NEFA levels. The values for NEFA were the same as those measured before dialysis; this test was done with sera containing high (1 meq l^{-1}) and low (0.2 meq l^{-1}) amounts of NEFA. We thus ruled out the potential problem of lipolysis during dialysis over two years ago, as Hutson *et al.* admit only parenthetically (page 143).
- In this same paper[4], we tested the method of Knott, Curzon, and their colleagues, which involves separation of free tryptophan using Amicon filter cones centrifuged at 800*g*. In this method, no attempt is made to control $p\mathrm{CO}_2$, and thus serum or plasma *p*H, during dialysis. Tryptophan binding is extremely sensitive to *p*H changes; using this method, the *p*H can run as high as 8.0 or more, as observed by Madras *et al.*[4]. We note that in the article by Hutson *et al.*[1], on page 143, *p*H values of 7.75, 7.78, and higher were recorded, which affirms the non-control of *p*H in this method, and confirms the findings of Madras *et al.*[4].
- Hutson *et al.*[1] claim that they obtain similar findings when they assay either plasma or serum. But they fail to provide data on free tryptophan values in serum; instead they give data for serum UFA—and assume that free tryptophan behaves similarly. This assumption must be proved in each new experimental situation.
- Finally, we would like to note the following: (1) Hutson *et al.*[1] provide little information about the diets consumed by their animals. What were the protein and fat contents of these diets? How can the authors call the standard laboratory chow diet a "control diet?" (2) How much food was consumed by each group? (3) Why was plasma total tryptophan lower in the group eating the high fat diet? It seems to us that this "diet" experiment is uninterpretable as it is presented.

Hutson, Knott and Curzon reply—We fail to see that the essential point of our letter is seriously affected by any of the issues raised by Fernstrom, Munro and Wurtman. They refer to the work of Madras *et al.*[2] in which rats on a high-fat diet apparently had high serum free tryptophan not associated with high brain tryptophan. Our own results lead us to question the physiological relevance of these findings as large amounts of unesterified fatty acids (UFA) can be formed by plasma or serum of fat-fed rats *in vitro* and this may lead to the liberation of tryptophan from albumin after blood collection.

Taking the points raised in their letter in order:

- In quoting the finding of Madras *et al.*[2] that UFA did not increase on dialysing serum at 37 °C our use of the grammatical convenience of parentheses was not intended in any way as a criticism of the validity of this result. However our own findings[1] suggest that UFA may have already increased during the preparation of serum from fat-fed rats.
- As already explained[1] the small *p*H differences between plasmas of control and fat-fed rats would have had negligible effects on free tryptophan concentration.
- It would be most surprising if UFA changes did not cause free tryptophan changes in rat serum as in plasma. We find a significant positive correlation ($P<0.01$, $n=16$) between percentage free tryptophan and UFA of human sera.
- We did not provide detailed information on the food presented to the rats or on the amount they ate, because this had little relevance to our main conclusion—that changes occur *in vitro* in rat plasma and serum taken from fat-fed rats.

In the circumstances, and considering the many findings consistent with free tryptophan influencing brain tryptophan (refs 3–8 are to papers published in 1976) the results of Madras *et al.*[2] can hardly be interpreted with confidence.

Dating earthquakes by mud profiles of lake sediments

Ben Menahem[1] asserts that the white laminae in the recent sediments of the Dead Sea represent past occurrences of earthquakes, and identifies in a single sediment core all major shocks of the past 2,000 yr. This exhumation of a long abandoned concept[2–6] relies on two fallacious assumptions. First, new springs are assumed to open up in the Dead Sea before an earthquake, and discharge a 'white material' which whitens the lake waters and deposits on the bottom a lamina of a thickness proportional to the earthquake magnitude. Second, the described 170-cm long core from the proximal part of the Jordan delta is assumed to represent the full record of deposition in the past 2,000 yr, and thicknesses of the dark-coloured sequences sandwiched between successive white laminae are assumed to be a measure of earthquake recurrence times[2,3,6].

Both these assumptions are incompatible with facts:

(1) No pre-earthquake emergence of new springs nor large fluctuations of flow from existing springs have been

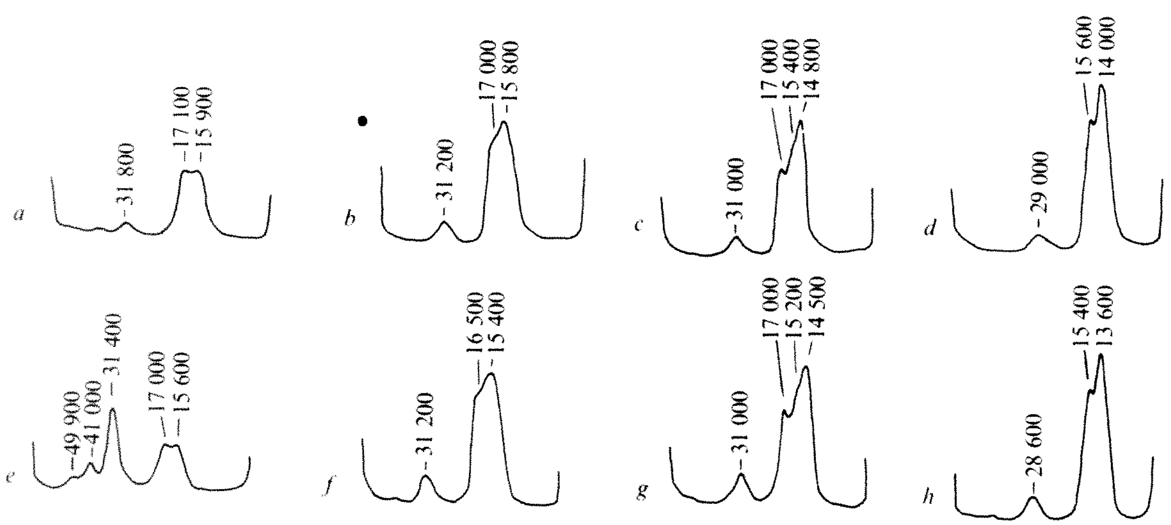

Fig. 2 Polyacrylamide gel electrophoresis (PAGE), in the presence (*a*–*d*) and in the absence (*e*–*h*) of reducing agent, of Fraction A_1 prepared by trypsin digestion of reduced wool in various conditions. *a*, 0 °C, 30 min, w/e (wool–enzyme ratio) 250:1; *b*, 0 °C, 60 min, w/e 50:1; *c*, 20 °C, 60 min, w/e 50:1; *d* 40 °C, 60 min, w/e 50:1; *e*, 0 °C, 30 min, w/e 250:1; *f*, 0 °C, 60 min, w/e 50:1; *g*, 20 °C, 60 min, w/e 50:1; *h*, 40 °C, 60 min, w/e 50:1. *a*–*d*, The most concentrated A_1 fraction from each chromatograph in Fig 1*a*–*d* was diluted to 0.2 mg ml^{-1} with 0.1 M Na_2HPO_4 buffer at *p*H 8.0, mixed with an equal volume of 8 M urea, 2% sodium dodecyl sulphate (SDS), 2% mercaptoethanol (ME) in distilled water and heated to 45 °C for 1 h. After cooling, one drop of the solution was applied to a 10% polyacrylamide gel cross-linked with 0.6% *bis*-acrylamide. After electrophoresis in 0.1% SDS, 0.1 M Na_2HPO_4, *p*H 8.0, the gels were stained overnight with 0.25% Coomassie brilliant blue dissolved in 20% trichloroacetic acid, destained in a mixture of 3 volumes acetic acid, 2 volumes methanol, 35 volumes water, and scanned with a Joyce–Loebl densitometer. Bovine serum albumin, pepsin, trypsin, myoglobin, haemoglobin, lysozyme and chymotrypsin were denatured in the same way and run at the same time as the A_1 fractions. The molecular weights of the bands from the A_1 fractions were estimated by interpolation on the line obtained when log (molecular weight) of the standards was plotted against the mobility during electrophoresis. *e*–*h*, The most concentrated fractions from Fig 1*a*–*d* were denatured as described above except that ME was omitted. The molecular weights of the component chains of A_1 were estimated as before, except that the standard proteins were also denatured without reducing agent.

a large peptide would account for the 41,000 molecular weight band in Fig. 1*e*.

The molecular weight of fraction A_1, prepared by trypsin digestion of reduced wool at 20 °C for 60 min with a 50:1 wool–trypsin ratio (A_1^{20}), is 50,000 to 60,000 measured at several *p*H values in the ultracentrifuge, using the Ehrenberg method; or 53,600 calculated from the sedimentation coefficient (3.22 s), the diffusion coefficient (4.83×10^{-7} cm^2 s^{-1}) and the partial specific volume (0.69 ml g^{-1}) at *p*H 6.0 using the Svedberg equation[6]. It is not possible to say definitely whether A_1^{20} has three or four component chains when these molecular weights of undissociated A_1^{20} are compared with the molecular weights of the component chains from denatured A_1^{20} Fig. 2*c* and *g* show that the proteins from A_1^{20} responsible measurements. Three is more likely because the molecular weights of undenatured A_1^{20} may be high because of aggregation in solution[8].

Assuming that the staining of each band is approximately proportional to the amount of protein in the band, Fig. 2*c* and *g* show that the proteins from A_1^{20} responsible for the two major peaks and the shoulder between them, are not present in equal amounts. Also, all the molecules in one PAGE band do not necessarily have the same composition. Therefore, each undenatured molecule may be composed of three chains, each slightly different in weight. The chain weights (and compositions) are not necessarily the same in different undenatured A_1^{20} molecules. This heterogeneity is an expected result of the limited proteolysis method of preparation.

The peptide bonds involving the carboxylic acid groups of the 26 lysine and 31 arginine residues in each undenatured A_1^{20} molecule[6] are not hydrolysed by trypsin during the preparation. This implies that the component chains of A_1^{20} are held in a rigid conformation throughout most of their length by hydrogen bonds and other secondary valence forces, so that the complexes which are necessary for hydrolysis to occur cannot form between trypsin molecules and the chains. The low yield of fraction A_1 (7.5% of the weight of the wool)[14] implies that, after reduction, the chains in the remainder of the microfibril component macromolecule may be more flexible and therefore digested to small peptides by trypsin. The role of the rigid part of the macromolecule may be to interact with the rigid parts of similar, neighbouring macromolecules to ensure their correct alignment and staggering in the microfibril, and experiments are in progress to investigate the aggregation properties of A_1. The flexible part of the macromolecule may be partly responsible for the mechanical resilience of the fibre, and it may interact with the high-sulphur proteins of the fibre matrix[5].

main bands, component 7 (molecular weight 46,000) and component 8 (molecular weight 51,000)[3,4], and it has been suggested that the microfibrils are composed of regularly arranged macromolecules (molecular weight 143,000) consisting of two component 7 molecules and one component 8 molecule[5].

Merokeratin A_1 is a rod-shaped, low-sulphur protein fragment (dimensions ~2×21 nm, molecular weight 50,000 to 60,000, 64%, α helix) which dissolves when reduced wool is treated with trypsin[6]. In the experiments described here, A_1 has been prepared in a variety of conditions and dissociated into its component chains using urea, sodium dodecyl sulphate (SDS) and, in some experiments, mercaptoethanol. The chain molecular weights have been measured by polyacrylamide gel electrophoresis (PAGE) and compared with the molecular weight of undissociated A_1. The results imply that A_1 consists of three protein chains, which suggests that it may be part, approximately one third of the length, of the microfibrillar macromolecular component protein.

Similar merokeratins have been prepared from low-sulphur wool proteins[7–9] and from epidermal keratin proteins[10–13] by protease digestion.

Different amounts of trypsin and different temperatures and times of digestion were used in four methods of treating reduced wool (Fig 1*a*–*d*). The wool debris was removed by centrifugation and the supernatant protein solutions were exposed to the air to reoxidise the thiol groups to disulphide bonds: the solutions were first diluted to favour the formation of intramolecular, interchain crosslinks[14]. Each solution was acidified to precipitate the protein. When the precipitates were redissolved in *p*H 8.0 buffer and fractionated on a Sepharose 6B column, the elution volume of the major retarded peak, fraction A_1, was independent of the severity of the trypsin treatment. The yield of A_1 was lower when the mildest conditions were used for the digestion (Fig. 1*a*). A small amount of protein (V) is eluted at the void volume of the column. Fraction B* is a heterogeneous mixture of low-sulphur peptides crosslinked by disulphide bonds: its composition varies with the method of preparation (S.S.L., unpublished results).

The most concentrated A_1 fraction from each of the Sepharose fractionations in Fig. 1 was denatured with urea and SDS in the presence and in the absence of mercaptoethanol. PAGE showed either two or three intensely stained, partially resolved bands, and one or more less intense bands (Fig. 2). Standard proteins were denatured in the same way and run in parallel to calibrate the gels. The molecular weights of the main bands were between 14,000 and 17,000. The proteins from the more severe trypsin digestions were slightly shorter than those from the less severe digestions. The calculated values of the molecular weights in Fig. 2 are probably within ± 10% of the true values[15].

All the gels showed a band of protein which migrated more slowly than the main bands, which had a molecular weight of about 31,000, or about 29,000 when digestion was at 40 °C. The band was most prominent when A_1 was prepared by the mildest digestion procedure and denatured with no reducing agent present (Fig. 2*e*). Its susceptibility to reducing agent (see Fig. 2*a*) suggests that the protein of the band may consist of two proteins with molecular weights between 14,000 and 17,000 crosslinked by one or more disulphide bonds. The lower intensity of the 31,000 or 29,000 bands when digestion was carried out under more severe conditions (Fig. 2*f*–*h*) suggests that the crosslinks are in the ends of the molecules prepared by mild digestion, and that these ends are removed in the more severe digestions. A weakly stained 31,000 or 29,000 band persists even when A_1 is denatured with a reducing agent present (Fig 2*a*–*d*). This could be explained if some cystine residues were converted to non-reducible lanthionine or lysinoalanine residues during the alkaline reduction of wool before the trypsin treatment[16,17]. The small peak of protein with a molecular weight of 49,900 in Fig. 2*e* suggests that after the mildest digestion there may be a small amount of material in which three protein chains with molecular weights between 14,000 and 17,000 are crosslinked. Two of these proteins crosslinked together and to

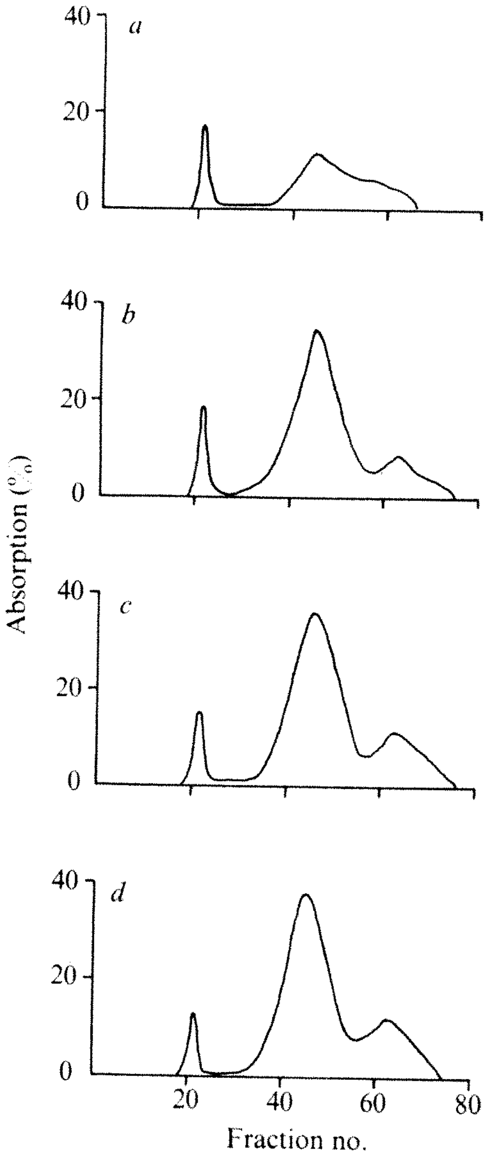

Fig. 1 Sepharose 6B chromatography of protein fragments dissolved from reduced wool by trypsin under various conditions. 2.0 g samples of purified Lincoln wool were reduced for 18 h at room temperature in 1.0 l of 0.1 M Na_2HPO_4, 0.2 M thioglycollic acid adjusted to *p*H 10, rinsed four times with 100 ml 0.1 M Na_2HPO_4 at *p*H 8.0, transferred to 40 ml of the *p*H 8.0 buffer, and treated with trypsin. Temperatures, times of digestion and wool–enzyme ratios (w/e) were as follows: *a*, 0 °C, 30 min, w/e 250:1. *b*, 0 °C, 60 min, w/e 50:1. *c*, 20 °C, 60 min, w/e 50:1. *d*, 40 °C, 60 min, w/e 50:1. After the digestions the trypsin was inhibited by 8 ml 0.25% phenylmethylsulphonylfluoride[18] in 50% v/v isopropanol–water. The digests were centrifuged at 50,000 *g* for 30 min. The supernatants were diluted to 1.5 l with 0.1 M Na_2HPO_4, *p*H 6.0, and exposed to the air in shallow dishes for 22 h at room temperature[14]. In each experiment, the reoxidised protein was precipitated by adjusting the *p*H to 4.8. The precipitates were collected by centrifugation at 1,000 *g* for 10 min, and redissolved in 5 ml 0.1 M Na_2HPO_4 *p*H 8.0 buffer. The solutions were dialysed for 2 h against the same buffer, clarified at 150,000 *g* for 10 min, applied in turn to the column, and eluted with the *p*H 8.0 buffer. Fraction A_1 is the major retarded peak. V and B* elute at fractions 21 and 62 respectively. The percentage absorption of the eluent from the column was measured at 254 nm in an LKB Uvicord I.

factor which reflects the decay of the population of the absorbing species being viewed. By defining a function $R(t) = (A(t)_\parallel - A(t)_\perp)/(A(t)_\parallel + 2A(t)_\perp)$ which is analogous to anisotropy commonly used for fluorescence polarisation[14], a purely exponential expression for dichroic decay is obtained.

$$R(t) = 3/10\alpha\beta \exp(\theta t) \qquad (3)$$

This is independent of the decay kinetics of the phototransient.

As reported previously[9], little decay in dichroism can be detected at room temperature in aqueous suspensions of purple membrane during the lifetime of $M(410)$. Transient lifetimes, however, increase markedly with decreasing temperature ($Q_{10} \approx 3$) and adequate first-order plots were obtained (s.d. $< 10\%$) consistent with equation (3). The results are presented in Fig. 2(A) in the form of an Arrhenius plot of the viscosity dependent ratio T/θ. The best straight line yields an energy of activation for microviscosity, E, of 7.4 ± 0.3 (s.d.) kcalorie mol^{-1}. This is significantly higher than that for water[15], and shows the presence of rotational freedom in addition to that of fragment tumbling. Purple membrane, when treated with the protein crosslinking reagent glutaraldehyde, continues to undergo reversible photochemical cycling. The lifetimes are slightly increased, facilitating a more extended Arrhenius plot. This (see Fig. 2(B)) yields $E = 4.4 \pm 0.04$ (s.d.) kcalorie mol^{-1}, consistent with published values for water[15]. The size calculated[16] for the membrane fragments (diameter $= 0.5$ μm) assuming them to simulate oblate ellipsoids is in excellent agreement with published values (diameter $= 0.5$ μm)[1], affording a test for the validity of the theory.

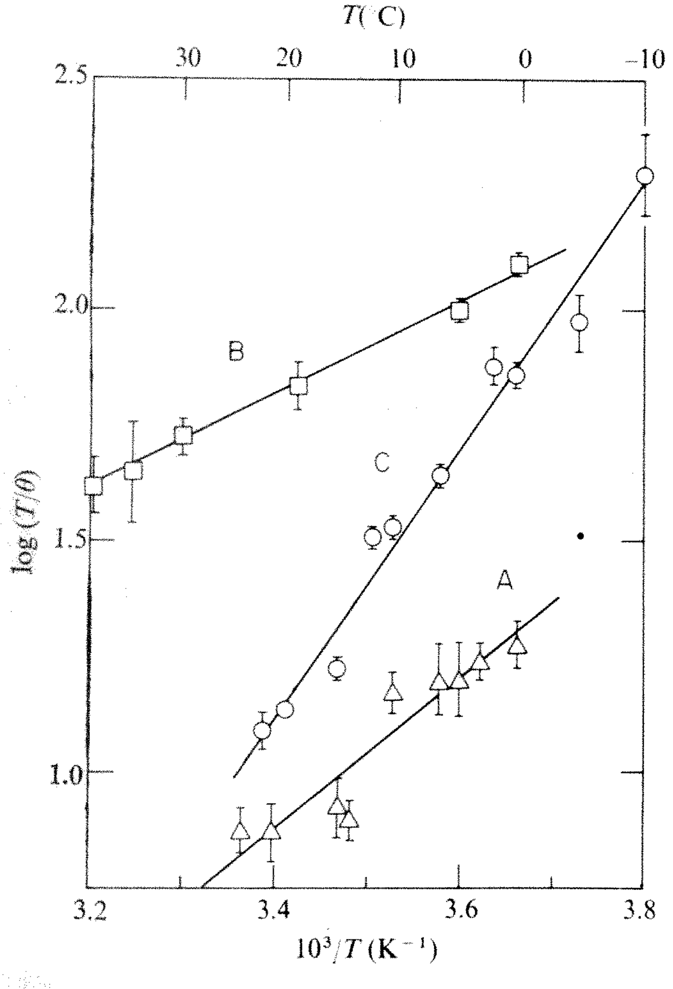

Fig. 2 Arrhenius plots of the viscosity-proportional function T/θ. Bars represent standard deviation in the measurement of θ. △, Membrane fragments in water; □, membrane fragments pretreated with glutaraldehyde and suspended in water; ○, membrane fragments in a 20% polyacrylamide gel.

Both untreated and glutaraldehyde-fixed purple membranes were incorporated into a 20% polyacrylamide gel by *in situ* polymerisation of acrylamide monomer added to aqueous purple membrane suspensions. At this concentration the membrane fragments may be expected to be completely immobilised. The photochemistry seems unchanged, with phototransient yields and lifetimes in the polymer indistinguishable from those in pure water. For the glutaraldehyde-fixed sample no dichroic relaxation was detectable within the whole temperature range (detection limits at 20 and 0 °C, respectively, $\theta = 10^{-1}$ and 10^{-2} s^{-1}). But for the unfixed polymer first-order dichroic decay was observed, yielding $E = 13 \pm 0.05$ (s.d.) kcalorie mol^{-1} (Fig. 2(C)).

The results presented here show that the chromophore of bacteriorhodopsin is not totally immobilised within the purple membrane. The significant rotational rate constants found, 20 s^{-1} at room temperature, are too high to be attributable to rotation of individual protein molecules *in toto* within the crystal lattice, and must indicate internal conformational change. It is tempting to speculate, based on the close coincidence of E for rotational mobility and that found for the formation of $M(410)$ (12 kcalorie mol^{-1})[12], that the deprotonation step which produces this intermediate is controlled by intramolecular movement involving the retinylidene group (which simulates Brownian motion). The establishment of internal mobility within bacteriorhodopsin suggests that it might be profitable to look for an analogous process, in contrast to the criticised tumbling mechanism, in the transmission of the visual signal in rhodopsin subsequent to the primary *cis–trans* isomerisation.

Three-chain merokeratin from wool may be a fragment of the microfibril component macromolecule

WOOL fibres consist mainly of long cortical cells filled with microfibrils, 7–8 nm diameter, embedded in a matrix. The microfibrils are composed of proteins with a lower sulphur content and a higher α-helix content than wool; the matrix proteins have a higher sulphur content than wool and no α helix[1,2]. When reduced and carboxymethylated low-sulphur proteins from wool (SCMKA) are separated by starch gel electrophoresis, there are two

Selectivity coefficients were calculated from the data. The average value of S_1 ^{3}H (for animals fed separate food sources) was 0.2 (±0.1) while the average S_2 ^{3}H value (for animals fed mixed food) was 0.5 (±0.1).

Lampert[7], using an exposure time of 15 min and mixed food only, showed that young daphnids are remarkably selective in their feeding habits. Table 2 shows that feeding rate is highest during the shortest exposure times and lower during longer exposure times. In all cases, however, no selectivity was found.

There are two possible reasons for this difference: (1) *Daphnia* may digest bacteria faster than algae, or (2) the accumulation, in long-term experiments, of bacterial material as opposed to algal material may be due to the shorter retention time of ^{14}C-labelled substances (algal source), which might be used for intensive metabolic activities such as respiration. The results presented here and derived from long-term experiments with *Ceriodaphnia*[6] and *Daphnia*[7] suggest the following processes. Initially ^{14}C-labelled algal materials are ingested in larger amounts during normal feeding. Later, the rapid digestion of bacterial materials results in the accumulation of ^{3}H-labelled substances. I conclude that the rate of ingestion is influenced by the size of the particles present in natural or artificial bodies of water. This is important in ecosystems containing suspended particles of a diversity of sizes.

I thank M. Shnipper for technical assistance, Dr B. Z. Cavari and Mrs T. Bergshtein for the preparation of bacterial cultures and Dr D. Wynne for reviewing the manuscript.

Chromophore mobility in bacteriorhodopsin

THE sole protein found in the purple membrane of *Halobacterium halobium* contains retinal covalently bound by means of a protonated Schiff base linkage to lysine[1,2]. The only established function of this protein is to act as a light-driven proton pump producing a transmembrane proton gradient, which is coupled to ATP synthesis in the living organism[2,3]. In so far as the retinal prosthetic group resembles that found in the visual pigment of vertebrates, rhodopsin, the name bacteriorhodopsin has been widely adopted for this protein[3]. Considerable work has been done on the biochemistry and photochemistry of the purple membrane, both for its intrinsic interest as a unique photosynthetic membrane and with respect to the identification of possible mechanistic relationships between its photochemical cycle and that of the visual process. We report here a study of the later stages of the photochemical cycle by flash photometry with plane polarised light. Our results indicate conformational change in the bacteriorhodopsin molecule at the site of the visible chromophore.

There has been speculation as to whether rotational motion of the visual pigment is an essential link in the signal chain in the visual process[4]. It has been demonstrated that rhodopsin molecules undergo rapid Brownian rotation within the membrane[4,5] and the theory has been proposed (but criticised on energetic grounds[6]) that rotation about an axis parallel to the plane of the rod disks ('tumbling') could enable rhodopsin to act as a transmembrane ion carrier[4]. In contrast, bacteriorhodopsin exists in a crystalline form in the purple membrane[7]. Consequently, Brownian diffusion of individual molecules would be expected to be severely restricted, and this has been confirmed[8,9]. But during a study[10] of the temperature dependence of the photochemical cycle in aqueous suspensions we were surprised that the measured rotational relaxation times gave an activation energy for the medium viscosity (see below) which differed significantly from that characteristic of water. If the protein chromophore is rigidly bound within a crystal lattice which has dimensions comparable with those of the membrane, then rotational relaxation would be exclusively a consequence of the tumbling of the individual fragments, constrained only by the viscosity of the water in which they were suspended. This consideration induced us to carry out a more extensive study of rotational mobility.

The bacteriorhodopsin photochemical cycle contains a sequence of phototransients of which one, *M*(410), has been shown to have the retinal Schiff base unprotonated[11]. The decay of *M*(410) is linked kinetically to the reappearance of the ground state *BR*(570), with a lifetime at room temperature in the millisecond region[12]. Rotational mobility was investigated by measurement of the time dependence of the decay of linear dichroism of the absorption band of *M*(410) at 410 nm. By means of a conventional flash photometer[9], purple membrane samples were excited with μs light flashes filtered successively through a 500-nm cutoff filter and a linear polariser with its optical axis vertical (laboratory *a* axis, Fig. 1). Light transmission was then viewed in the *c* direction with a beam polarised alternately parallel and perpendicular to the exciting light. The time dependence for absorption of the two polarised analysing beams is given by[13]

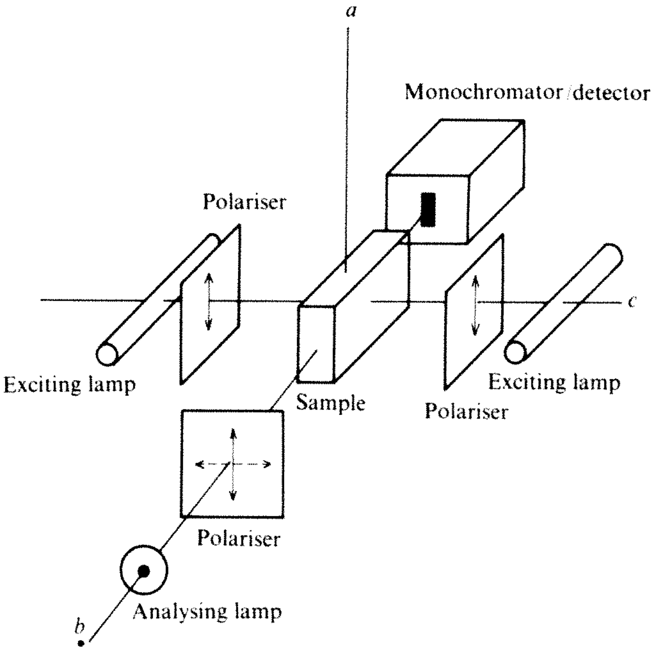

Fig. 1 Optical layout of flash photometer for measurement of relaxation of linear dichroism in phototransient absorption.

$$A(t)_{\parallel} = 5/3 - \alpha\beta\exp(\theta t) \qquad (1)$$

$$A(t)_{\perp} = 5/3 - \tfrac{1}{2}\alpha\beta\exp(\theta t) \qquad (2)$$

where θ is the rotational rate constant, proportional to temperature and inversely proportional to medium viscosity and shape and size of the rotating species ($kT/V(\mathrm{r})\eta$), β is a function of the optical transition moments of the chromophore absorbing the exciting light and the species being viewed (*M*(410)), and α is a randomisation factor ($\alpha < 1$) which encompasses instrumental artifacts in addition to unidentified (non-Brownian) causes of depolarisation[13]. Total time-dependent absorption is then given by equations (1) and (2) multiplied by a weighting

Table 1 Content of food source, suspension and incubation times

the feeding mechanism of *Daphnia magna* (Strauss) during short exposure to bacteria, algae or a mixture of the two.

Chlamydomonas reinhardti (Dangeard), cultured in Bristol's medium and labelled with ^{14}C (ref. 6) and *Chlorobium phaeobacteroides* Pfennig cultured on Pfennig's medium and labelled with ^{3}H (ref. 6) served as food sources. They were collected and resuspended in filtered lake water and 0.3 ml of each suspension was solubilised in 5 ml of Aquasol Universal LSC cocktail, and radioactivity was determined in a Packard liquid scintillation counter. The cell concentration of the suspension was determined by counting the algae on a haemocytometer and by measuring the specific absorbance of bacterial chlorophyll at 715 nm. The correlation between absorbance at 715 nm and cell number was obtained by incubating serial dilutions of the cell culture in Agar-shake tubes containing Pfennig's medium and counting the colonies that developed after 3 weeks. By this method an absorbance of 1 was equivalent to 4.35×10^{7} cells per ml (B. Z. Cavari, unpublished results).

The volume of cells was measured and their wet weight was calculated by assuming a density of 1.0. Values of 1.5×10^{-4} μg per cell and 1.6×10^{-8} μg per cell were found for *Chlamydomonas* and *Chlorobium*, respectively.

Several hundred newborn daphnids were pipetted from the culture into filtered lake water. They were starved for 24 h in the dark at room temperature (22–24 °C). Each experiment was carried out as follows: ten animals were introduced into tubes containing algae, bacteria or mixtures of both and incubated for different times (Tables 1 and 2). All experiments were done at room temperature in the light. With exposure for more than 5 min, the test tubes were mixed gently every 5–10 min. At the end of the exposure, the daphnids were removed as quickly as possible by sieving through a nylon net and washed with filtered lake water. They were then transferred into scintillation vials and 5 ml of Aquasol was added. After 24 h, radioactivity was determined. The samples were then sonicated in an ultrasonicator (MSE) at high power, in ice for 2 min. This treatment disintegrated the organisms. Counts after sonication were higher by a factor of 1.5 (±0.2) for ^{14}C and a factor of 1.1 (±0.1) for ^{3}H. Therefore all samples were sonicated before counting.

The ingested biomass is shown in Table 2. The average bacterial biomass ingested in each experiment was 1.3 (±0.3) times greater when the animals were fed on mixed food compared with bacteria alone. In contrast, the ratio between ingested biomass of algae by the daphnids that were fed mixed food compared with those fed algae alone was 0.5 (±0.1).

It is likely that in the presence of *Chlorobium* alone the rejection rate is higher than in the presence of the relatively large algal cells. Conversely the presence of bacterial cells in the mixed food source lowered the ingested biomass of *Chlamydomonas*. As Table 2 shows when fed bacteria alone, the daphnids ingested $0.1–4.2\times10^{-3}$ μg per animal, and $0.1–5.7\times10^{-3}$ μg per animal when exposed to mixed food. The similar ranges of ingestion of algae were 0.1–12.3 μg per animal when the daphnids were fed on algae, and 0.1–10.7 μg per animal when given mixed food.

Table 1 Effect of SHAM on the motility of bloodstream form *T. brucei* incubated in a glucose–glycerol mixture

Substrate present (mM)		SHAM added	Motility after		
Glucose	Glycerol	(1 mM)	5 min	15 min	30 min
25	0	—	++++	+++	+++
25	0	+	+++	+++	++
25	0.5	+	+++	+++	++
25	1.0	+	+++	++	+
25	2.0	+	++	+	±
25	5.0	+	+	—	—
25	10.0	+	+	—	—

Heparinised rat blood infected with *T. brucei* EATRO 427 was diluted 1:1 with 50 mM phosphate buffer, *p*H 8.0, containing 45 mM NaCl and 50 mM glucose. Samples (1 ml) were incubated at room temperature with various amounts of glycerol plus SHAM. Samples were taken at the times indicated and examined by phase contrast microscopy within 30 s for motility.

pathway for the reoxidation of NADH, which allows the synthesis of 1 mol of ATP per mol of glucose when the glycerolphosphate oxidase is blocked[9,10]. An inhibitor of this pathway, combined with SHAM, might therefore be lethal to the trypanosome, though either inhibitor alone would be ineffective[10]. We have found that SHAM and glycerol represent such a lethal combination. We were led to these experiments by previous work by Ryley[11], who has shown that glycerol inhibits glucose utilisation by trypanosomes in anaerobic conditions.

Table 1 shows that SHAM alone does not abolish motility of trypanosomes incubated in blood with glucose as substrate, but that motility progressively decreases when increasing amounts of glycerol are included in the mixture. In other experiments with purified trypanosomes glycerol concentrations as low as 1 mM were sufficient to immobilise the trypanosomes. A more quantitative analysis of the effects of glycerol is given in Fig. 2. In this experiment the rate of glycolysis was monitored by measuring pyruvate production. Glycerol has little effect on glycolysis in the absence of SHAM, but in the presence of SHAM 5 mM glycerol is sufficient to inhibit pyruvate formation by 99%. Half-maximal inhibition was obtained with 0.8 mM glycerol (0.4 and 1.2 in two other experiments). This inhibition by glycerol can be explained by product inhibition of the putative alternative pathway for NADH reoxidation[9,10], but other explanations remain to be excluded.

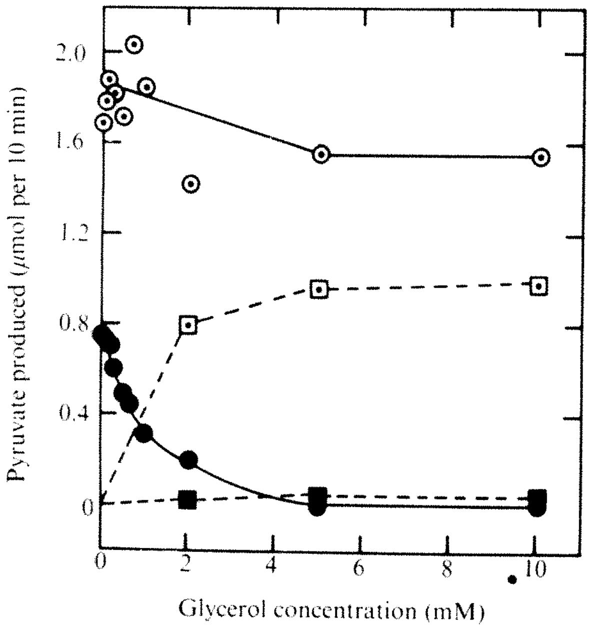

Fig. 2 Effect of SHAM on pyruvate production by *T. brucei* incubated in glucose–glycerol mixtures. Purified trypanosomes (0.7 mg of protein) were incubated at 37 °C in a 1-ml reaction mixture containing 50 mM sodium phosphate buffer, 45 mM NaCl, *p*H 8.0, with glucose and/or glycerol as substrate. SHAM was added as a solution in dimethylformamide; an equal volume of dimethylformamide was added to the control incubations. Samples were deproteinised with perchloric acid at zero time (to correct for any pyruvate in the trypanosomal suspension) and after 10 min of incubation. After neutralisation the supernatants were assayed for pyruvate. Further details of the methods used are given in ref. 9. Circles, trypanosomes incubated with 10 mM glucose plus 0–10 mM glycerol; squares, trypanosomes incubated in glycerol alone. Open symbols, no SHAM added; closed symbols, plus 1 mM SHAM.

As it is possible to obtain plasma SHAM levels that completely block the glycerolphosphate oxidase[10] and glycerol levels exceeding 5 mM (ref. 12), our results predict that it should be possible to kill *T. brucei* also in the living rat with SHAM+glycerol. This prediction has been verified[13]. Glycerol administration might also potentiate the therapeutic action of suramin, a drug used in the treatment of human sleeping sickness, as the glycerolphosphate oxidase system is the only trypanosomal enzyme reported to be inhibited by low suramin concentrations[14]. Finally, our results show how insight into trypanosome metabolism could lead to the development of drug combinations that would not have been detected in a conventional screen for trypanocidal drugs, because neither of the drugs alone has measurable trypanocidal action. It might be useful to extend present drug screening procedures to include screening of drugs in the presence of SHAM or glycerol.

We thank Miss Arja S. W. Span for technical assistance. This work was supported in part by a grant from SON (ZWO). A.H.F. was a recipient of a travelling fellowship from the MRC.

Feeding of *Daphnia* on *Chlamydomonas* and *Chlorobium*

AMONG investigations of filtration mechanism and food selectivity of filter feeders[1–7], Gophen *et al.*[6] have used double labelling to show the preferential absorption of bacteria by *Ceriodaphnia reticulata* (Jurine) in long term experiments. Lampert[7], using the same technique but with a 15-min exposure, reported a coefficient of selection greater than 1 for bacteria ingested by small daphnids in the presence of mixed food. I present here the results of a study of

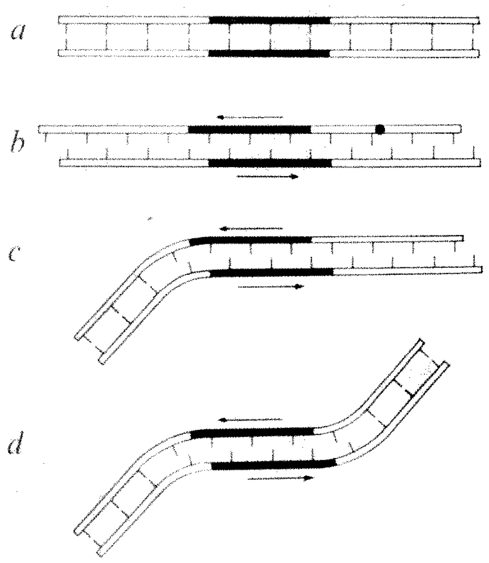

Fig. 2 Diagrams showing how a local active sliding (indicated by arrows) between two flexible filaments is converted into a bending. *a*, Before sliding. *b*, If there is no resistance to sliding between the filaments, active sliding does not lead to bending. This is presumably what happened to the trypsin-treated model of Summers and Gibbons[3]. *c*, If there is a region with resistance to sliding (stippled) on one side of the active region, a bend will be formed between these regions, compare Fig. 1*c*. *d*, If there is resistance to sliding on both sides of the active region, two bends will be formed in opposite directions, compare Fig. 1*b*.

one experiment, for example, bending of the proximal region required ATP at 2.0 nC while 0.2 nC was sufficient to straighten the same region. This indicates the possibility that once a bending wave is formed, it can be propagated in a concentration of ATP which is lower than is necessary to initiate a new wave. To test this, we placed the model in a solution containing 8 μM ATP. This concentration has been known to be lower than that required for the reactivation of bending, although enough to relax the "rigor waves"[8]. An iontophoretic application of ATP to the model in this solution induced a bending wave which was propagated down the flagellum. Propagated waves were also produced when the glass needle holding the sperm head was vibrated by a light tap at its handle. This also depended on the presence of a low concentration of ATP, since no such propagation was observed without ATP in the bathing solution. Our results indicate that a localised sliding between axonemal elements leads to bending, and also provide observations that may be important in understanding the mechanism of flagellar wave formation and propagation. The iontophoretic technique has proved useful for studying flagellar movement; it will be used to advantage in the studies of various aspects of cell motility at the cellular or organellar level.

New approach to screening drugs for activity against African trypanosomes

THE African trypanosomes are unicellular eukaryotic parasites responsible for serious diseases in man (such as sleeping sickness) and domestic animals (such as nagana in cattle). The chemotherapy of these diseases is unsatisfactory[1]. Only a few drugs are available: these have serious side effects, drug resistance is a problem and "new drugs for clinical use are too expensive to develop and produce"[2] using classical empirical screening methods. We report here how knowledge of trypanosome metabolism has led to a new method for screening drugs against trypanosomes. This could provide a short-cut to new drugs or drug combinations.

The bloodstream forms of African trypanosomes are completely dependent on glycolysis for their energy supply, because the biogenesis of a mitochondrial respiratory chain is suppressed in the vertebrate host[3,4]. As Fig. 1 shows, aerobic glycolysis proceeds through the Embden–Meyerhof pathway similar to the glycolytic pathway of the host with the exception that pyruvate is excreted into the host's bloodstream as it cannot be metabolised further because long slender bloodstream trypanosomes lack both a functional Krebs cycle[4,5] and lactate dehydrogenase[6]. The NAD^+ reduced in the glyceraldehyde phosphate dehydrogenase step is reoxidised by a mitochondrial[7], CN^--insensitive L-glycerol-3-phosphate oxidase system[8] (boxed in Fig. 1), which is not present in the vertebrate host.

When the oxidase is completely inhibited by anaerobiosis or salicylhydroxamic acid (SHAM)[9], the bloodstream trypanosomes convert glucose into equimolar amounts of pyruvate and glycerol. According to Fig. 1, the net synthesis of ATP in this pathway should be zero. It has been demonstrated, however, that this is not the case and that high SHAM concentrations neither block trypanosome motility *in vitro*[9] nor affect the course of a fulminant *Trypanosoma brucei* infection in rats[10]. This has led to the conclusion that the scheme in Fig. 1 is oversimplified and that the bloodstream trypanosomes contain an, as yet unknown, extra

Local reactivation of Triton-extracted flagella by iontophoretic application of ATP

IN spite of recent progress in ultrastructural and biochemical studies of cilia and flagella[1], the mechanism of their movement is still poorly understood. Much circumstantial evidence, however, supports the sliding microtubule model of ciliary and flagellar motility[2] which involves active sliding between axonemal microtubules to provide the motive force for bending. For example, ATP-dependent sliding of microtubules has been demonstrated in the Triton-extracted axoneme lightly digested by trypsin[3]. To produce a bend in the sliding microtubule model, there should be local differences in the amount of sliding along the axoneme. Morphological evidence indicates the presence of such differences in the bent region of cilia[4]. We now report experiments involving local, brief reactivation of Triton-extracted sea urchin spermatozoa by iontophoretic application of ATP. Our results support the idea of sliding within the axoneme as the basis of flagellar bending.

Spermatozoa from the sea urchin, *Anthocidaris crassispina*, were extracted as described before[5]. The extracted spermatozoa ('models') were placed in a 'reactivating solution without ATP' (for composition, see legend to Fig. 1) and a single model was held by attaching its head to a polylysine-coated glass needle[6] mounted on a micromanipulator. A glass capillary microelectrode, filled with a solution containing 10 mM ATP and with a resistance of about 500 MΩ, was used to activate the model locally by iontophoresis. The movement of the model was observed by an inverted microscope (Nikon MD) fitted with phase-contrast optics (objective: Nikon BM 40×), and was filmed on Kodak Double=X or Plus=X 16 mm film at 32–64 frames per s with a Bolex H16 ciné camera.

When the tip of the ATP electrode was placed close to the axoneme and ATP was applied as a negative pulse lasting 100–300 ms, the axoneme typically showed a localised, brief (less than 3 s) oscillation in the vicinity of the electrode. The frequency of observed oscillation was 2–7 Hz. The amount of ATP, expressed in nC, necessary to bring about the oscillation, varied with the specimen and also with the electrode used, but a few nC was usually sufficient. With this amount of ATP, it was possible to induce the response in any region of the axoneme, but the response was always localised and did not propagate beyond 5–9 μm of the electrode. This shows that any region along the length of the flagellum is capable of active bending[7], and also that a truly local application of ATP was achieved with our method. With less ATP, the duration of induced oscillation was shorter, and below a certain level a full cycle of movement was no longer obtained. Instead, the axoneme changed its form by a localised unidirectional movement of the region near the electrode (Fig. 1). By a few repetitive applications of the small amount of ATP to the same place, however, it was possible to induce one or more complete cycles. In other words, it was possible to break down a beat cycle of a segment of flagellum into a few steps.

The small amount of ATP applied to a more or less straight region of the axoneme typically elicited a local bending response (Fig. 1*a–c*). Usually, a pair of similar bends was formed in opposite directions (Fig. 1*a* and *b*) except in the distal region where only a single bend was formed (Fig. 1*c*). There was no fixed relation between the positioning of the electrode relative to the axoneme and the direction of bending, which seemed to depend on the orientation and other conditions of the axoneme. The above result is just what the sliding microtubule model predicts, if it is assumed that ATP causes a unidirectional sliding near the electrode and there is resistance to sliding outside the range of action of ATP. Diagrams illustrating this interpretation are shown in Fig. 2.

When the small amount of ATP was applied to the bent region, the bend moved some distance distally as the region directly under the electrode straightened (Fig. 1*d*). If the electrode was moved distally and ATP was applied to the newly formed bend, the bend was displaced further distally: this procedure could be repeated several times until the bend disappeared from the distal end of the flagellum. If there were two bends in the shape of an S, an application of ATP to the proximal bend had no visible effect on the distal bend: only the proximal bend moved distally (Fig. 1*e*). Similarly, ATP applied to the distal bend caused a distal displacement of this bend only, with no influence on the proximal bend.

The amount of ATP necessary to unbend the axoneme with consequent displacement of the bend tended to be lower than that necessary to bend the straight region. In

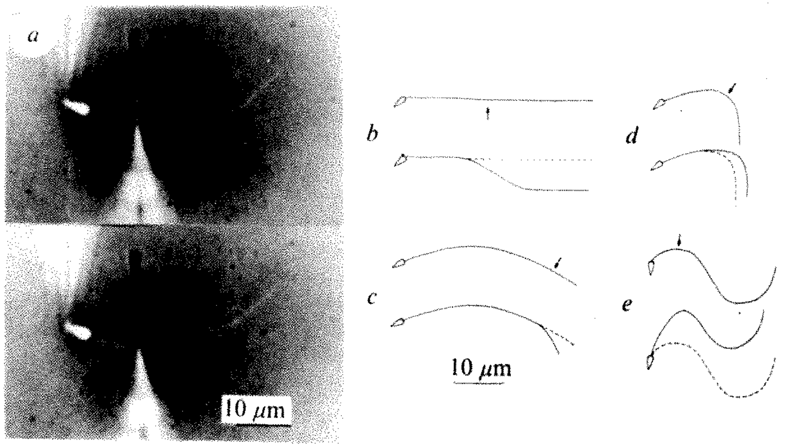

Fig. 1 Response of Triton-extracted flagella to local appliction of ATP. Spermatozoa of *Anthocidaris crassispina* were first suspended in 25–50 volumes of Ca-free artificial seawater buffered to *p*H 8.0 with Tris–HCl. Two drops of this suspension were added to 5.0 ml of extracting solution consisting of 0.15 M KCl, 4 mM $MgSO_4$, 0.5 mM EDTA, 0.5 mM mercaptoethanol, 0.04% (w/v) Triton X-100, 2 mM Tris–HCl, *p*H 8.0, at room temperature (25–28 °C), and were swirled gently for 30 s–1 min. The resultant suspension of extracted spermatozoa ('models') was transferred to 2 volumes of 'reactivating solution without ATP', which consisted of 0.15 M KCl, 2 mM $MgSO_4$, 0.5 mM EDTA, 5 mM dithiothreitol, 2% (w/v) polyethylene glycol and 20 mM Tris-HCl, *p*H 8.0, and was used immediately for local reactivation experiments. A single model was attached by its head to a polylysine-coated glass microneedle obtained by dipping the tip in 0.1% (w/v) polylysine, followed by a brief rinse in distilled water. At the end of local reactivation experiments, each model was exposed to bath application of 10–100 μM ATP, and models that failed to propagate normal waves were discarded. *a*, Prints from a 16-mm ciné film, showing a model both before and about 0.4 s after an iontophoretic application of ATP (0.13 nC). Note the position of the ATP-electrode and the induced local bending of the axoneme. *b–e*, Tracings from ciné films, each showing a model before (upper) and after (lower) application of ATP. Each arrow indicates the position of the ATP-electrode. The form of the axoneme before application of ATP is also shown superimposed on lower traces (dashed lines). The amount of ATP and the interval between the time of ATP pulse and the time of recording of the response were: *b*, 1.4 nC, 300 ms; *c*, 1.2 nC, 210 ms; *d*, 0.6 nC, 330 ms; and *e*, 0.8 nC, 350 ms, respectively.

up to about 3 μmol ml^{-1}, comparable with the level of histidine in histidinaemics. The offspring from treated mothers had no balance defects, deafness or vestibular damage (although litter size was reduced considerably on the 10% lysine or phenylalanine supplemented diets). The balance defect in offspring of histidinaemic mothers is therefore not the result of a simple increase in any amino acid to these concentrations during pregnancy although other, untested amino acids could be effective.

Table 4 Abnormalities of the inner ears of +/+ animals born to histidinaemic mothers after egg transfer

	Damage to inner ear

15	Normal	Normal	Normal	Normal

Blastocysts were transferred 3.5 d *post coitum* into the uteri of recipient females 2.5 d *post coitum* by the technique of McLaren and Michie[13]. Animals 1–12 were C57BL +/+ eggs transferred into *his/his* hybrid females (50% Peru/50% C57BL). Animals 13–15 were Peru +/+ eggs transferred into *his/his* Peru females. All animals behaved normally and were not deaf. The ears were prepared and scored as in Table 1.

Our previous work[5] suggested that *his*/+ offspring from histidinaemic mothers were less severely affected than *his/his* offspring. Because the only offspring obtainable from histidinaemic mothers are of *his/his* or *his*/+ genotypes, we investigated this offspring-genotype effect further by +/+ egg transfers[12] into pregnant histidinaemic mothers. The transferred eggs had coat colour markers distinguishing them from the recipient's own eggs. No +/+ offspring with any visible balance defects or deafness were found. The ears of two groups of litters, however, showed subclinical damage (Table 4). This is significantly different from both +/+ and *his*/+ animals born of heterozygous mothers (which show no subclinical damage) but suggests that offspring genotype at the *his* locus in some way modifies the severity of the maternal effect.

Table 5 Effect of genetic background on the proportion of balance defective offspring produced by histidinaemic parents

			Affect on balance						Affect on hearing					
Genetic background	No. of litters	No. of animals	severe	No. of mild	normal	% Affected	χ^2	*P*	severe	No. of mild	normal	% Affected	χ^2	*P*
Peru	12	57	16	5	36	36.8	—	—	18	5	34	40.4	—	—
Hybrid Peru/C57BL	12	51	5	3	43	15.7	11.3	<0.02	8	1	42	17.6	12.4	<0.01

Some *his/his* mice from the Peru stock were crossed to C57BL and the offspring were intercrossed to produce *his/his* animals which were used as hybrid (50% Peru/50% C57BL) parents. The animals were scored for balance as in Table 1 and tested by χ^2 as in Table 3.

The original strain of Peru mice, in which the *his* allele occurred, had been selected for high penetrance of the balance-defective character without the knowledge of the presence of the allele and of the effect of maternal histidinaemia[5,13,14]. It is possible that this strong selection for several years may have accumulated modifying genes increasing the penetrance of the maternal effect on balance. These genes could operate through the maternal uterine environment or through the susceptibility of the offspring.

We tested this possibility by (1) putting the *his* allele into a different genetic background, and (2) relaxing selection for the balance defect. First, the Peru stock was crossed to C57BL mice, and offspring from histidinaemic mothers of this hybrid stock were examined (Table 5). There was a significant reduction in balance defective offspring (37% to 16%) from the hybrid stock although maternal histidine levels were the same in the hybrid and Peru strains (Table 1). Preliminary results of backcrosses of the *his* allele into C57BL suggest that the proportion of balance-defective offspring can be reduced still further. Similarly, a line in which selection was relaxed for 4 yr (about 12 generations) has reduced the proportion of balance defective offspring from more than 80% to below 10% although, again, the plasma histidine levels are the same in the relaxed and selected stocks. The nature of these modifying effects is being investigated. Preliminary results on reciprocal crosses between the 'high' and 'low' penetrance lines showed a low penetrance for both types of mother. This strongly indicates foetal susceptibility as the major component in penetrance difference and 'dominance' of 'low' over 'high' genes.

It is possible to draw some firm and some tentative conclusions from our observations. The developmental abnormality, whether subclinical or overt, is caused by abnormally high histidine or imidazole derivatives during the second week of pregnancy. These may be due to the genotype of the mother or to her diet. The teratogenic effect can be ameliorated (and possibly eliminated) by dietary management of genetically histidinaemic mothers during the critical period. The alternative explanation that the teratogenic effect is caused by the reduction of flux through histidase in histidinaemic mothers, is unlikely as heterozygotes have no reduction in flux (A. Whitehouse and G.B., in preparation) but can produce affected offspring when fed the 8% histidine supplemented diet.

The effect of the offspring genotype at the *his* locus on the penetrance and severity of the damage seems to be: *his/his*>*his*/+>+/+. This is, however, difficult to reconcile with the fact that histidase, which differs in adults in three genotypes, is not measurably different until about a day after birth. Furthermore, treatment of *his*/+ mothers during the third week of pregnancy was ineffective. A possible explanation involves the assumption that, contrary to other evidence, there are continuing metabolic effects on ear development after birth when the offspring's metabolism is significantly different in the three genotypes.

There is firm evidence that the genetic background is a contributing factor. This effect is, however, not due to any alteration in the histidine levels and it seems likely that it is offspring susceptibility rather than maternal uterine environment which is affected by modifying genes.

We thank Mrs L. MacIntyre for looking after the mice, the MRC for financial support and Drs E. Russell and R. Blake of the Jackson Laboratory for *Pro-1*^{b}/*Pro-1*^{b}

mice. We are grateful for some special diets from Messrs Cow and Gate.

Survival of dinoflagellate blooms in the western English Channel

DURING the summer of 1976, for the second successive year, blooms of the dinoflagellate *Gyrodinium aureolum* Hulburt have occurred at the western entrance to the English Channel. The influence of tidal mixing on the temperature structure of the water column and the availability of light and nutrients for phytoplankton growth in this region have already been described[1,2]. Here we report a frontal movement in response to the cycle of tidal mixing induced by the alternation of neap and spring tides, and suggest that plant populations both in surface water on the stratified side of the front and in the thermocline are dependent on the associated periodic release of nitrate and inorganic phosphate from the cold, nutrient-rich, bottom layer. We also describe the effects of phytoplankton on nutrient gradients across the thermocline.

To use ship time as efficiently as possible, both surface and subsurface measurements of temperature, salinity and chlorophyll *a* were recorded continuously while steaming[2,3]. Surface water was sampled through the ship's hull from a depth of 2 m, and sub- to surface water was pumped up (~ 100 l min^{-1}) from about 20 m through polyvinyl chloride tubing (4 cm internal diameter) attached to a V-fin depressor with a span of 1.3 m. Standard automated analytical techniques[4] were used to monitor silicate and nitrate in surface or subsurface water. Nitrate was chosen in preference to inorganic phosphate because, after the spring diatom outburst, the low (< 2) nitrate-N to phosphate-P ratios in surface waters suggest that nitrate is the limiting nutrient for the growth of dinoflagellates[5]. An example of records across a frontal boundary, where particularly high levels of chlorophyll a were encountered, is given in Fig. 1. Vertical profiles for the same water properties were obtained at a series of stations by lowering the salinity–temperature–depth measuring system and the inlet tube the pump into the water. Data on zooplankton distribution, based on samples taken from the outflow of the pump, will be reported elsewhere.

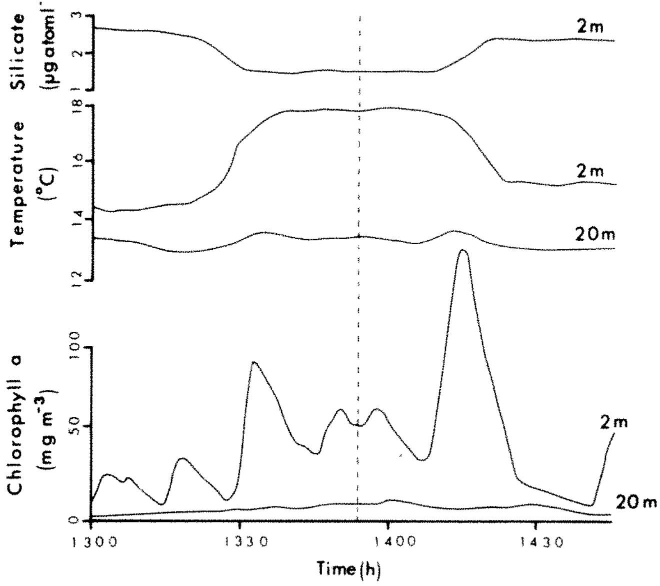

Fig. 1 Surface (2 m) and subsurface (20 m) records for chlorophyll *a*, temperature and silicate (surface only) across a frontal region (49 10′N, 4 48′W, August 3, 1976). At 1352 h the ship altered course to make a second crossing of the front (speed ~ 9 knots).

By comparing the records for temperature and chlorophyll *a* obtained just before (July 27–28, 1976) and just after (July 31–August 2, 1976) spring tides, the changes that occurred during the period of increased tidal mixing are clearly apparent (Fig. 2). In the former period the temperature front, as defined by the 15–16 °C contours, was close to the French coast. Then, as bottom turbulence increased at spring tides, the thermocline was eroded from below and a large area of cold well-mixed water (< 13 °C) was produced around the French coast. The frontal region between well-mixed water and stratified water had been displaced further towards the centre of the English Channel. At one place north-west of Ushant the vertical mixing was sufficiently severe to produce a reduction of nearly 6 °C in surface temperature.

The limits of frontal movement define an area where phytoplankton populations tend to be dispersed at spring tides but experience conditions suitable for growth as the water column stabilises at neap tides[1]. The most notable feature of the chlorophyll distribution maps, however, is the large area on the stratified side of the front where the concentration of chlorophyll *a*, which was already > 16 mg m^{-3}, appeared to increase during the period of strong tidal streaming. In the most dense patches of *G. aureolum* the water was chocolate brown in colour, and lines of white or yellowish brown detritus (Fig. 3) were again observed[1]. Associated with these scum lines, and also indicative of zones of water convergence, were reddish patches of *Noctiluca scintillans* (Macartney) Ehrenb., and large numbers of the copepod *Anomalocera patersoni* Templeton. Further to the west, where greater water depths and weaker tides make possible a deeper and more stable thermocline, and extending across the edge of the continental shelf, surface chlorophyll *a* values were generally less than 0.5 mg m^{-3}.

Vertical sections of water properties through the front show the position of the phytoplankton bloom in relation to the temperature structure and nutrient distribution (Fig. 4). While taking samples of phytoplankton from the thermocline, differences in the concentration gradients for nitrate and silicate were observed. In a typical vertical profile these are difficult to demonstrate because of the time lag of the analyser system and because most of the change between surface and bottom mixed layers occurs in a few metres within the thermocline. But by taking advantage of the calm conditions and leaving the hose inlet and temperature probe at a fixed depth corresponding to the mean depth of the chlorophyll-rich layer, it was possible to measure levels of the two nutrients at various positions across the temperature gradient as the passage of internal waves (period 5–10 min) caused slow up and down movement of the thermocline[6]. Figure 5 shows that while there is approximately a one to one correspondence between the temperature and silicate traces, the nitrate values increase significantly only

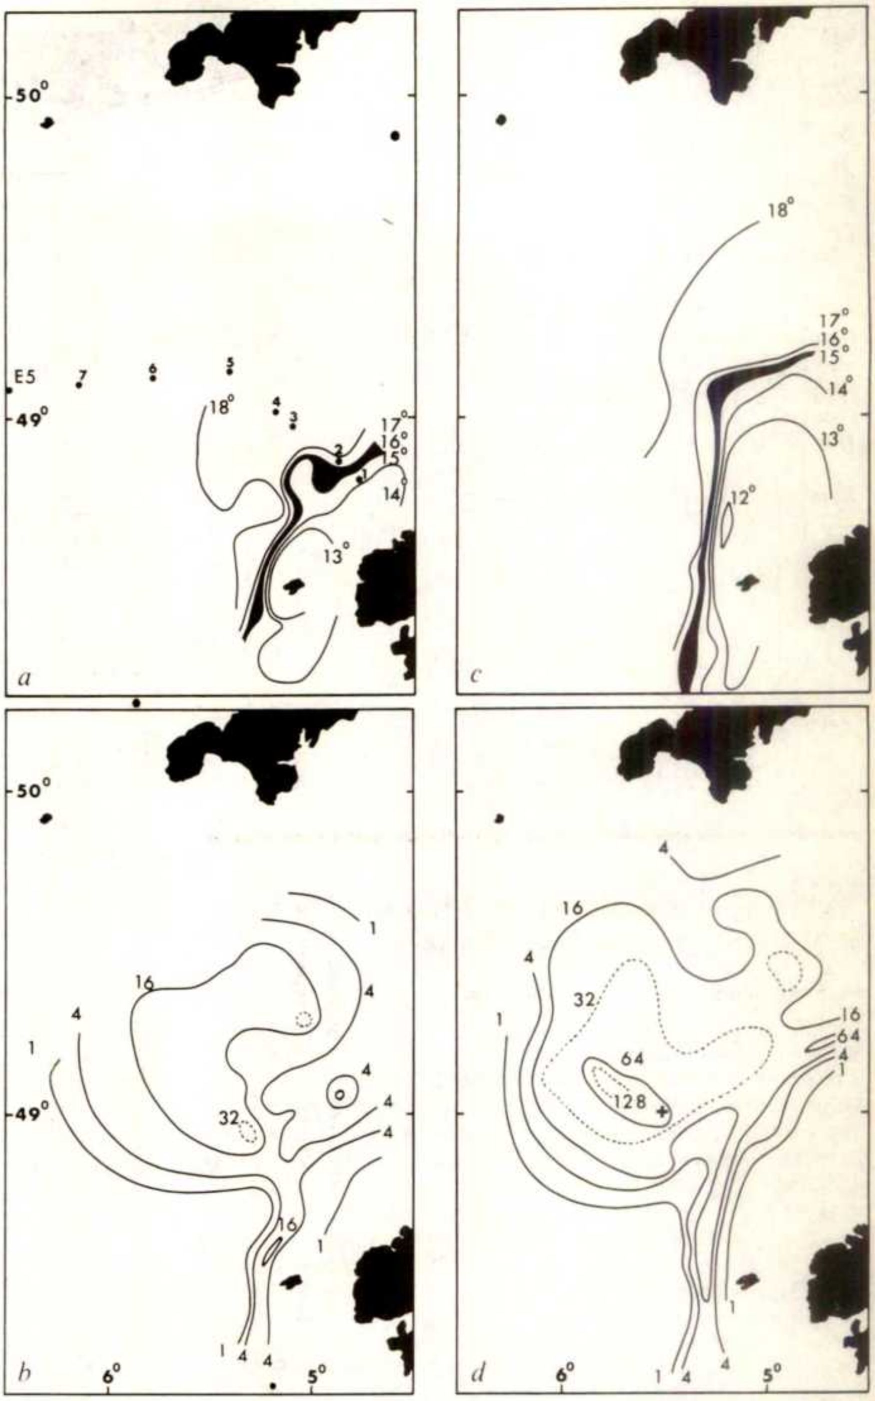

Fig. 2 *a*, Surface temperature (°C); *b*, surface chlorophyll *a* (mg m^{-3}) distributions for July 27–28, 1976. *c*, Surface temperature (°C); *d*, surface chlorophyll *a* (mg m^{-3}) for July 31–August 2, 1976 (+ marks the position at which Fig. 3 was taken).

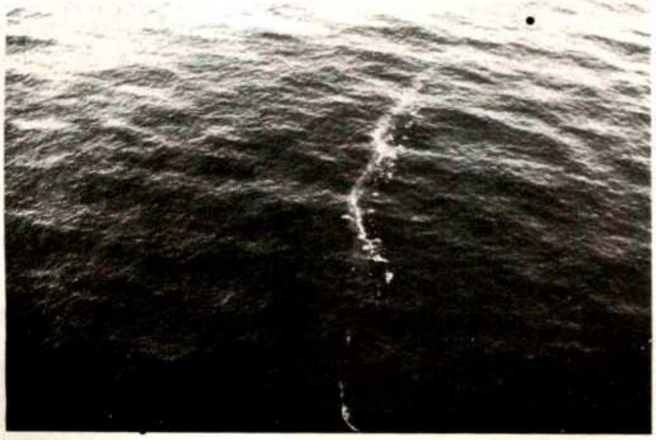

Fig. 3 Surface scum at 49°00'N, 5°30'W Fig. 2*d*), 1150 h GMT, August 9, 1976, from 100 m.

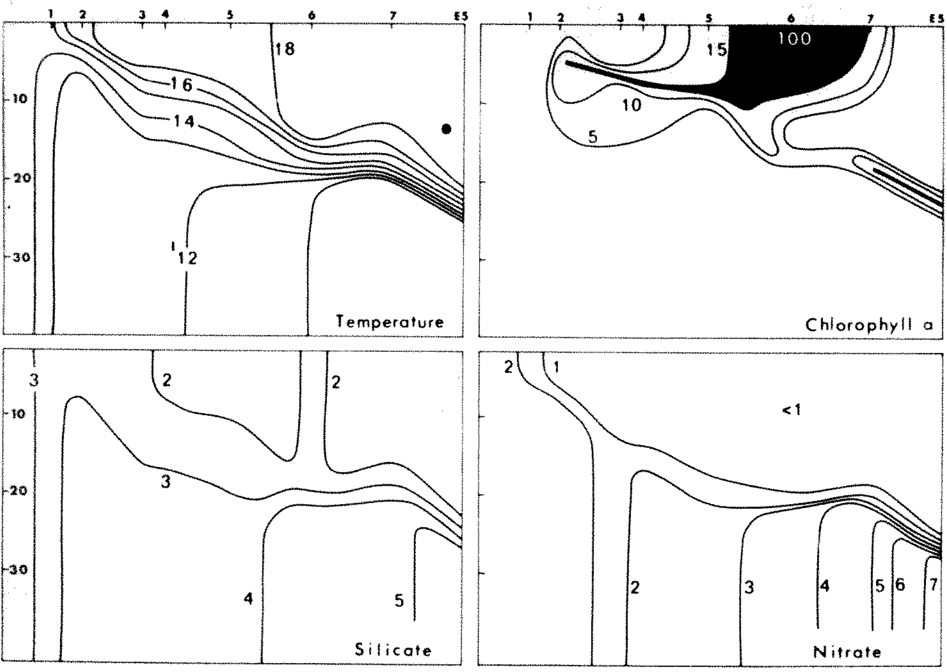

Fig. 4 Vertical sections from temperature (°C), chlorophyll *a* (mg m^{-3}), and silicate and nitrate (μg atom l^{-1}) from mixed (station 1) to well stratified water (station E5). The station positions are shown in Fig. 2*a*. Extreme values for inorganic phosphate, the distribution of which was similar to nitrate, were 0.13 and 0.71 μg atom l^{-1} for surface and bottom water at station E5.

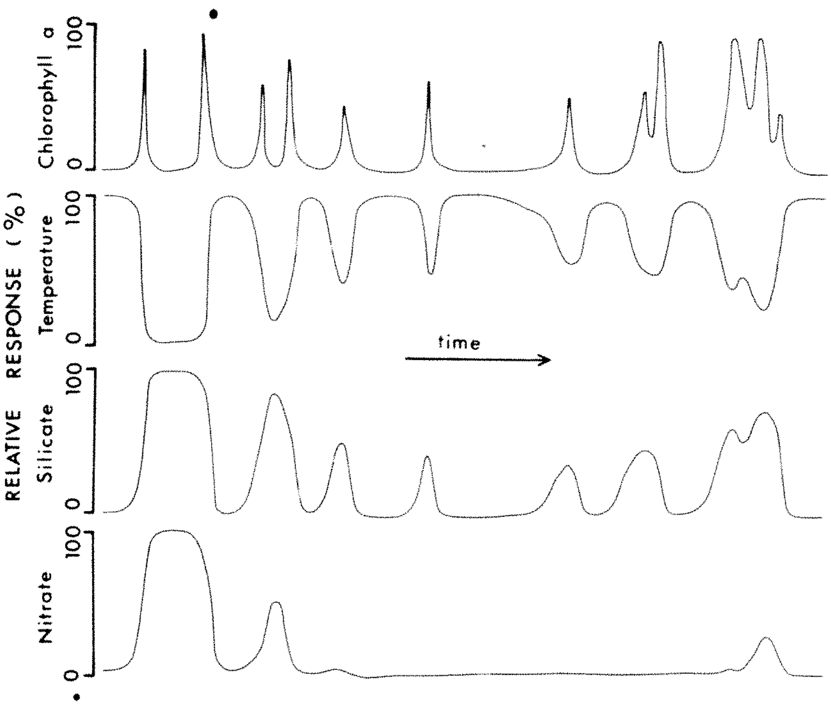

Fig. 5 Records from station E5 (1450–1610 h GMT, August 10, 1976) for nitrate, silicate, temperature and chlorophyll *a* at the mean depth of the thermocline (25 m). Each is presented on a scale of percentage change between values for the surface and bottom mixed layers (Fig. 4).

near the base of the thermocline and below the chlorophyll peak. Analysis[7] of discrete samples indicates that the vertical distribution of inorganic phosphate is similar to that of nitrate.

Dinoflagellates, unlike diatoms, do not have a high requirement for silicate and this is reflected in the relatively high surface values for silicate (Fig. 4)[8]. But the survival of dense populations of these organisms, in both the thermocline and frontal surface water, must depend on an injection of nitrate and inorganic phosphate and this, we suggest, takes place at the base of the thermocline during spring tides at fortnightly intervals. Where the thermocline is relatively shallow, the increased bottom mixing at this time will also affect surface water. Thus the eastern boundary of the more persistent part of the dinoflagellate bloom is marked by the position of the front at spring tides, whereas the western limit is controlled by a deeper and more stable thermocline through which there is little or no exchange of water properties between the surface and bottom mixed layers. Any upward movement of the plant cells during spring tides will minimise the risk of thermocline populations being mixed downwards into the poor light regime of the bottom mixed layer, as well as help to explain the very high surface chlorophyll values which are more than ten times those found in typical spring outburst conditions[2]. We predict the occurrence of similar phytoplankton blooms and gradients in nutrient concentrations on other parts of the Shelf region of the British Isles where comparable hydrographic conditions exist; for example in the North Sea near the Farne Islands, to the east of Orkney and Shetland, and to the west of the Outer Hebrides[9].

We thank G. T. Mardell and Linda Carpenter for assistance at sea, and D. Nicholson for the aerial photography.

bounding the external acoustic meatus and ensheathing a bony styloid process which is still in place. Portions of the base of the cranium are available, including the lateral occipital with occipital condyle and the posterior part of the basi-occipital; portion of the floor and anterior wall of the middle cranial fossa, including the root of the lesser wing of the sphenoid bone. One lateral pterygoid lamina has been identified.

Of the face, there are present both nasal bones, complete from nasion to rhinion, supported by the left and right frontal processes of the maxilla. The pyriform aperture is virtually complete, including part of the floor of the nasal cavity. Most parts of the two maxillary bones are available, including the subnasal clivus, the palate and the alveolar processes. We have a large portion of the palate; the two maxillae have disarticulated neatly in the middle line. All of the front tooth sockets are present, though none of the front teeth has yet been found. On the right, all five cheek-teeth from P^3–M^3 are available, with superbly preserved crowns and intact root systems. On the left, four of the five cheek-teeth are present; only the M^1 is lacking.

The mandible is thus far represented by only a good piece of the right ramus and possibly one or two additional fragments.

Morphology of calvaria

Salient features of the cranial and dental morphology are as follows. The skull as a whole is very small, though the curvature of the vault bones in the temporal fossa is full and rounded, quite unlike the marked constriction of this region found in the australopithecines, for example, Sts 5.

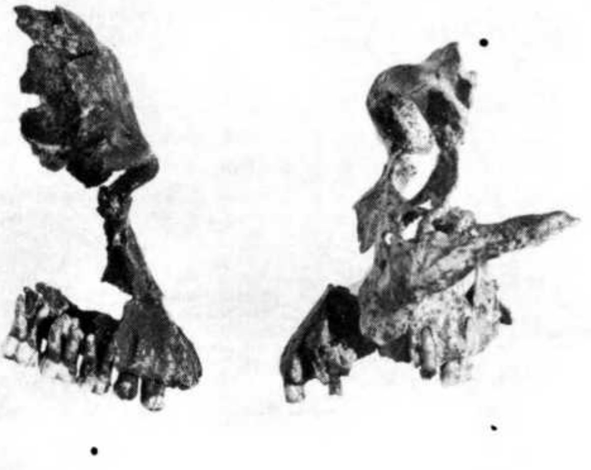
It is impossible at this stage to give an estimate of the cranial capacity, but we are confident that enough of the vault is preserved to make a reasonable estimate possible later. Two indications suggest a capacity that is moderately large for so small an individual: first, the well-filled vault in the temporal fossa and, secondly, the disposition of the temporal lines. These lines are modestly developed and they are well separated from the midline, both anteriorly on the frontal bone and posteriorly on the left parietal bone. The morphology of these temporal lines strongly suggests the pattern in *H. habilis* of East Africa.

The brow is very thin and moderately protuberant; in its delicacy and slight vertical thickness, it is reminiscent of Olduvai hominids 16 and 24, two of the specimens that have been referred to *H. habilis*.

The nose

The nasal bones are set at 180° to each other, except superiorly, where they have a slight linear elevation in the midline just below nasion. The well-preserved floor of the nose, anterior nasal spine, nasal sill and subnasal maxilla are virtually identical to the maxilla from Swartkrans (SK 80) that Robinson[8] recognised as 'Telanthropus III'. It was SK 80 that R. J. Clarke later found to join perfectly with cranium SK 847 and which he and Howell[9] described as belonging to a species of *Homo*. The criteria that Robinson[8] enunciated to distinguish between this area in *Homo*, on the one hand, and *Australopithecus* (both *A. africanus* and *A. robustus*), on the other hand, are still valid and they clearly distinguish the new Stw 53 maxilla from that of *A. africanus* and align it with *Homo*.

Fig. 1 Maxilla of the new Sterkfontein skull, Stw 53, compared with SK 80, a Swartkrans maxilla of *Homo* species, originally called 'Telanthropus III'.



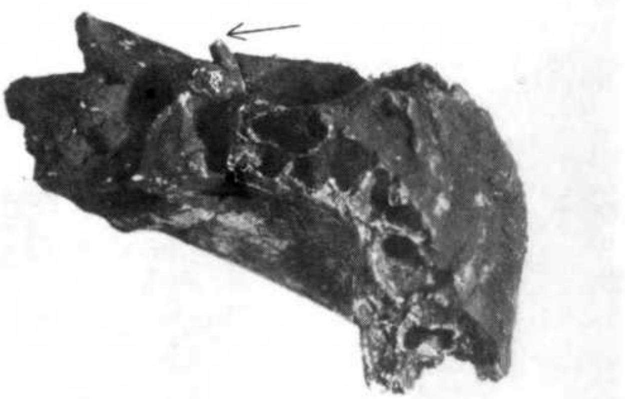


Fig. 2 Base of temporal bone of Stw 53 showing the ossified styloid process (arrowed).

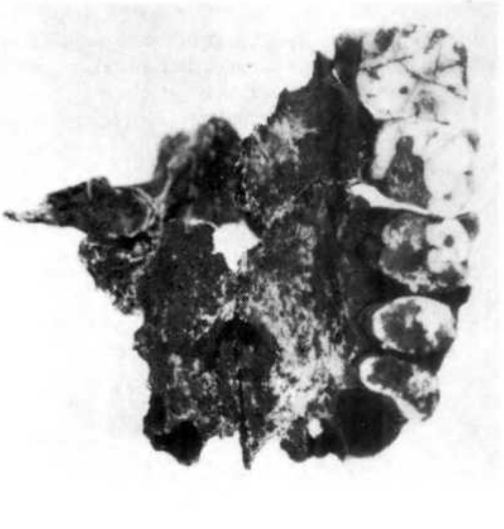
Cranial base

On the base of the cranium, the presence of an ossified styloid process is a feature that distinguishes Stw 53 from all previously described specimens of *Australopithecus* (Fig. 2). The lateral pterygoid plate, as R. J. Clarke pointed out to us, has a nearly vertical, notched posterior margin, like that of *Homo* and unlike the full, posteriorly-expanded, oblique posterior margin, in both robust and gracile australopithecines.

The teeth

The teeth are heavily worn, especially P^3, P^4, M^1 and M^2, while there is moderate attrition even on the M^3 (Fig. 3).

Fig. 3 Palatal view of right maxilla with all five cheek teeth from P^3 to M^3 in position five.



A most striking feature of the teeth is the number and complexity of the roots. Both the P^3s and P^4s have three roots each, two buccal and one lingual. The position on P^3 is encountered in a few of the Sterkfontein *A. africanus* teeth: according to Sperber[10], of 7 Sterkfontein P^3s, 1 has a single root, 3 possess two roots and 2 have three roots. Thus, in comparison with the Member 4 sample from the same site, the roots of the Stw 53 premolars are unremarkable. The position is, however, different with the P^4. All 8 *A. africanus* P^4s, the roots of which could be observed, display two roots[10]. In this respect, the P^4 of the new Member 5 skull distinguishes itself from all specimens thus far known from Member 4 (Fig. 4).

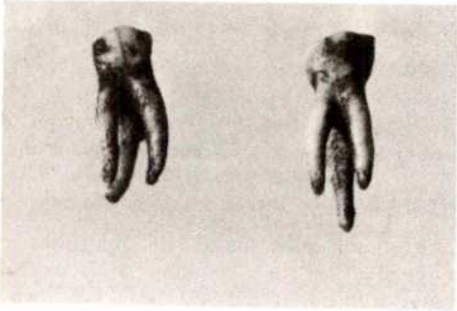


Fig. 4 Upper third and fourth premolars (isolated) to show the three roots of each.

It is interesting to note that in the Swartkrans maxilla (SK 80), which the Stw 53 so strongly resembles, Robinson states, " . . . it is quite clear from the sockets on the right side that P^3 had three separate roots, the mesio-buccal one being closely approximated to the canine root"[8]. Unfortunately, only a part of the root and crown of "what is probably the right P^4" is present and he did not refer to the root pattern reflected in the sockets for the P^4 roots.

Three-rooted premolars are common in the Swartkrans fossils attributed to *A. robustus*. Thus, 8 out of 14 P^3s and all but one of the P^4s, from Swartkrans have three roots[10].

There is a highly distinctive and florid development of the root system in the three molars. Each is furnished with two buccal roots and a sturdy lingual root, but each of these three roots is itself manifestly double and, at the tips, partially bifid. The duality of each of these three roots is more striking in M^2 than in M^1 and the degree of separation of each pair of two components is more marked. This is especially true of the mesio-buccal root, whose lingual component is so sundered from the buccal component as to place it virtually in the bucco–lingual midline of the tooth; its appearance is abnormal and this lingual rootlet curves strongly bucco–distad. The graded series apparent from M^1 to M^2 is continued into M^3, where the process of root doubling of the mesio–buccal root reaches a climax with the marked distal recurvation of its lingual moiety (Fig. 5). In contrast M^3 shows less duality of the disto–buccal root and of the lingual root. This pattern is sharply distinct from those of the australopithecines: in the latter group, scarcely a single one of the upper molars shows even a trace of grooves on the roots, let alone a frank doubling of each!

The mandible

The mandibular ramus is slender and gracile. The sculpturing on its medial face is clear cut and there is an acute angle between the endocoronoid and endocondyloid crests. The mandibular fossa is moderately developed as a flange in front of the endocoronoid ridge. The mandibular notch is somewhat excavated and it is fronted by an acuminate coronoid process. There is a distinct lingula. The features bear comparison with the corresponding part of Olduvai hominid 13 ('Cinderella'); but in the latter, the sculpturing is accentuated and there is not so distinct a lingula. The part as a whole bespeaks a high, narrow, modern-looking ramus of the lower jaw.

All these features add up to a skull that seems to have a preponderance of individual features aligning it with early *Homo* species. It clearly has very little in common with *H. erectus* and would seem to be far too small-brained, thin-skulled and mildly crested to be accommodated in that taxon. On the other hand, the total picture indicates a strong affinity with the small-skulled, moderately-brained and structurally distinctive *H. habilis*. Stw 53 differs from *A. africanus* in much the same way as does the roughly contemporary, pygmoid, brainy *H. habilis* of East Africa, now known from Olduvai (1.8 Myr), Omo (1.85 Myr)[11] and East of Lake Turkana (?2.0–1.8 Myr)[12].

Conclusions

In this new discovery, we believe we have for the first time, convincing evidence that the Sterkfontein tool-maker belonged to the genus *Homo* and either to *H. habilis* or to a form closely related (*H. aff. habilis*). Furthermore, the positions of *A. africanus* in Member 4 and of *Homo* and stone tools in Member 5 strengthen the long-established hypothesis that *A. africanus* was earlier in time than early *Homo* (such as *H. habilis*).

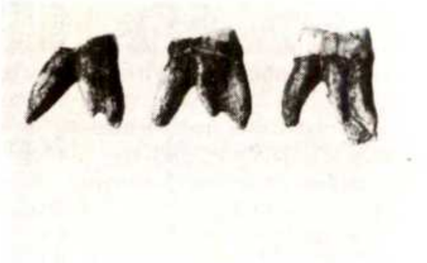

Fig. 5 Mesial views of M^1, M^2, M^3 to show the increasing degree of separation, from M^1 to M^3, of the mesio-buccal root into two rootlets. The lingual component of the mesio-buccal root becomes progressively closer to the bucco-lingual midline of the tooth and is strongly recurved buccally and distally.

This view has gained important support from the newest evidence from East Africa[11,12]. Moreover, the relative ages of *A. africanus* and *H. aff. habilis*, as revealed at Sterkfontein, supplemented by the evidence from East Africa are in keeping with the widely-held and strongly supported view that *A. africanus* is still the most likely claimant to have been ancestral to *H. habilis* and to later species of man.

We thank the following for financial support, assistance in excavation, helpful discussion and other aid: The Council for Scientific and Industrial Research (Pretoria), the Bernard Price Institute for Palaeontological Research, University of the Witwatersrand, T. and decreases with the square of the deviation from this optimum amount, then, if mating is random and if recombination is equally likely to increase or decrease the genome length, Crow and Kimura[40] show that the chromosome length will be normally distributed about $N = N_0$. The gambler's ruin model should thus only be considered as an idealised model which gives another and independent estimate of the gene fixation time.

Multiple mispairing

To estimate the fixation time with multiple mispairing we shall use the diffusion equation method of population genetics[40]. If x is the frequency of occurrence of a particular repeat, say the ith, we need to compute the mean $M_{\Delta x}$ and variance $V_{\Delta x}$ of the frequency change per unit time. We shall continue to assume that there is no selection so that $p = 1/2$. To maintain $N(t) = N_0$, however, we shall follow Ohta[41] and assume that unequal crossovers occur in cycles composed of a duplication of m repeats followed by a deletion of m repeats, where the amount of mispairing per cycle, m, is a random variable. If the repeats of type i are distributed randomly among the N_0 repeats of the multigene family, then the probability of increasing the number of type i repeats by $\xi_1 N_0$ during a duplication event in which the mispairing is by m is given by the binomial distribution

$$P_{x\to x+\xi_1} = \binom{m}{\xi_1 N_0} x^{\xi_1 N_0}(1-x)^{m-\xi_1 N_0},\quad 1 \leqslant \xi_1 \leqslant m \qquad (18)$$

Analogously, the probability of then decreasing the number of type i repeats by $\xi_2 N_0$, given a mispairing by m, is

$$P_{x+\xi_1\to x+\xi_1-\xi_2} = \binom{m}{\xi_2 N_0} x^{\xi_2 N_0}(1-x)^{m-\xi_2 N_0},$$
$$0 \le \xi_2 \le m \qquad (19)$$

where we have neglected the small changes in the gene frequency and repeat length caused by the preceeding duplication event. Thus, for a series of cycles with random mispairings m occurring with frequency $f(m)$, and ξ_1 and ξ_2 taking on all possible values for a given m,

$$V_{\Delta x} = \sum_{m=1}^{N_0} f(m) \sum_{\xi_1=0}^{m} \sum_{\xi_2=0}^{m} (\xi_1-\xi_2)^2 P_{x\to x+\xi_1} \times P_{x+\xi_1\to x+\xi_1-\xi_2} \qquad (20)$$

$$= \frac{2\bar{m}x(1-x)}{N_0^2} \qquad (21)$$

where

$$\bar{m} = \sum_{m=1}^{N_0} m f(m)$$

Similarly, $M_{\Delta x} = 0$.

Using the results of Kimura and Ohta[42] we then find that the mean fixation time measured in crossovers is

$$t_1 = \frac{-2N_0^2}{\bar{m}}(N_0-1)\ln(1-1/N_0) \qquad (22)$$

For unit mispairing the same results obtain with $\bar{m}$ replaced by one[41]. Thus the effect of multiple random mispairings is to decrease the fixation time by the mean mispairing $\bar{m}$.

Ohta[41], using a similar diffusion equation analysis for the case of unit pairing unequal crossovers, computed $V_{\Delta x}$ and t_1 and obtained equations (21) and (22) with $\bar{m} = 1$. If we compare the diffusion equation results with the fixation time estimate derived by the birth–death process we find

$$t_1(\bar{m} = 1) = -N_0\ln(1-1/N_0)T_{\text{bd}} \sim (1 + \frac{1}{2N_0} + \frac{1}{3N_0^2} + \ldots)T_{\text{bd}} \qquad (23)$$

where T_{bd} is given by equation (11). As N_0 becomes large the two estimates converge to the same result. For small values of N_0, T_{bd} is probably a more accurate estimate since we do not need to assume that the repeat frequencies are continuous variables nor do we need to assume that duplication and deletion events strictly alternate (although we do assume that the average number of duplications and deletions are equal).

In Smith's[27] Monte-Carlo simulations $N(t)$ varied between 0.9 N_0 and 1.1 N_0. For $N_0 = 500$, mispairings between 1 and 50 occurred. If we assume that these occurred uniformly then $\bar{m} \approx 25$ and $t_1 \approx 2\times10^4$, which is in agreement with the Monte-Carlo results.

Future problems

We have constructed four mathematical models of unequal crossing over between sister chromatids. For the case in which there are equal probabilities of the offspring retaining the expanded or contracted chromosome (that is $p = 1/2$), we have given explicit solutions. The solutions have been interpreted to show that at long times one gene in a multigene family becomes fixed while the other genes are lost. Hence, as Smith[27] has pointed out, if the average time for a gene to acquire a mutation (the gene mutation time) is long compared with the time for gene fixation a very homogeneous multigene family would result which would seem to show coincidental evolution. On the other hand, if the gene mutation time was short compared with the gene fixation time a heterogeneous multigene family would be formed.

One might expect that selection would influence the relative probabilities of retaining the expanded or contracted chromosome. In *D. melanogaster* Tartof[13] has found that even though expansion and contraction are concurrent events, offspring containing an expanded amount of rDNA are more prevalent than offspring containing a decreased rDNA content. It would be interesting to solve equations (1)–(3) or the related multidimensional random walk problem when $p \neq 1/2$ and $N(t) \neq$ constant. Mathematically, one can view this unit mispairing problem as an urn problem in which N_0 balls each of a different colour are placed in a container at $t = 0$. A ball is chosen at random and replaced by two balls of the same colour as the chosen ball with probability p, and not replaced with probability $1-p$. We present this problem as a challenge to mathematicians.

We have shown that, using a diffusion model, the time to gene fixation can be estimated for unequal crossing over in which the mispairing is a random variable. But we had to impose the rather stringent and biologically unreasonable assumption of the crossovers occurring in cycles of duplication and deletion events of identical length. Further, we assumed that the repeats were randomly arranged along the chromosome since correlations in the positions of initially adjoining genes will influence the probabilities of genes being duplicated or eliminated by unequal crossovers in which mispairing occurs by two or more repeats. To assess these correlations in analytical form and to relax the constraint that $N(t) = N_0$ seems to us to be an extremely challenging and difficult problem which we hope will attract some mathematical attention.

A realistic, but difficult mathematical problem is to enlarge the basic model so as to allow crossing over between homologous chromosomes in a diploid organism. At least in the case of *D. melanogaster* this does not seem to be necessary, for Tartof[13] has found that unequal crossing over occurs predominately between chromatids on the same chromosome. Whether such restrictions also occur in other species where unequal crossing over has been adopted as an evolutionary mechanism remains to be seen.

This work was done under the auspices of ERDA. We thank G. P. Smith for helpful comments, J. A. Black for raw data from his

Monte-Carlo simulations and L. Hood, D. Blackwell, G. Watson, M. Kac and C. Lipow for interest and instructive remarks. We also thank Mrs Mary Plehn for prompt secretarial assistance.

A fossil skull probably of the genus *Homo* from Sterkfontein, Transvaal

Alun R. Hughes & Phillip V. Tobias

Department of Anatomy, University of the Witwatersrand, Johannesburg, South Africa

A skull with numerous Homo *features was discovered at Sterkfontein, near Krugersdorp, Transvaal, in August 1976. It stems from member 5 of the Sterkfontein Formation, with stone tools and with fauna pointing to an age of 2.0–1.5 Myr. The underlying member 4 contains* Australopithecus africanus, *no stone tools, and fauna dated 3.0–2.5 Myr. The new find supports the view that the Sterkfontein toolmaker was not the earlier* A. africanus, *but a later hominid related to* Homo habilis.

By a remarkable double coincidence, the first pieces of the new skull, Stw 53, were found on August 9, 1976, 40 years to the day after Robert Broom's first visit to Sterkfontein, while the last part came to light on August 17, the 40th anniversary of Broom's first discovery of a hominid cranium at Sterkfontein. Although most of the fragments were found in a decalcified pocket of cave earth, one large part of the calvaria was still present in the calcified wall of the pocket, thus establishing indisputably the provenance of the specimen.

THE Sterkfontein cave deposit near Krugersdorp, Transvaal, has previously yielded a large number of fossil hominid bones that form the major part of the hypodigm of the species, *Australopithecus africanus*[1]. Recently we extended our operations to a previously overburdened area south of the West Pit (formerly called the Extension Site). Here, between August 9 and 17, 1976 we brought to light a new fossil skull which, we believe, provides the first good evidence that the stone tools in the upper part of the Sterkfontein cave deposit were made by a hominid very similar to the early species of man originally described from Olduvai Gorge and designated *Homo habilis*[2].

The discovery was made 3 m south of the breccia from which, in 1956–1958, Brain and Robinson[3] had recovered the first stone tools from Sterkfontein. The breccia exposed in this part of the cave comprises Member 5 of the Sterkfontein Formation, according to Partridge. Member 5 contains a mammalian fauna that is much younger than that of the subjacent Member 4: according to Vrba's[4,5] study of bovids in the two Members and other evidence, there may well be a lapse of ~0.5–1.0 Myr between the two Members. The long gap in the depositional sequence is the result of a marked unconformity between Members 4 and 5.

Apart from strong differences in bovid fauna, Members 4 and 5 differ in other respects: 4 contains no stone implements, while 5 contains an abundance of them. All of the hominid fossils unequivocally assigned to *A. africanus* emanate from 4, while until the new find was made, Member 5 had yielded only a handful of hominid teeth and jaw fragments. So unsatisfactory were these Member 5 remains that the identity of the hominid represented was uncertain. Robinson[6] considered them to belong to *A. africanus*, like those from the deeper part of the cave, while Tobias[7] regarded them as belonging to the genus *Homo* and probably to the species *H. habilis*. The new discovery provides the first unequivocal evidence of the nature of the Member 5 hominid and, probably, of the Sterkfontein stone tool-maker.

The new skull Stw 53

It is clear that we have a large part of the complete skull. We have the right brow, frontal bone and partially exposed frontal sinuses, several parietal fragments, including a posterior part of the left parietal bone articulating across the lambdoid suture with part of the occipital. The occipital includes a portion of the planum occipitale as well as of the planum nuchale, with a small, sharp nuchal crest on the medial, but not the lateral part of the bone. On the side of the cranium, we have a temporal, with well-preserved mastoid process, petrous pyramid and part of the tympanic

letters to nature

On the optical observation of galaxies with large redshifts

IT IS well known that the energy distributions of spiral galaxies rise sharply in the ultraviolet. Recent observations of six Sb and Sc galaxies[1] made with the TD1 satellite place this steep rise at considerably longer wavelengths than the earlier observations made with the OAO-2 satellite[2,3] If the TD1 results are correct, the large ultraviolet flux, which is now considerably closer to the U band, suggests the possibility of detecting more distant galaxies with deep ultraviolet plates than the usual deep B, V or R plates, since this region of high flux will be redshifted into the U band.

The problem of whether distant galaxies fall within the limiting apparent magnitude of a plate can be examined from the published energy distributions. Figure 1 shows the absolute energy distribution adopted for an Sb/Sc galaxy. Below 2740 Å the fluxes represent the average of the six galaxies measured by the TD1 satellite, the various intrinsic luminosities being allowed for by using published V magnitudes[4] and normalising to a constant V magnitude. Above 2700 Å the relative fluxes taken from Pence[3] were made absolute by using the flux for M31 (ref. 5) scaled to the chosen V magnitude, Pence's results below 3500 Å are, however, an extrapolation. It is encouraging to note the continuity between the two portions of the energy distribution, considering the large errors which may be involved.

Now the apparent magnitude, m, of a galaxy with absolute magnitude M is simply

$$m = M + 25 + 5\mathrm{lo}_{10}(d_L) + K_1(z) + K_2(z) \qquad (1)$$

where d_L is the luminosity distance in Mpc given by[6]

$$d_L = \frac{c}{H_0 q_0^2}(q_0 z + (q_0 - 1)\{(2q_0 z + 1)^{1/2} - 1\}) \qquad (2)$$

and the K-corrections are

$$K_1(z) = 2.5\log_{10}\left[\int_0^\infty F(\lambda)S(\lambda)\mathrm{d}\lambda \Big/ \int_0^\infty F\{\lambda/(1+z)\}S(\lambda)\mathrm{d}\lambda\right] \qquad (3)$$

$$K_2(z) = 2.5\log_{10}(1 + z) \qquad (4)$$

where $F(\lambda)$ is the radiation flux at wavelength λ and $S(\lambda)$ is the detector response. Following Oke and Sandage[7] we have separated the effect of the redshift on the bandwidth, that is, the K_2 term, from the effect of simply translating to the redshifted wavelength, that is, the K_1 term. Our point is that for the U band, K_1 eventually starts decreasing with redshift, whereas K_2 increases monotonically. The essence of the present problem is the competition between these two terms.

For a deep plate, the detector response will depend on the film, its filter and the sky transmission. As the flux has only been measured for a few wavelengths, we have made the approximation

$$K_1(z) = 2.5\log_{10}\left[F(\lambda_e)\Big/F\left\{\lambda_e/(1+z)\right\}\right] \qquad (5)$$

with effective wavelengths λ_e of 0.33 μm for the U band and 0.44 μm for the B band. Using the curve in Fig. 1 together with equations (1), (2), (4) and (5), we have calculated the apparent magnitude for the Sb/Sc galaxy at various redshifts. This was done for $q_0 = 0.2$ and for an absolute magnitude corresponding to the turn in the differential luminosity function. This occurs at $M_B^* = -21$ mag 1 and $M_U^* = -21$ mag 2 for $H_0 = 50$ km s^{-1} Mpc^{-1} and U − B = −0 mag 1 (ref 3). The results are shown in Fig. 2. A calculation with $q_0 = 0.02$ leads to little difference for redshifts below 1.0.

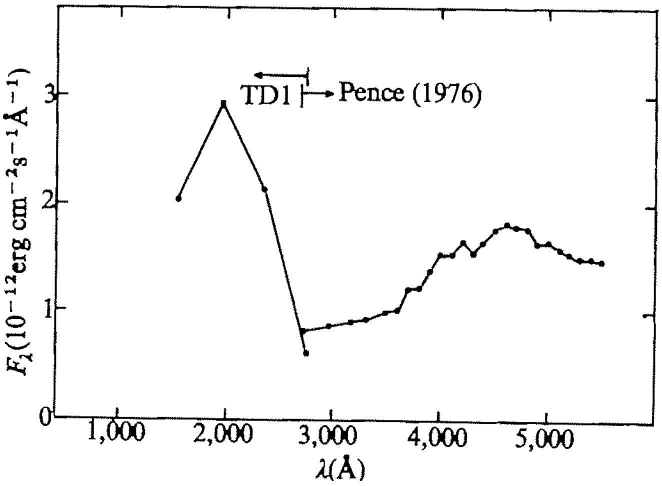

Fig. 1 Observed absolute spectral energy distribution for an Sb/Sc galaxy, normalised to $V = 8$ mag 49 (NGC 4258)

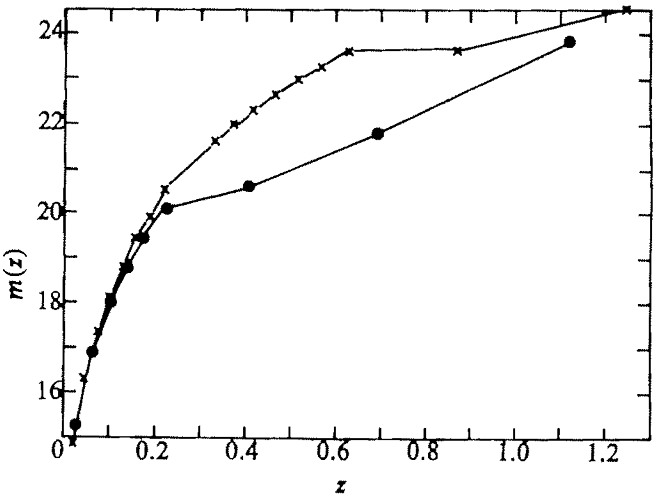
The distribution of visible galaxies with redshift on a U plate depends mainly on its limiting apparent magnitude We have been unable to calculate this directly; instead we have arrived at an approximate value by comparing each factor involved with its appropriate counterpart when taking a deep B plate The sensitivity of a B plate (nitrogen-soaked Kodak IIIa-J plus Schott GG395 filter) is close to that of a U plate (nitrogen-soaked Kodak

Fig. 2 Apparent U and B magnitudes at various redshifts ×, $m_B(Z)$; ●, $m_u(Z)$.



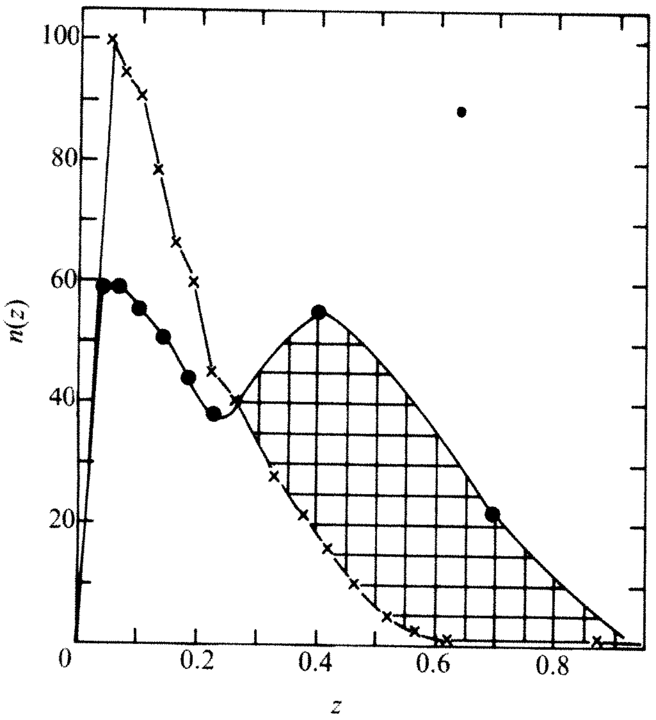


Fig. 3 Relative numbers of Sb and Sc galaxies visible on deep B and U plates at various redshifts. The hatched area represents the excess observed when blinking from the B plate to the U plate. ●, U plate; ×, B plate.

Ha-O plus Schott UG1 filter)[8,9]. The major difference with deep U plates lies in the sky brightness. For the two wavelengths considered, Simkin[10] quotes U–B = −0mag 7. It has already been demonstrated that images as faint as B = 23mag 0 have been recorded on IIIa-J photographs taken with the UK 48-in Schmidt. Hence we have considered here a limiting magnitude of U = 22mag 3 as fairly realistic.

We can show that there is an excess of distant images on the U plate, as compared with those on a B plate. These could be readily identified by comparing the images on the two plates, for example via the COSMOS machine[11]. In order to estimate how many galaxies would be on the U plate but not on the B plate, we have used Christensen's[12] absolute luminosity function. The loss of galaxies caused by atmospheric 'seeing' has been ignored. The effect of evolution has also been neglected, but it can be readily seen that the predicted time variation of the energy distributions[13] will make the detection of distant galaxies even more favourable, mainly because distant, and thus younger, galaxies will be more luminous. The frequency of galaxies at various redshifts for plate limits B = 23mag0 and U = 22mag3 is plotted in Fig. 3. The excess shaded region on the graph corresponds to about 700 Sb and Sc galaxies for an area of 1 square degree, that is, about 15% of the total number of all types on 1 square degree of the B plate. The interesting feature is that most of these galaxies lie in the redshift range of 0.3–0.8.

As in the identification of QSOs, blinking between U and B plates can produce a host of other interlopers[14], though the images sought here are close to the plate limit (Fig. 2); further comparisons with deep red plates might eliminate some of these. The fainter QSOs might be expected to have very large redshifts and neutral colours[15] and hence appear on all three plates.

The suggestion depends on the approximate validity of the TD1 results. With respect to the discrepancy between the TD1 and OAO-2 results, we note that there is a similar discrepancy between the OAO-2 and the recent Skylab ultraviolet observations[16]. There is evidently an urgent need for further accurate extragalactic observations in the ultraviolet. Deep U plates have been taken recently with the UK 48-inch Schmidt telescope and we intend to pursue the matter discussed in this note further using the COSMOS machine.

The polarisation of nova Vulpeculae

MEASUREMENTS of the polarisation of nova Vulpeculae 1976 are reported. The linear polarisation seems to have an interstellar origin and so can be used to estimate the reddening and distance of the nova. Nova Vuleculae 1976 was discovered at about the peak of its brightness on October 21 by the British amateur astronomer Mr Alcock.

Observations were made at the 90-inch (2.3-m) telescope of Steward Observatory on the evenings of October 25–27, 1976 using a dual-channel Pockels cell polarimeter with GaAs photomultipliers (RCA C31034A). Six passbands from 0.35 to 0.86 μm were defined with either interference filters or combinations of coloured glass filters and the spectral response of the photomultipliers. The details and results are given in Table 1 and Fig. 1. Quoted errors are 1σ from photon counting statistics.

The polarisation seems to have an interstellar, rather than intrinsic, origin. The wavelength dependence of linear polarisation is descrbed well by Serkowski's empirical formula for interstellar polarisation[1], with the parameters $p_{\max}$ = 3.35% and $\lambda_{\max}$ = 0.59 μm as shown in the figure. Furthermore $\lambda_{\max}$ and the position angle 12° (72° galactic) are typical for stars in this region[1,2]. There is no evidence for (intrinsic) circular polarisation larger than 0.08% (3σ). Interstellar circular polarisation, however, is likely to be quite small; for example the circular polarisation of HD183143, a more strongly linearly polarised neighbouring

Fig. 1 Linear polarisation of nova Vulpeculae 1976. Curve is empirical formula for interstellar polarisation[1] with $p_{\max}$ = 3.35% and $\lambda_{\max}$ = 0.59 μm.

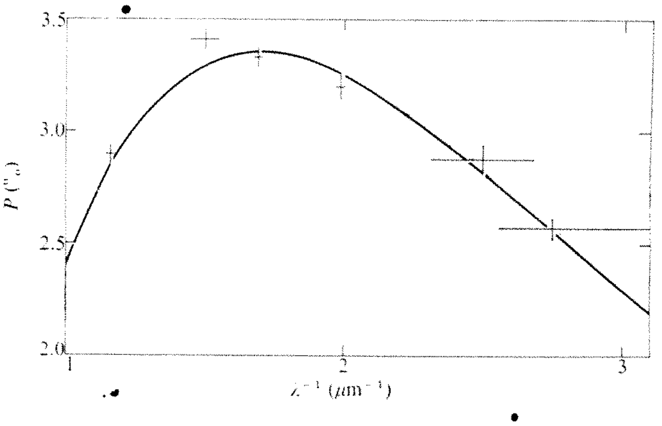

Table 1 Polarisation of nova Vulpeculae 1976

Date (Oct. 1976)	λ^{-1} ($\Delta\lambda^{-1}$ μ^{-1})	Polarisation (%)		
		Linear	Position angle	Circular
25	2.75 (0.57)			0.03±0.02
25	2.75 (0.57)	2.57±0.04	12.2±0.5	
27	2.50 (0.37)	2.88±0.06	10.1±0.6	
26	1.99 (0.03)	3.20±0.06	11.2±0.5	
26	1.69 (0.03)	3.33±0.04	11.1±0.3	
27	1.50 (0.11)	3.41±0.04	12.5±0.3	
26	1.16 (0.03)	2.90±0.04	13.8±0.4	
27	1.16 (0.03)			0.02±0.02

star, is only about 0.01% (ref. 3).

If an interstellar origin is accepted, then the amount of polarisation may be used to estimate the reddening, the distance and thus the absolute magnitude (at maximum) of the nova. Hall[2] lists the colour excess E_{B-V} and the degree of polarisation p (at 0.45 μm) for about two dozen stars within several degrees of the nova. The subset of these that are polarised about the same amount as the nova give p (%) $\simeq$(3.5±1.2 E_{B-V}. For the nova p(0.45 μm)=3.1%, so that the estimated E_{B-V} is 0.9±0.3.

The same subset of stars range in distance modulus from 8.8 to 12.2, the average being about 11. The colour excess in this area of the sky is known[4] to increase linearly with distance to 0.9 at 1 kpc, after which there is little further increase. Therefore a distance modulus of 11±1 for the nova would be consistent with all of the data, though a larger value is possible.

The above estimates, together with a ratio of total to selective extinction of 3.3 and the reported m_V=6.5 near maximum[5], lead to $M_{V,max}$=−7.5±1.5, a reasonable value for a nova. This estimate should be compared to that which can be derived from the timescale of the decay of the nova light, when the latter becomes available.

Radio 'jets'

FANAROFF and Riley[1] classified extragalactic radio sources according to whether high brightness radio hot spots are observed close to their outer extremities. A change in morphology is found when going from high (typically 10^{26} W Hz^{-1} sr^{-1}) to relatively low (10^{24} W Hz^{-1} sr^{-1}) luminosity at 178 MHz. The more luminous sources have pronounced outer hot spots and are all highly collimated double sources such as Cygnus A. On the other hand, their fainter cousins, which are less commonly found in radio surveys, contain no outer hot spots and comprise sources with relaxed double structure or having head–tail or complex morphologies. So far, little is known how these apparently different classes[1] of sources are related. In particular, one might enquire whether the collimating process is less efficient in the nuclei of the fainter, more relaxed radio sources. Here we present new observations made with the Westerbork Synthesis Radio Telescope (WRST) which show that three of these relaxed type sources with intermediate 178 MHz luminosities have collimated structures emanating from their radio cores. Our high resolution observations show that these coherent structures are embedded in the otherwise smooth radio sources. These 'radio jets' may be similar in nature to the narrow structures recently observed (with less sensitivity) in the collimated double source 3C219 (ref. 2) and the complex radio galaxy 3C66B (ref. 3). We shall briefly discuss the consequences of these radio jets for models of radio sources.

Table 1 Observing parameters

Source	Observing frequency (MHz)	Observing dates	Half-power beamwidth (RA×dec) (arc s)	Effective noise at field centre (10^{-29} W Hz^{-1} m^{-2})
B0844+31	4995	14 Jan. 76 16 Jan. 76	6×12	0.8
	1415	1 July 76	22×42	1.0
	610	Dec. 72– May 73	52×98	4.6
3C310	4995	4 May 73 18 May 73	6×14	0.8
	1415	14 May 71	22×50	1.0
3C129	4995	Dec. 72– Feb. 73	6×9	0.6

New observations were made at 5 GHz of the relaxed double galaxies B0844+31 and 3C310 and of the head–tail galaxy 3C129. B0844+31 was originally classed as a QSO but the high resolution observations of Grueff and Vigotti[4] showed that this was a misidentification. In fact the source is associated with a 15.5 magnitude giant elliptical galaxy[5]. The morphology of 3C310 was discussed by Miley and van der Laan[6] and 3C129 is one of the most studied head–tail galaxies[7,8].

The Westerbork Telescope is described elsewhere[9,10] and relevant parameters pertaining to the present observations are shown in Table 1. Contour maps of the 5 GHz total intensities are shown in Figs 1–3 side by side with lower resolution Westerbork maps made at 1.4 GHz and

*Estimate from fringe amplitudes at shortest baseline.
†Single dish observations (ref. 21).

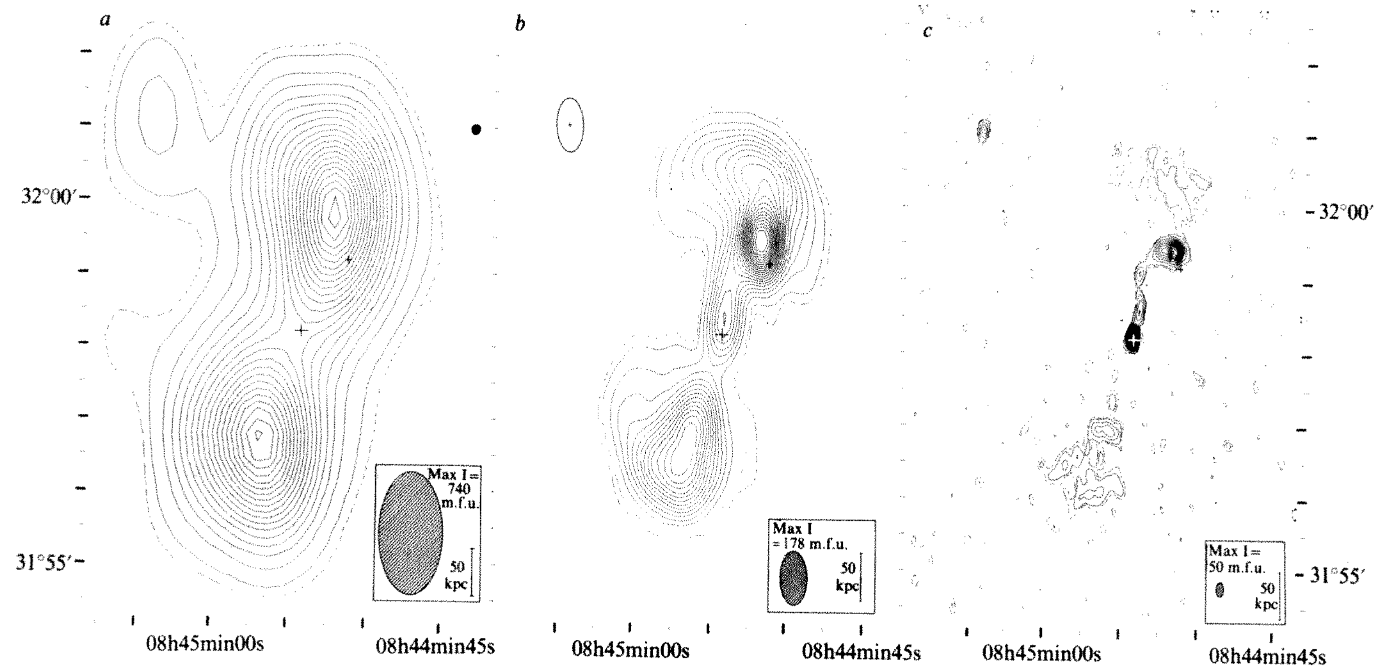

Fig. 1 Total intensity distribution of B0844+31 at 0.6, 1.4 and 5 GHz. Continuous contours are plotted at 5% intervals from 5% to the indicated value of MAX. I. Long dashed contours represent the 3% level and short dashed contours the −5% level. The shaded ellipse represents the half-power level of the synthesised beam and the crosses the position of the galaxy and the QSO. In *b*, an unresolved (presumed background) source is subtracted. Also indicated are the relevant linear scales.

(in the case of B0844+31) at 0.6 GHz. All maps are corrected for primary beam attenuation. The linear scales were obtained using the redshifts listed in Table 2 and a Hubble constant of 75 km s^{-1} Mpc^{-1}. The cross at the central radio component indicates the identified galaxy. For B0844+31, the QSO (at the edge of the northern hot spot in Fig. 1*c*) is also indicated as well as a subtracted (presumed background) point source in the north-east part of Fig. 1*b*.

Note the relaxed appearances of B0844+31 and 3C310 apparent in the lower resolution maps (Figs 1*a*, *b* and 2*a*). By contrast, the 5 GHz observations show a considerable amount of small scale structure. Both sources contain compact radio cores with relatively flat radio spectra coincident with the visible galaxies. Most remarkable are the highly collimated elongated structures emanating from these cores. This is most pronounced in the case of B0844+31 but present to a lesser extent in the southern part of 3C310. From the latter source, however, another characteristic seems to show up more clearly: comparison of Fig. 2*a* and *b* suggests that the coherent, elongated structure is embedded in a larger region of low brightness.

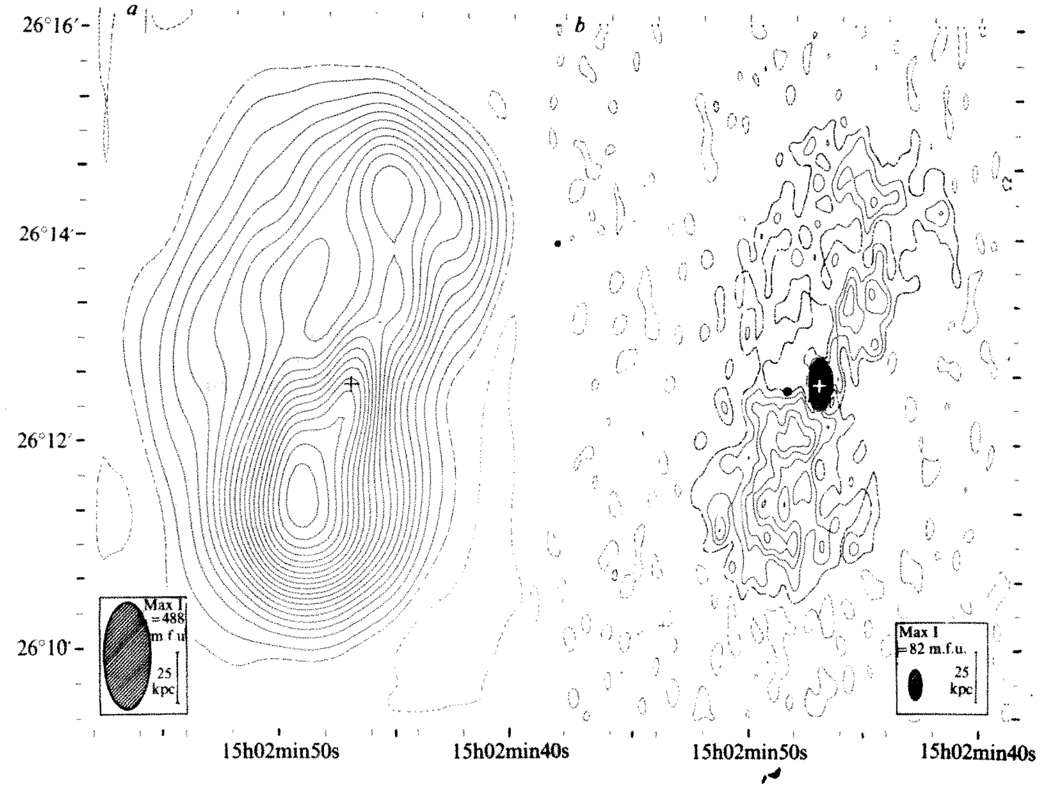

Fig. 2 Total intensity distribution of 3C310 at 1.4 GHz and 5 GHz. Low intensity contours are 2, 5 and 10% in *a* and from 2 to 10% in intervals of 2% in *b*. Further contours are as in Fig. 1. Negative contours are −2% (short dashed). The +2% contours are long dashed.

The radio jet in the northern part of B0844+31 terminates in a region of relatively high brightness situated about half way to the edge of the source. A weaker hot spot is apparent to the south. Beyond the hot spots the emission is relatively uncollimated.

Although the jets are very narrow they are not straight. One can distinguish 'wiggles' on several different scales. For both sources the shape of the wiggles is suggestive of an S-type symmetry[11] close to the radio cores. However, from Fig. 1*b*, the outer parts of the northern and southern components of B0844+31 have relatively sharp gradients to the west and tail off gradually to the east so that the large scale structure of this source may exhibit a C-type symmetry[11].

It is interesting to compare the morphologies of these two relaxed double sources with that of the head-tail source 3C129. Figure 3 shows an unpublished 5 GHz map of the head made with the WSRT. Again there is a compact radio core near the centre of the visible galaxy. According to the radio trail hypothesis[12] the head-tail morphology is formed when a 'normal' double radio source is distorted by the motion of its parent galaxy through a dense intergalactic medium. Without this distortion one might expect the head of 3C129 to resemble the central part of B0844+31. The pair of highly elongated arms stretching back to the north-west are then analogous to the radio jets in Figs 1 and 2. The set of parallel wiggles in the two arms of 3C129 would correspond to the S symmetry in the jets of the relaxed double radio sources. (In the case of 3C129 these wiggles can be traced a distance of several hundred kiloparsecs along the tail.)

Other possible examples of radio galaxies with jets are 3C83.1 (NGC 1265) (ref. 13), 3G130 (ref. 14), 3C402 (ref. 6), 3C449 (ref. 14), 3C465 (ref. 6), Virgo A (ref. 15), Centaurus A (ref. 16), and NGC 315 (ref. 17). When most of these relatively relaxed sources are observed with sufficient sensitivity and linear resolution better than a few tens of kiloparsecs, jet-like features are seen protruding from their radio cores into more extended, low brightness regions. This indicates that although these sources are relatively relaxed, they still have a very efficient collimating process in their nuclei.

Table 2 compares the observed flux densities for the jets with those of other features in the sources. An examination of the data available for the sources presented here together with those of possible candidates indicate that the radio jets typically have 5-GHz luminosities of 10^{22} W Hz^{-1} sr^{-1} and sizes of a few tens of kiloparsecs. The contribution of the jet to the total flux is small, so that for beam widths much greater than the jet widths (a few kiloparsecs), their structure is 'smeared out' over the more extended low brightness regions. The detection of the jets therefore requires a combination of sufficient sensitivity and linear resolving power. The collimated Cygnus A type sources are on average about a hundred times further away and with currently available instruments it is impossible to say whether they also have comparable jets protruding from their cores. However, the 2-kpc component within 3C236 (ref. 18) and the jet component in 3C219 (ref. 2) may represent similar but more powerful phenomena.

How are these radio jets to be interpreted within the framework of current theoretical efforts? In recent years a large body of evidence has built up in favour of models of highly collimated double sources in which energy is supplied quasi-continuously from an active nucleus (at the radio core) to the outer components. The energy is transported by a succession of ejected plasmoids or by a relativistic beam. The existence of the jets suggests that such quasi-continuous energy transport also takes place in the weaker relaxed sources. One can envisage the jet as a tunnel along which the energy is channelled. The hot spots at the outer edges of the collimated doubles have their counterparts in the regions of enhanced radio brightness where the tunnels terminate. In these regions the energy density builds up and results in enhanced synchrotron emission. In the less luminous sources the hot spots are found relatively close to the core. Possibly, since less energy is involved, in this case the energy transport is more influenced by conditions within the parent galaxy.

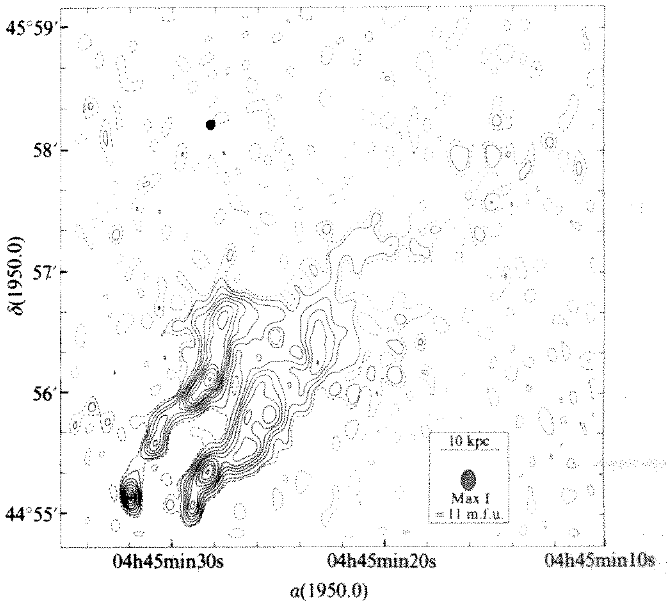

Fig. 3 Total intensity distribution of 3C129 at 5 GHz. Continuous contours are plotted at 10% intervals from 10% to the indicated value of Max. I. A 5% contour (long dashed) and −10% contour (short dashed) are added.

Of particular interest are the S-shaped wiggles in the jets. They appear to occur on a scale about half that of the jets themselves, corresponding roughly to the size of the associated visible galaxies. This correspondence could be indicative of a hydromagnetic instability due to the interaction of the galaxy with the ambient medium. Alternatively the wiggles may be caused by a change in the orientation of the nuclear powerhouse during the source lifetime[19,20]. Such a wobble in the collimation axis could account for the symmetries apparently seen in B0844+31, 3C310 and 3C129 as well as in several other sources[19]. The C-type symmetry in the large scale structure of B0844+31 (Fig. 1*b*) is most probably due to translational motion of the source through an ambient medium.

Analysis of the spectral and polarisation data for these sources may give more insight into the exact role that the jets play in the energy transport process. In the coming year the sensitivity of the WSRT, at 5 GHz, will be improved by a factor of ten. Further effort will then be made to find more sources with radio jets.

We thank our colleagues at Westerbork, Dwingeloo and Leiden who made these observations possible and acknowledge useful discussions with Professor van der Laan. The Westerbork Synthesis Telescope is operated by the Netherlands Foundation for Radio Astronomy with financial support of the Netherlands Organisation for the Advancement of Pure Research (ZWO).

Frequency of nearby supernovae and climatic and biological catastrophes

McCREA[1,2] has proposed that the encounter of the Solar System with a dense cloud of interstellar material during its passage through a spiral arm of the Galaxy may produce such climatic catastrophes on Earth as the ice epochs. His thesis, an extension of several earlier investigations[3,4,5], is based on the expected effect on the solar constant of an increased accretion rate. Unfortunately, the cloud density necessary to produce the required variation is 10^5 to 10^7 cm^{-3}, and although clouds with such extreme densities are thought to exist[6], Begelman and Rees[7] point out that they are so compact and unusual as to reduce the likelihood of the Sun ever encountering one. (Dennison and Mansfield's suggestion[8] that there is no evidence for the existence of a nearby super-dense cloud which could have caused the most recent ice epoch has been answered by McCrea[9].) Begelman and Rees[7] in fact showed that a much more modest cloud density ($\simeq 10^2$ to 10^3 cm^{-3}) would prevent the solar wind from reaching the Earth, with resulting modification of the near-Earth environment; however, the climate consequences of such a modification are not well understood. We present here an alternative hypothesis which still retains McCrea's association with the passage of the Solar System through a spiral arm, but which relates the initiation of an ice epoch, plus biological catastrophes, to an encounter of the Solar System with a nearby supernova outburst rather than a super-dense interstellar cloud.

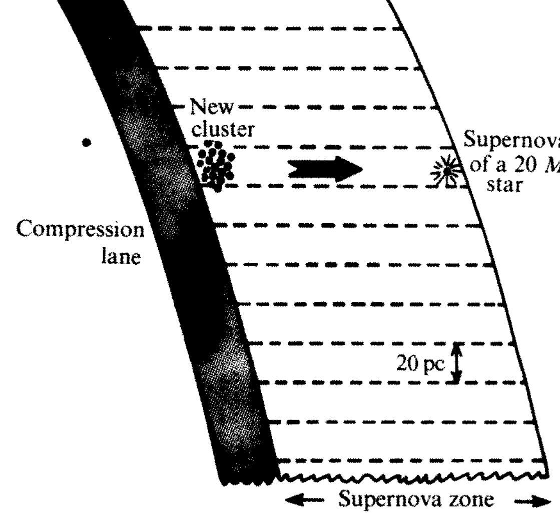
The spiral structure of our Galaxy indicates the regions where bright, short-lived stars illuminate the interstellar gas and dust. The two principal spiral arms are believed to reflect a self-sustaining density-wave pattern through which the disk of stars and gas move. Observations indicate dust lanes along the inner (concave) edge of each arm, and this is interpreted as a shock-wave effect whereby clouds become temporarily compressed as they cross the lane. A cloud of interstellar matter in its orbit round the Galaxy is liable to enter a spiral arm by way of its compression lane about once in $\simeq 10^8$ yr. In general the cloud material will re-expand on emerging from the lane after $\simeq 10^6$ yr (the cloud not necessarily retaining its original identity). But sometimes a cloud is compressed to a condition for star formation, and the result is a new galactic cluster which proceeds to traverse the associated spiral arm itself, taking $\simeq 10^7$ yr to do so. If this cluster contains a star of mass some $10 M_\odot$ or greater it would be expected to evolve rapidly over less than $\simeq 10^7$ yr, terminating in a supernova outburst of Type II before emerging from the spiral arm in which it is formed. In this view supernovae of Type II would occur only in spiral arms (or near galactic nuclei), in accord with observation. Indeed, a 'supernova zone' might be defined beyond the compression lane of a spiral arm; such a zone is depicted diagrammatically in Fig. 1, in the assumption of a $20 M_\odot$ stellar lifetime of $\simeq 5 \times 10^6$ yr and a transverse velocity (at about the solar distance from the galactic centre) of 200 km s^{-1} giving a zone width of $\simeq 1$ kpc.

The occurrence rate of supernovae within the Galaxy is still only poorly determined. At least five historically observed supernovae occurring on the near-side of the Galaxy during the past millennium[10,11] would seem to place a lower limit on their frequency throughout the Galaxy of about one per 100 yr. It must, however, be stressed that the short interval between some actial sightings of supernovae can give a grossly misleading impression of the frequency of events because of the extreme distances involved. For example, the AD 1006 supernova occurred at a distance of about 3,000 light years from the Earth[12], while that of AD 1054 occurred at a distance of over 6,000 light years (ref. 12), so that although first sighted on Earth within half a century of each other the outbursts were actually separated in time by over 3,000 yr. Clark and Caswell[13] have concluded from a statistical analysis of the radio remnants of supernovae that the average interval between outbursts leaving long-lived observable remnants (that is, those lying within spiral arms and evolving only slowly) is $\simeq 100$ yr. Shklovsky[14] prefers an interval of a mere 30 yr for Type I (population 2) events, but accepts a longer interval of $\simeq 100$ yr for those of Type II (population 1). Results from other investigators range between these extremes. In the absence of a more define estimate, we will take an average interval between Type II supernovae of 100 yr.

If there is one Type II supernova per 100 yr, and if, as seems reasonable, this is localised to one of the 'supernova zones' proposed above, then this implies 5×10^4 such supernovae in one (of two) spiral arms in a period of $\simeq 10^7$ yr (the time for the Sun to traverse a spiral arm). Since a spiral arm is $\simeq 2 \times 10^4$ pc long, this suggests that 50 supernovae will occur in a 20-pc strip of a spiral arm's 'supernova zone' each time the Sun crosses it. Thus at least one supernova would be expected to occur within 10 pc of the Sun each time it crosses a spiral arm (that is, about once every 10^8 yr). Note that this simple calculation takes no account of the thickness of a spiral arm perpendicular to the plane; however, since the bulk of supernova remnants are concentrated to within a few tens of pc of the plane[13], this simplification is not expected to increase the above estimate for the interval between nearby supernovae by more than a factor of two.

Estimates of the radiation flash[15] emitted (mainly in γ and X rays) in a supernova explosion vary from $\simeq 10^{47}$ to 10^{50} erg. (This represents a very small fraction of the total energy of the outburst of $\simeq 10^{52}$ erg.) Assuming the lower value, the peak integrated energy flux expected above the Earth's atmosphere from a supernova at $\simeq 10$-pc distance is $\simeq 10^6$ erg cm^{-2} (this compares with the solar flux of $\simeq 20$ erg cm^{-2}s^{-1} in the wavelength range of interest). Absorption in the upper atmosphere means that this flash gives no significant surface radiation dose initially. Nevertheless, Ruderman[15] has predicted catastrophic effects on the Earth's protective ozone layer. The ionising radiation from the supernova

Fig. 1 Schematic representation of a supernova zone (not to scale).



flash produces excited free nitrogen atoms in the atmosphere which quickly oxidise. The oxides of nitrogen catalytically destroy ozone, and Ruderman claims that by this mechanism the ozone layer density may be temporary depleted. Such destruction of the ozone layer would expose the Earth's surface, and more particularly life on it during the past 600 Myr, to lethal solar ultraviolet radiation.

The expanding shell of ejecta from a supernova at 10-pc distance would reach the Earth after about 2,000 yr, with the passage of the shell taking several hundred years. During this latter period the density of primary cosmic rays would be expected to be enhanced by perhaps a factor of a hundred[14]. About one third of the background radioactivity level at the Earth's surface is contributed by cosmic radiation (the remainder being due to terrestrial factors). Thus a hundredfold increase in cosmic ray intensity would produce a drastic thirtyfold increase in mean level of radioactivity. In addition, the enhanced cosmic-ray flux would be expected to produce the same destruction of the ozone layer as produced by the initial radiation flash. The possible biological consequences of such dramatic increases in background radioactivity and ultraviolet radiation fluxes expected for protracted periods some time after a nearby supernova outburst may have been catastrophic for certain species. Ruderman[15] has suggested that in man the huge increase in ultraviolet radiation would give rise to a vast increase in the incidence of skin cancer; in animals with calcified internal skeletons the increased vitamin D production might have been toxic.

The supernova-initiated destruction of the ozone layer would be expected to have climatic as well as biological consequences. Whether ozone removal would heat or cool the Earth is unclear; the main argument for cooling is that ozone contributes (in the 2-μm region) significantly to the greenhouse effect, so that its removal could lower the Earth's temperature and thus possibly initiate an ice age.

The question arises as to whether one would be able to observe the nearby remnant of the supernova which might have initiated the last major ice age $\simeq 10^5$ yr ago. Unfortunately, after such a period the remnant of this supernova would already have reached its extinction phase[13], and would almost certainly be impossible to identify with certainty.

The possible astronomical influences on the Earth's climatic and biological history must remain a matter of speculation. Nevertheless, we suggest that the evidence that the Solar System encounters a nearby supernova (that is closer than 10 pc) on average once per orbit of the Galaxy must be included in any future consideration of these topics.

Note added in proof: In a recent note, Whitten *et al.*[17] have independently considered the effects of a nearby supernova on atmospheric ozone. From a consideration of the galactic distribution of supernova remnants given by Clark and Caswell[13], they concluded that the probability of a supernova occurring within 10 pc of the Earth during the past 10^8 yr is only 1–5%. Our somewhat greater estimate of a 50% probability during any 10^8-yr period is a consequence of our confining (at least Type II) supernovae to the galactic spiral arms, in accord with the observational evidence[12,14], and assuming that within the spiral arms the rate of occurrence of supernovae is independent of distance from the galactic centre.

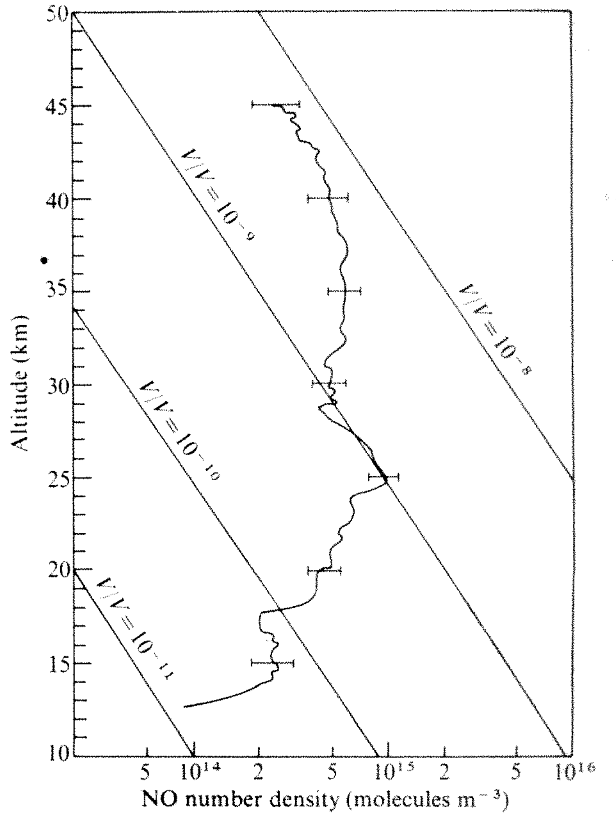
Balloon-borne chemiluminescent measurement of NO to 45 km

MEASUREMENT of nitric oxide (NO) above an altitude of 40 km is of interest because in this region of the stratosphere >70% of the total odd nitrogen ($NO+NO_2+HNO_3+N_2O_5$) is thought to exist as NO, and at 45 km the NO is predicted to be approximately 90% of the total[1]. This measurement thus provides an important test for odd nitrogen concentrations as predicted by theoretical models for ozone chemistry. Some models show that of the total ozone destruction necessary to explain the observed ozone concentration, approximately 50–70% is due to the odd nitrogen catalytic cycles[2].

We have made direct measurements of the nitric oxide (NO) concentration between 12 and 45 km with a balloon-borne chemiluminescent detector. This is the first balloon-borne chemiluminescent measurement to an altitude of

Fig. 1 Vertical profile of the nitric oxide concentrations for the June 27, 1976, balloon flight from Sioux Falls, South Dakota (1 atmosphere 43°26′N). The instrument was launched at 1108 GMT and the data were taken on ascent. The local Sun times for the data at 12 km and 45 km were approximately 0530 and 0730, respectively. The marked increase in NO at 18 km correlated with the altitude of the stratospheric wind reversal. The altitude of the tropopause was 10.5 km.



45 km. The data above 40 km are particularly useful to test theoretical models of ozone chemistry because above 40 km most of the odd nitrogen is thought to be in the form of NO. The data from a balloon flown on June 27, 1976, from Sioux Falls, South Dakota (Fig. 1), show a nearly constant mixing ratio of 6.5 p.p.b.v. from 40 to 45 km, with a possible peak value at 43 km. One other high-altitude stratospheric NO measurement has been made by a rocket-borne chemiluminescent detector but the data were taken quickly (in 25 s) and without on-board flow measurements, zeroing, or calibration[3]. Several chemiluminescent devices, interferometers, spectrometers, and lasers have been flown on balloons to a maximum altitude of 35 km (refs 4–7). These measurements indicate a large range in NO concentrations which suggests that transport plays a strong role for odd nitrogen and thus ozone chemistry in the lower stratosphere.

Our instrument was similar in principle to other chemiluminescent NO detectors[8], and a brief description of the device follows. Ozone for the photon producing reaction $NO+O_3 \rightarrow NO_2+h\nu$ was carried as ozone absorbed on silica gel at dry ice temperatures. The O_3 source was servoed to produce a constant concentration of O_3 in the reaction vessel at all ambient pressures. The sample gas was drawn through a 1.2-m pyrex tube and heated to 30 °C before entering the gold-plated reaction vessel. A positive displacement blower was specially developed to provide a constant 3 l-s^{-1} flow rate at all altitudes encountered during the flight. The blower exhausted the sample gas–ozone mixture through a 3-m flexible tube located on the side of the instrument opposite the sample inlet tube. The balloon ascent provided a 15-km-h^{-1} vertical flow rate so that the exhausted ozone did not pollute the sample. The instrument was suspended 100 m below the balloon and flight control package. Zero NO signal levels were taken every 40 s by destroying the NO in the sample gas with ozone upstream of the reaction vessel. The instrument was calibrated every 2.5 min by pumping NO (in N_2) calibration gas into the sample inlet tube.

The data for the ascent are shown in Fig. 1. The mixing ratio from 40 to 45 km is essentially constant at 6.5 p.p.b.v. with a possible peak at 43 km. The results show considerable structure in the NO concentration in the lower stratosphere. There is a marked increase in NO mixing ratio at 18 km which corresponds to the altitude of the wind reversal for that day. Where data can be compared, our results show general agreement with other measurements[1,9].

The funding for the 15×10^6 cubic foot balloon and the balloon launching crew (we thank Raven Industries) was provided by the United States Office of Naval Research.

Sea surface temperature related to rain in Ceará, north-eastern Brazil

RAINFALL in Ceará is correlated with sea surface temperature in the south Atlantic Ocean. Knowledge of sea surface temperature makes possible a useful rainfall forecast before the rainy season begins. The mechanism may be that sea temperature affects the height of the trade wind inversion, and thus the height of the moist layer. The data also suggest in association between below normal sea temperatures in the south Atlantic and the El Niño in the Pacific.

Ceará is the node of Brazil's drought-prone north-east. Here severe drought, and its antithesis, flooding, both occur about once per decade, arriving without warning. The human misery that follows in their wake might be reduced if they could be forecast. We found that sea surface temperature (SST) in the south Atlantic Ocean and rainfall in Ceará are correlated in time, and if SST is known, a useful preliminary rainfall forecast can be made.

Brazilian climatologists have long believed rain in the north-east to be related to fluctuations in SST, but have been unable to show such a relationship owing to lack of sufficient SST reports. We investigated this relation by using a data file containing all available surface marine weather reports from ships of many nations. This file, Tape Data Family -11, was assembled by NOAA's National Climatic Center. Working in conjunction with the Fleet Numerical Weather Central and the North Pacific Experiment (NORPAX) the National Marine Fisheries Service has used the tape data file to compute mean sea surface temperatures by 5° latitude-longitude quadrants for each month in the period October 1947 to December 1967. We used these computations to map the correlation coefficient between SST and a rainfall index in Ceará. Later, after we had identified a key 5° quadrant where correlation was particularly high, monthly SSTs were recomputed for the period 1907–72, and used in a regression analysis to develop a forecasting equation. Our results may be somewhat biased by the selection of this particular quadrant, and further research may show that improved forecasts can be made using data from other areas.

The density of SST observations is far from uniform over the South Atlantic. Reports are most abundant along shipping lanes between the Cape of Good Hope and Cape Verde, and along the South American coast. Data are extremely sparse over the central South Atlantic, and are not sufficient to map correlation coefficients over the entire area. Data are not available in all quadrants in all years, and different years are missing from different quadrants. Nevertheless, when considered as a whole, the data form a picture that is coherent and of predictive value.

The rains in Ceará are highly seasonal, about 40% coming in January-February-March, and about half in April-May-June. Almost no rainfall occurs in the months August to November. Fortaleza and Quixeramobím are two weather stations in Ceará about 120 km apart that have long series of rainfall observations extending back to 1849 and 1896, respectively. We correlated monthly mean SST data with rainfall at both stations, but found that a combined index of simultaneous data from both stations gave higher correlation coefficients. The combined index smooths local variations of rainfall to emphasise large scale influences affecting both stations. Since the mean annual rainfall at Fortaleza, on the coast, is about twice that of Quixeramobím, in the interior, we gave each station equal weight in the index by using twice Quixeramobím's rainfall plus Fortaleza's.

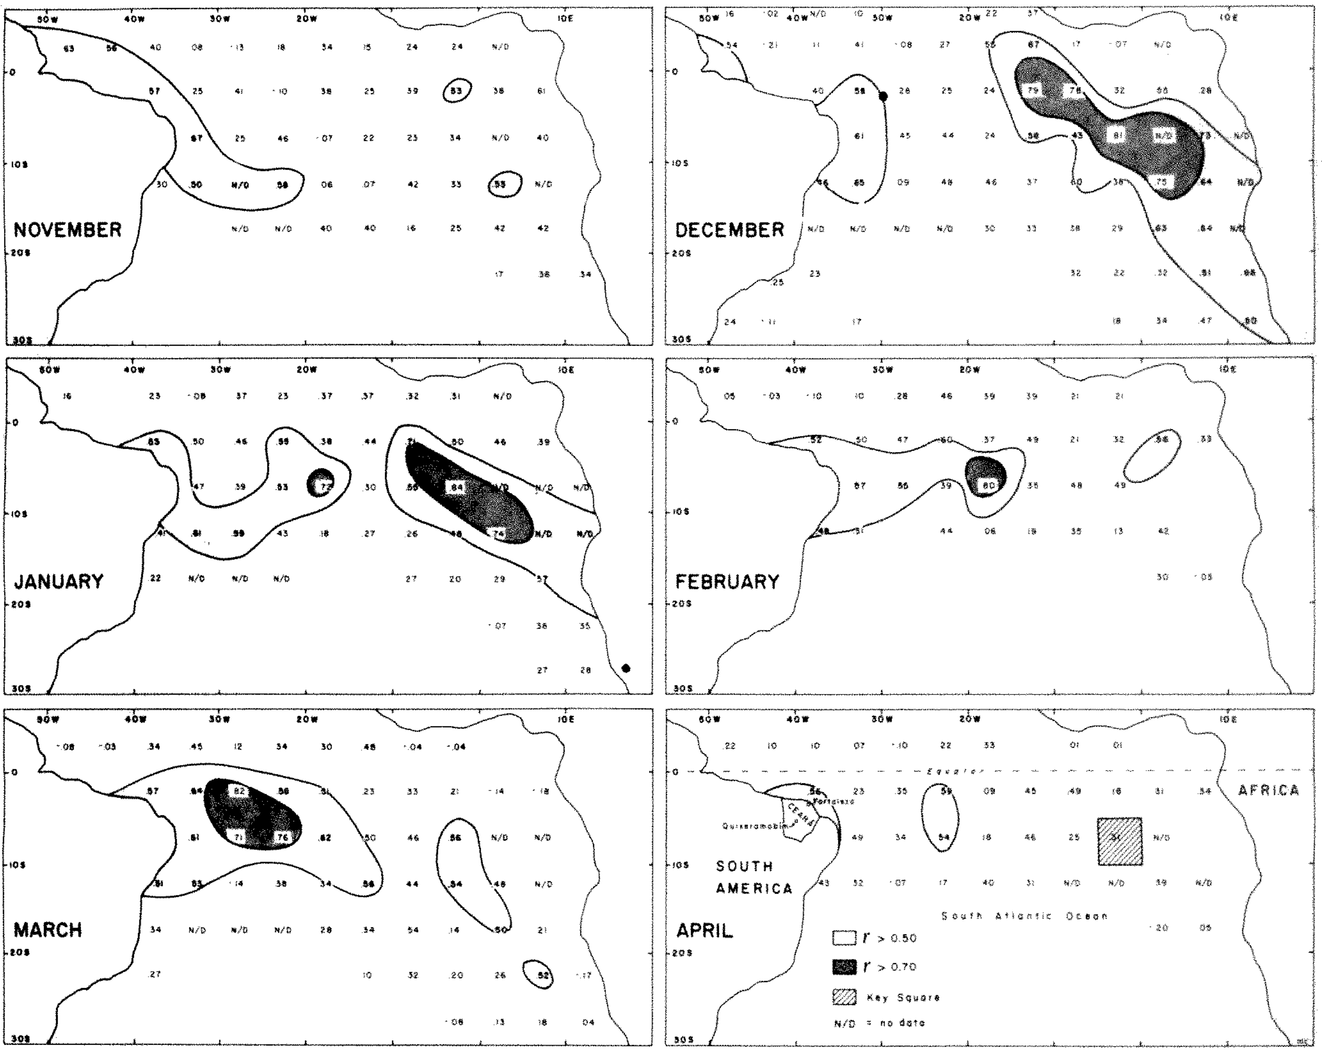

Fig. 1 Correlation between SST and January-February-March rainfall indices in Ceará. An area of high coefficient of correlation appears off the African coast in November, becomes strong in December, moves westward with the South Equatorial Current during January, February and March, and disappears in April.

We computed correlation coefficients (r) for each of the 5° quadrants in the South Atlantic for which data are available, between the monthly values of SST and the rainfall index for the combined months of January-February-March, as well as for the annual rainfall indices. SSTs for November and December were correlated with rainfall indices for the coming year, while SSTs for January through April were correlated with the current year.

Maps of correlation coefficients (Fig. 1) show an apparent westward movement of high correlation during November to April. This may be related to the westward drift of water in the South Equatorial Current. In December the quadrant where correlation is highest is centred at 7°30′S, 2°30′W (Marsden Square 300, Quadrant 3). For this area r was 0.81 for January-February-March rainfall, and 0.73 for annual rainfall. Ceará tends to be dry when water here is cold, and wet when it is warm. Moreover, since December precedes the rainy season in Ceará, December SST can be used to forecast rainfall with useful lead time. Thus we selected Quadrant 300-3 as the key area for regression analysis with Ceará's rainfall.

The 1947-67 data used for our correlation maps are means of all reports within a given 5° quadrant and thus might be biased by clustered reports. This possible bias can be reduced by making individual means for each 1° area, then averaging the 1° means to obtain a 5° mean. This latter procedure was used to obtain data points for our long term regression analysis (Fig. 2).

We noticed a long term warming trend of 0.51 °C between the years of 1907 and 1972, in our SST means at Quadrant 300-3. The trend could be caused by real warming, or by differences in measurement techniques that have occurred over the period. If it is assumed that the latter is true, and if the effects of the trend are removed from the regression, r for the period increases from 0.61 to 0.66, Kendall's rank-order coefficient, τ increases from 0.20 to 0.41. This increase in order through detrending suggests that the apparent trend is instrumental and not a real warming.

Depending on the sets of data, r values range from 0.61 in the 1907–72 data uncorrected for trend, to 0.81 in the 1947–67 data used in making the correlation maps. Values of τ range from 0.21 to 0.50. All are for correlation between December SST and the Ceará rainfall index for the following January-February-March period. If we assume r to be 0.71, then r^2, the coefficient of determination, is 0.50, indicating that half of Ceará's January-February-March rainfall can be predicted by mean SST in Quadrant 300-3 in December. If we assume $\tau = 0.40$, we can say that the odds are 70/30 that a change in SST will be followed by a change in rainfall index of the same sign. Our rainfall forecast ranges from 500 mm with an SST of 22 °C to 2300 mm

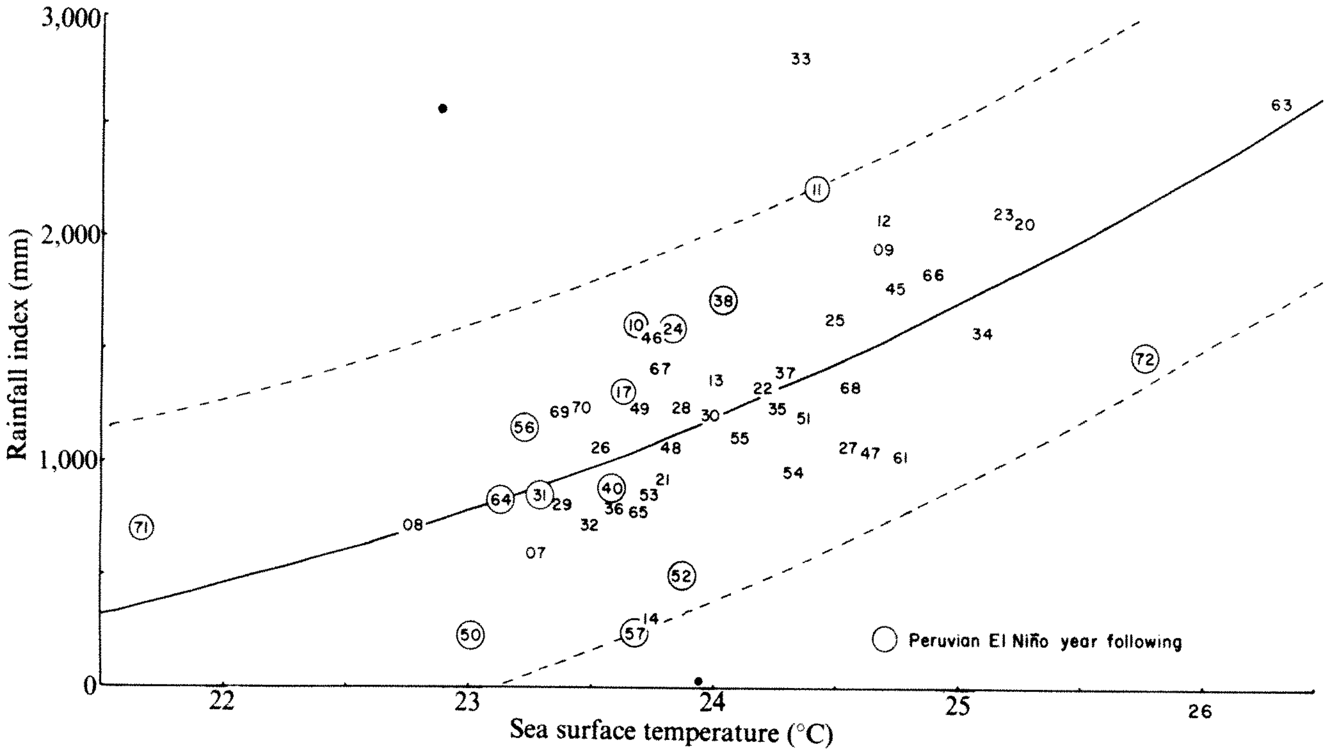

Fig. 2 January-February-March rainfall indices in Ceará plotted against December SST in Marsden Square 300, Quadrant 3. Years indicated are for December SST values. Data has been detrended by adding 0.0078 °C times the number of years before 1972. Second degree regression lines and 95% confidence limits are shown. El Niño years (taken from Caviedes (1973) and Quinn[6]) are circled.

	1907–72 Detrended	1907–72 Not detrended	1947–67 From Fig. 1
n	53	53	16
r	0.66	0.61	0.81
α	0.001	0.001	0.001
τ	0.41	0.20	0.50
α	0.001	0.04	0.007

with an SST of 26 °C; a considerable improvement over the climatic normal value of 1267 mm. If we define drought as the lack of rainfall and flooding as an excess of it, from Fig. 2 we can state that drought is unlikely when SSTs at Quadrant 300-3 are warmer than 24.5 °C, and that flooding is unlikely when SSTs are colder than 23.5 °C. If we are given some particular SST value, say 24.0 °C, our best estimate for the rainfall index is 1200 mm, and we can say with 95% confidence that it will fall between 350 and 2050 mm. These are much wider limits than we should like but suggest that eastern Atlantic SST in December, albeit important, is only one of a number of factors influencing Ceará's rainfall.

A suggested mechanism for the correlation is as follows: cold water stabilises the overlying air and decreases wind flow and convection over the Atlantic. The trade wind inversion represents the boundary between subsiding air from aloft and convective air from below. When convection is weak and winds are light, the trade wind inversion is lowered, and the thickness of the layer carrying moisture into north-eastern Brazil is reduced. Similarly, warm seas strengthen wind flow, and mixing and increased convection raise the trade inversion to deepen the moist layer. Further, the Intertropical Convergence Zone (ITC) and its attendant raininess would tend to lie in the region of warmest water, and would retreat from the hemisphere with cold water.

Namias[1] found intense cyclonic activity near Newfoundland to be highly correlated with rain at Quixeramobim. He hypothesises the following chain of events. The North Atlantic Subtropical High is strengthened when the trough in the Newfoundland land area deepens. The trough is held in place by blocking toward the east. The strengthened subtropical High increases the north-east trade winds which in turn require the south-east trades to respond by strengthening, thus increasing the flow of moisture into Ceará. An alternative explanation for Namias' correlation is its reverse. Warm South Atlantic sea temperatures produce heavy equatorial rains. These release large quantities of latent heat, strengthening the Hadley circulation in both hemispheres, and inducing a blocking High in the North Atlantic. The increased flow from the Equator, accompanied by the blocking, results in increased cyclonic activity in the Newfoundland area, with a concurrent deepening of the trough. To support this latter explanation, Markham[2] found that a strong South Atlantic High and strong south-east trades seem to decrease, rather than increase, rain in Ceará. The rainiest periods do not occur when the south-east trades are strong, but when the High is weak or has retreated toward the south, allowing flow with a northerly component to penetrate Ceará. There is little doubt that the Newfoundland trough and rain in Ceará related, but which is the cause and which the effect is unclear. In any event, precipitation over northeastern Brazil is important to the general circulation because it represents a significant energy input to the atmosphere, and with large variations from year to year. The magnitude of this variation is shown by the annual rainfall index which varied from a low of 884 mm in 1915 to a high of 5505 mm in 1964.

From the work of Namias[3] and Bjerknes[4], a body of literature on large scale ocean–atmospheric interactions is growing. Recently Caviedes[5] has related drought in northeastern Brazil with the El Niño—the appearance of anomalously warm water off the Peruvian coast. Temperatures in Quadrant 300-3 also seem to be related to El Niño. The years preceding El Niño are circled in Fig. 2.

The hypothesis that cold December SSTs precede El Niño has a one-tailed significance level of about 0.0125 when the non-parametric Wilcoxson two-sample test is applied[7]. The coldest December temperature in Quadrant 300-3, 21.67 °C in 1971, was followed by an El Niño of exceptional severity in 1972. The El Niño of 1972 may have persisted into 1973 and thus may account for the anomalous point for 1972 circled in Fig. 2. If this did occur, the correlation is greatly improved. Quinn[6] has related El Niño to the difference in surface pressures between Easter Island and Darwin, Australia. This difference is an index of the Southern Oscillation and suggests that the occurrence of warm water off Peru simultaneously with cold water off Africa is related to the Southern Oscillation. The mechanisms for this phenomenon are poorly understood.

Upper Jurassic pyroclastic rocks in Skye, west Scotland

DURING a systematic sampling of shale lithologies in the Jurassic beds of Skye, an examination was made of sections in the Staffin Shales[1-3] in Staffin Bay. Two localities were visited, one immediately south of the landslip at point 6 (ref. 4) [NG470712] and the other at point 7 (ref. 2) [NG468715]. Six shale samples were collected at the former section, representing the *Kosmoceras jason* and *Erymnoceras coronatum* zones (Middle Callovian), the *Peltoceras athleta* and *Quenstedoceras lamberti* zones (Upper Callovian), and the *Quenstedoceras mariae* and *Cardioceras cordatum* zones (Lower Oxfordian). Four shale samples were collected from the section at point 7, representing the *Ringsteadia pseudocordata* zone (Upper Oxfordian) and the *Pictonia baylei*, *Rasenia cymodoce*, and *Aulacostephanus mutabilis* zones (Lower Kimmeridgian).

The shale samples were thus representative of the bulk of the sequence, but further samples were collected from two of three distinctive pale grey mudstone bands present in the point 6 section. The lowest of these mudstones (here termed the *athleta* band) lies about 0.75 m above the base of the shales of the *Athleta* zone. The upper two bands, about 1.7 m apart, could not be zonally dated from field observations alone, but foraminiferans from the lower band have been identified by Dr A. W. Medd as belonging to the lower part of the *Cordatum* zone (*Bukowskii* or *Costicardia* subzone) of the Lower Oxfordian. As the upper part of the *Cordatum* zone (*Cordatum* subzone) is at least 4.8 m thick[1], the upper band must also belong to the *Cordatum* zone. The upper two mudstone bands are therefore referred to as the lower and upper *cordatum* bands, respectively.

Petrographical examination of the shale samples has revealed the presence of minor amounts of pyroclastic material, as discussed below. More striking evidence of volcanic ash-fall is, however, provided by the mudstone bands. These are internally structureless apart from mottling due to burrows. They shrink and break into small angular fragments on drying at room temperature and on subsequent immersion in water they rapidly swell and disintegrate to a flocculent mass of clay and a residue of fine particulate material. The residual particles consist largely of irregular grains composed of isotropic material, chlorite or calcite. Thin sections reveal a poorly defined normal grading of these grains, some of which display elliptical structures similar to amygdales in basic volcanic glass. Accessory grains include euhedral or fractured-euhedral prismatic apatite crystals and fresh euhedral or angular-anhedral flakes of biotite. By contrast the associated shales contain a typical detrital assemblage of abundant quartz, with minor feldspar, muscovite, chlorite and biotite.

X-ray diffraction analysis shows the clay fraction to consist of pure montmorillonite in the lower *cordatum* band and montmorillonite and kaolinite in the *athleta* band. The clay fractions of the associated shales in both cases consist principally of mixed-layer montmorillonite–illite and kaolinite.

In their physical properties and mineral composition these mudstones are comparable with some of the well-documented American bentonites[5], and there can be little doubt that the mudstones represent tuffs which have undergone diagenetic alteration to bentonitic clays. The absence of quartz and zircon in the residues suggests that the tuffs were not acidic and the absence of attenuated shard structure in the glass particles also implies a basic or intermediate composition. The presence of biotite indicates that the source lavas were at least in part of andesitic or trachytic type. Feldspars are absent in both of the mudstone bands but it is probable that scattered patches of coarsely crystalline calcite represent the replacement of primary feldspar crystals.

Undoubted volcanic material (altered glass particles and euhedral apatite crystals) also occurs in minor amounts in otherwise 'normal' detrital shale samples from the *Coronatum*, *Athleta*, *Lamberti*, *Mariae* and *Pseudocordatum* zones (the *Plicatilis*, *Transversarium* and *Cautisnigrae* zones were not sampled). Altered glass particles also seem to be present in the *Baylei* and *Cymodoce* zones of the Lower Kimmeridgian, although they are too finely grained to display diagnostic amygdaloidal textures. No volcanic constituents have been recognised in samples of the *Mutabilis* zone of the Kimmeridgian or of the *Jason* zone of the Middle Callovian.

Microscopic examination of Bajocian and Bathonian shales collected in the same area has not revealed any recognisable volcanic components, although the abundance of montmorillonite in some beds is suggestive of a volcanic contribution[6]. Thus although volcanism may have contributed finely divided ash to the Middle Jurassic sediments, it would appear that a phase of stronger volcanic influence started in the Middle Callovian and lasted at least until the Lower Kimmeridgian. Phases of maximum activity during the Upper Callovian and Oxfordian are indicated by the altered tuff bands.

Jurassic volcanicity in the continental shelf area around Britain is now well established with the discovery of lavas and tuffs in Middle Jurassic beds of the Piper–Forties area of the North Sea[7]. These volcanics are dated as Bathonian and Bajocian. Another volcanic centre or centres to the south-west of Britain may have been the source of volcanic components of the Bathonian Fuller's Earth of the Bristol district[8], and perhaps also of the montmorillonite bands in the Bathonian of the East Midlands[6]. Upper Jurassic (?Kimmeridgian) tuffs have been recorded from the Brent area of the North Sea[7], and a possible tuff reported in the Kimmeridgian beds of Andøy, Norway[9].

If its inferred Jurasic age is correct, the Piper–Forties volcanic centre cannot have been the source of the Upper Jurassic pyroclastic deposits of Skye, although it is possible that the North Sea eruptions are represented in Skye by the high proportion of montmorillonite in Middle Jurassic beds (ranging from the Dun Caan Shales, Bajocian (Aalenian), *Ludwigia murchisonae* zone to the Ostracod Shales, ?Lower Bathonian).

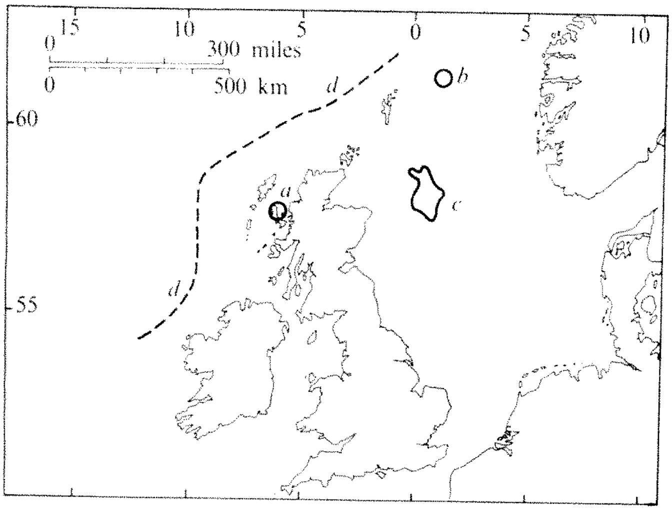

Fig. 1 Location of Upper Jurassic tuffs in Skye (*a*) and in the Brent area of the North Sea (*b*). The Piper–Forties volcanic centre (*c*) is essentially of Middle Jurassic age and Upper Jurassic volcanism may have occurred in a zone of potential rifting (*d*) to the west and north of Britain.

A possible alternative source area for the Upper Jurassic tuffs is the zone now represented by the series of NE–SW troughs[10] which follow the present-day shelf margin to the west and north of Scotland. The closest of these, the Rockall Trough, may not have developed until Cretaceous times but a period of initial rifting and volcanism may have begun as early as the Middle Jurassic[11]. With the limited information at present available it seems most likely that the volcanic source for the Skye and perhaps Brent tuffs lay within this zone of potential late Jurassic rifting (Fig. 1).

An unusual electromagnetic surface force

IN a recent experiment[1] a disk of high dielectric constant material (barium titanate) was suspended as a torsional pendulum in an intense axial magnetic field. It was found that if a radial electric field was applied to the disk in time quadrature with the magnetic field a substantial torque was produced which, to within experimental accuracy ($<5\%$), was in agreement with a force density $\dot{\mathbf{P}} \times \mu_0 \mathbf{H}$ in the disk. The surprising feature of the torque was that it had a time average, contradicting the 'Abraham force' which predicts a force density of $\partial(\mathbf{P} \times \mu_0 \mathbf{H})/\partial t$ with zero time average. The experiment seemed to suggest that the quantity $\dot{\mathbf{P}} \times \mu_0 \mathbf{H}$ does not produce a force since its time average would be equal but of opposite sign to the time average of $\mathbf{P} \times \mu_0 \dot{\mathbf{H}}$.

In order to obtain a high electric field strength in the dielectric a thin metal coating was evaporated on to the outside edge of the disk and the edge of the central hole. The electrical resistance of these coatings was sufficiently high so that induced currents due to the time-varying magnetic field had a negligible effect on the total electric and magnetic fields. As a check, cuts were made in the coatings, thereby preventing any circulating current flow, with no observable change in the behaviour of the system.

On further investigation it seems that the metal coatings have a most unexpected effect, as may be seen from the following argument. Suppose that air gaps are created between the coatings and the dielectric surfaces, the gaps being small enough to cause no significant perturbation of the electromagnetic fields. Three mathematical closed surfaces can be described, one just outside and surrounding the dielectric and the other two just outside and surrounding the metal coatings. The moment of the electromagnetic surface stress for each surface can be obtained from the Maxwell tensor by evaluating the integral

$$\int \mathbf{r} \times [\varepsilon_0 \mathbf{E}\,(\mathbf{E}.\mathbf{n}) + \mu_0 \mathbf{H}\,(\mathbf{H}.\mathbf{n}) - \tfrac{1}{2}(\varepsilon_0 \mathbf{E}^2 + \mu_0 \mathbf{H}^2)\,\mathbf{n}]\,\mathrm{d}S$$

For the surface enclosing the dielectric it may be shown that this has zero time average but for the surfaces enclosing the metal coatings the moment reduces to $\int \mathbf{r}(\varepsilon_0 E_r) E_\theta \mathrm{d}S$ where the latter is taken over the parts of the mathematical surfaces in the air gaps. When this is evaluated the measured value of torque results. The interpretation is that an electrical charge of density $\varepsilon_{0r} E$ is induced on the surface of the coating adjacent to the dielectric and a drag action is exerted on this surface charge by the azimuthal electric field component E_θ.

In light of this, the experiment verifies that the total mechanical force on the dielectric has no time average, as is consistent with the Abraham force. That the term $\mathbf{P} \times \mu_0 \dot{\mathbf{H}}$ produces a force can be understood by considering the Kelvin force $(\mathbf{P}.\nabla)\mathbf{E}$ which may be written $\frac{1}{2}(\varepsilon - \varepsilon_0)\nabla \mathbf{E}^2 + \mathbf{P} \times \mu_0 \dot{\mathbf{H}}$. In the above experiment $\mathbf{E}$ is independent of θ and so $\nabla \mathbf{E}^2$ does not contribute to the torque. A further conclusion to be drawn is that the experiment is consistent with a force density in the dielectric given by $\dot{\mathbf{P}} \times \mu_0 \mathbf{H} + (\mathbf{P}.\nabla)\mathbf{E}$ provided $\mathbf{E}$ is the macroscopic internal field and not a 'local' field as proposed in different forms by a number of authors.

Insect growth regulator and sterile males for suppression of horn flies

A RECENT trend in the control of insects has been the development of pest management systems whereby combinations of control methods, applied to one or more stages of the life cycle, increase efficiency and optimise effectiveness of individual methods. The potential of an integrated programme involving the release of sterile insects in combination with other control methods was discussed by Knipling[1]. He pointed out that two properly chosen and implemented systems might be regarded as synergistic in effect. Kunz and Eschle[2] have proposed an integrated programme against the horn fly, *Haemotobia irritans* (L.), and they have suppressed the reproduction of a semi-isolated population 98% by releasing sterilised horn flies[3]. In the spring of 1973, we began a pilot test on the island of Molokai, Hawaii. The objective was to develop a control system whereby a natural population of horn flies could be suppressed by chemical means and then eradicated through the release of sterile flies.

Harris *et al.*[4] have demonstrated that the development of horn flies is inhibited in the faeces of cattle fed methoprene (isopropyl (*E*,*E*)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate), an insect growth regulator (IGR). Because methoprene would affect only the reproduction of the native population, it could be used simultaneously with releases of sterile insects. In a preliminary experiment on the Kalaupapa peninsula of Molokai, continuous treatment of the drinking water of cattle with methoprene for 6 weeks reduced the estimated number of horn flies from 360 to seven per animal[5].

We report here the elimination of a wild population of horn flies through the simultaneous application of the IGR and the release of sterile males. The experiment was begun March 1975 on Puu-O-Hoku Ranch (POH), a 3,000-acre ranch with improved pasture and about 900 cattle (cows and calves), primarily Charolais and some Hereford.

POH is at the extreme eastern end of Molokai. The north-easterly trade wind, prevalent throughout the year in Hawaii, has a mean flow of 20 knots at POH and through the Pailolo channel that separates Molokai from Maui; it blows an average 90% of the time during April to September[6]. Theoretically, the test site was thus afforded some degree of protection from reinfestation by horn flies moving from cattle on other parts of Molokai and also on the island of Maui 9 miles to the south-east. When we released about 1.5×10^6 marked horn flies on the west end of Maui, none were recovered from cattle on Molokai. The only movement of marked flies observed when releases were made on Molokai was from east to west and from north-east to south-west.

The experiment was conducted on the north-eastern section of POH only (about 750 cattle) so that all other cattle on Molokai were downwind from the test area. South-west POH was not included because the pastures there contained streams which were impractical to treat with the IGR.

Methoprene was added to the drinking water of the test cattle as a tablet formulation. An automatic dispensing system[7] was attached to the outlet of the float-controlled valves of each water trough. Thus, the water was maintained with a concentration of 0.05–0.1 p.p.m. of methoprene, a level in the drinking water adequate to inhibit development of the horn fly in the manure of treated cattle[7]. Levels of methoprene in water samples from selected troughs were determined by gas chromatography. Effectiveness of treatments was confirmed by a bioassay in which samples of field-collected manure were seeded with horn fly eggs.

The sterile horn flies were provided from two colonies, one at Kerrville and another in Hawaii on the island of Oahu[8]. Chilled adult flies were sterilised with 2,500 rad (^{137}Cs source in Kerrville and ^{60}Co in Hawaii),

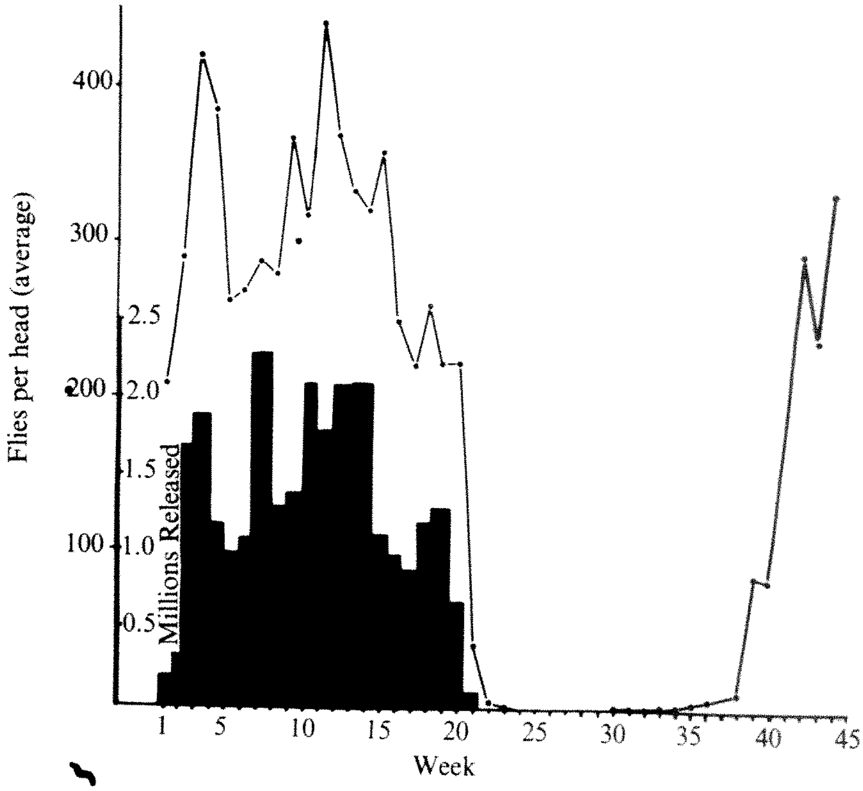

Fig. 1 Numbers of sterile horn flies released per week (bar graph) and estimated numbers of adult horn flies per head of cattle (line graph) on Puu-O-Hoku Ranch (March 17, 1975 to January 18, 1976).

marked with a fluorescent pigment, and placed in perforated paper bags. The bags were sealed in insulated containers and shipped by air to Molokai (in transit about 30 h from Kerrville and 16 h from Oahu). During shipment the flies were maintained in a chilled state by frozen eutectic material; O_2 was provided to sustain the lower metabolism, and an absorbent was used to avoid accumulation of CO_2.

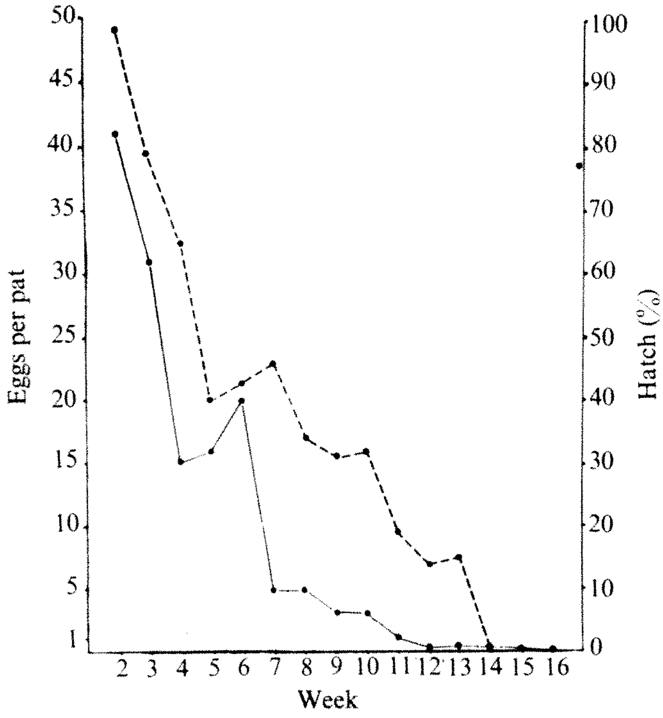
Sterile flies were released daily in the vicinity of cattle. Although released flies were marked, we could not consistently obtain samples of adult flies from test cattle to determine the ratio of released to native flies. Therefore, the frequency and rate of release in each pasture were determined by the number of flies available, the need for sterile flies as indicated by the current sterility of eggs sampled from the pasture, and the estimated number of adult horn flies on the cattle. From the volume (ml) of dead flies that remained 24 h after release, we estimated that more than 80% of the sterilised flies escaped from the release boxes.

The combined effect of the IGR and release of sterile flies were assessed from estimates of numbers of adult horn flies per animal and from numbers and fertility of horn fly eggs collected from manure pats in test pastures[3].

Methoprene treatment began on March 13–14, and release of sterile flies 1 week later (week 1). For the first 14 weeks of the experiment an average of 1.6×10^6 sterile flies per week were released. The population of adult flies (Fig. 1) averaged 300 per animal for weeks 1 to 14. But a steady decline in numbers and fertility of eggs, from an average 41 eggs per pat and 98% hatch during week 2 to 0.4 eggs per pat and complete sterility during week 14, indicated a decline in the population of native horn flies (Fig. 2). Therefore, we reduced the number of sterile flies released by about half (an average of slightly more than 800,000 per week). Beginning on week 16, no horn fly eggs were found on any of the pats in spite of intensified examinations; this indicated that the native population had been eliminated.

Release of sterile flies in the test pastures was discontinued after week 21. To prevent reinfestation, however, we released the bulk of sterile flies on cattle in south-west POH and made periodic, low-level releases in a buffer zone (pastures on the south-west border of the test area). Three weeks after the last release and for the next 6 weeks no adult horn flies were found on the cattle nor eggs in the manure. Meanwhile we continued to find a few, mostly sterile, eggs in the buffer zone, an indication that releases there were effective. Nevertheless, reinfestation occurred during week 30 when cattle from south-west POH were moved into the test area without our knowledge. By week 39, native populations had become re-established.

Fig. 2 Effect of combined use of methoprene and the sterile-male technique on production and fertility of eggs from horn flies on Puu-O-Hoku Ranch (March 24 to July 6, 1975). ——, Eggs per pat; – – –, per cent hatched.



All treatments were discontinued on POH during week 39. At that time we were devoting more attention to treatments in the buffer zone, and on south-west POH and other ports of Molokai. Thus we were unable to maintain the methoprene treatments as carefully as during the initial weeks of the experiment. The concentration of methoprene in water samples was found to be inadequate (<0.05 p.p.m.) in five of six troughs sampled in the test area during week 39. The population of adult horn flies had increased to an average 333 per animal by week 44 (Fig. 1).

The experiment demonstrated that methoprene in combination with releases of sterile males can be used to eliminate a native population of horn flies. Furthermore, the results suggested a strategy that could be used to implement a suppression–eradication programme involving a larger area such as the entire island of Molokai and, ultimately, the entire state of Hawaii. The control system could be used in a stepwise sweep from one end of the island to the other; the sweep would be planned so as to take advantage of natural isolating factors such as wind and geographical characteristics. A major advantage of such a strategy is that the size of the control area in each step could be controlled conveniently to fit the available personnel and mass rearing capabilities.

Implementation of the system on a large scale would require further refinements in rearing methods, the registration of methoprene for use in drinking water of cattle, and an understanding of the economic benefits.

Y chromosome controls mating behaviour on *Anopheles* mosquitoes

SEVERAL species of *Culex* and *Anopheles* mosquitoes differ in their ability to breed in a relatively small space under laboratory conditions. When paired matings or mass rearings are carried out in small laboratory cages, males of some species are able to copulate while those of others are not. These characteristics have been named respectively stenogamy and eurygamy and reflect the field requirement for a small or a large space to perform the pre-copulative

Table 1 Results of paired matings between *Anopheles atroparvus* × *Anopheles labranchiae* hybrids with different sex chromosome combinations

A. a. = *Anopheles atroparvus*; *A. l.* = *Anopheles labranchiae*. The subscripts *a* and *l* under X and Y indicate their origin from *A. a.* and *A. l.* respectively. The *A. a.* strain has been reared in the laboratory for 20 yr. The *A. l.* mosquitoes were captured in the North of Sardinia as 3rd or 4th instar larvae. All crosses were performed in 20-cm cubic cages kept at room temperature of 25–28 °C, with humidity of 80–90%, in an undarkened room. Crosses were made by paired mating, using males at least 5 d old and females to which one or two blood meals had been given. Mass rearing was performed in the same type of cages with the number of mosquitoes given in parentheses: cross 5 (58 ♂ × 21 ♀); cross 7 (80 ♂ × 40 ♀); cross 11 (7 ♂ × 5♀); cross 12 (50 ♂ × 25 ♀); cross 14 (257 ♂ × 126 ♀); cross 15 (23 ♂ × 18 ♀); cross 18 (5 ♂ × 3 ♀).

*Artificial insemination.

‡ Only one female offspring was reared from this cross.

§Mass rearing resulted sterile.

¶Mass rearing resulted fertile.

flight[1]: in stenogamous species the male performs an almost stationary flight with short, quick movements followed by mating with the female which remains motionless on a wall; conversely, the males of eurigamous species form small swarms of several individuals into or near which the females fly and copulation takes place in flight. These behavioural characteristics are inherited and, although the dominance of stenogamy over eurygamy has been suggested[2–5], previous data are inconclusive mainly because of the lack of informative F_2 and backcross experiments[5]. In fact, in *Anopheles*, though all types of F_1 hybrid females are fertile when backcrossed to the parental species, the F_1 hybrid males are usually sterile[5].

To investigate the genetic control of the eurygamy/stenogamy polymorphism we did a series of crosses between the sibling species of the genus *Anopheles*, *A. labranchiae*, which is eurygamous and *A. atroparvus* which is stenogamous, using artificial insemination[6] whenever the male was unable to copulate because of its stenogamous behaviour. For comparison we also performed a number of mass rearings. We found that the polymorphism is controlled by the Y chromosome

The results of our crosses are shown in Table 1, in which the basic character taken into consideration is stenogamy in the male parent. These experiments first confirmed the sterility of all males which are hybrids for the sex chromosomes irrespective of their autosomal constitution; this is obvious from crosses 4, 5 and 15. Whenever the sex chromosomes belong to the same species, the male is fertile, as seen from crosses 6, 9, 10, 13. 16 and 18. Furthermore, when segregation for the X chromosomes of the two species is expected in the male progeny and these males are crossed, a corresponding 1 : 1 ratio of sterile and fertile paired matings is found, as in crosses 7, 8, 11, 12, 17 and 19. We made histological and meiotic studies of the sterile males and found that the sterility is due to arrest of spermatogenesis before first meiotic metaphase.

Whenever the male carries the Y chromosome of *A. atroparvus* the mating behaviour is stenogamous and copulation takes place spontaneously in cages, as shown by crosses 1, 3, 4, 5, 6, 7, 8, 9, 13, 16 and 17. Conversely, all males with the Y chromosome of *A. labranchiae* are eurygamous (see crosses 2, 10, 11, 12, 14, 15, 18 and 19) and artificial insemination was necessary for their reproduction.

Reproductive success of the male is therefore controlled on the one hand by the Y chromosome which determines mating behaviour and on the other by testicular fertility which is determined by the constitution of the XY pair, as exemplified in Table 2.

Table 2 Sex chromosome constitution controls testicular fertility and pre-copulative flight behaviour in *A. atroparvus* (*a*) × *A. labranchiae* (*l*) *hybrids*

	Testicular sterility	Testicular fertility
Eurygamy	X_aY_l	X_lY_l
Stenogamy	X_lY_a	X_aY_a

In conclusion, the behavioural polymorphism stenogamy–eurygamy is obviously controlled by one or more genes located on the Y chromosome. To our knowledge this is the first example of direct chromosomal control of a behavioural characteristic involved in reproduction.

Cadmium tolerance in populations of *Agrostis tenuis* and *Festuca ovina*

IT is well known that plant populations growing on soils contaminated with heavy metals are genetically tolerant to those metals. This adaptation is not found in populations growing on normal soils (ref. 1 and review in ref. 2). Most of the literature is concerned with the resistance of plants to Pb, Zn and Cu[3–8], but Cd salts too are often present in the soils of areas polluted by those metals. I have therefore investigated the occurence of Cd tolerance in some Belgian and German populations of *Agrostis tenuis* Sibth. and *Festuca ovina* L. *sensu lato*.

Population samples of at least 25 individuals of *A. tenuis* and *F. ovina* were collected from sites contaminated with heavy metals and from normal sites, and transplanted for 2 yr in an experimental garden. Populations are described in Table 1. Soil samples corresponding to each population were analysed in three ways. (1) Total heavy metals were measured by extraction with concentrated nitric acid at 25 °C (10-g soil sample, dried at 105 °C with 25 ml of HNO_3 for 48 h). (2) Exchangeable cations were measured by extraction with 1 M NH_4COOH at *p*H 7. (3) Water-soluble elements were measured by extraction in distilled water at 25 °C (10-g soil sample, dried at 105 °C, shaken, in 25 ml of H_2O for 48 h). Plant samples (aerial green parts) collected at random in the different localities were dried at 105 °C and reduced to powder. Samples of 1 g of powder were digested with a mixture of nitric and perchloric acids. After filtration the samples were analysed by atomic absorption for Cd, Zn and Pb.

Table 1 Localities and plant populations with their characteristics

Localities	Description of localities	Species collected and transplanted
Belgium, Plombières	Old Pb and Zn mine in eastern part of Province de Liège; soil very rich in Pb and Zn in form of ore and blast furnace scorias; vegetation consists of turf of *F. ovina*, *Armeria maritima*, *Viola calaminaria*; soil *p*H 6.0–6.5	*Festuca ovina* and *Agrostis tenuis*
Belgium, Prayon	Industrial area near Liège characterised by aerial pollution consisting of Zn, Pb, Cd and SO_2; old soils colonised only by *A. tenuis* and *Thlaspi coerulescens* ssp. *calaminare*; soil *p*H 4.5–5.5	*Agrostis tenuis*
Belgium, Trazegnies	Uncontaminated area near Charleroi; soil *p*H 6.0–6.5	*Agrostis tenuis*
Belgium, Frasneslez-Couvin	Uncontaminated area in Province de Namur; turf with *F. ovina* and *Bromus erectus*; calcareous soil	*Festuca ovina*
Germany, Breinig	Near Aachen; calcareous hills with Zn and Pb ore; turf rich in *F. ovina*, *Bromus erectus*, *Armeria maritima*, *Viola calaminaria*, etc.	*Festuca ovina*
Germany, Mausbach	Near Aachen; sandy artificial hill formed by accumulation of the tailings of Zn and Pb ores; vegetation includes *Molinia coerulea*, *F. ovina* and *Armeria maritima*	*Festuca ovina*
Germany, Strempt	Near Aachen; sandy artificial wastes formed by accumulation of tailings of Zn and Pb ores; vegetation includes mainly *F. ovina* and *A. tenuis*	*Festuca ovina*

Figures are given in mg per kg of dried soil at 105 °C; means of 20 samples.

Heavy metal tolerance was determined by Wilkins's method, based on comparative root growth in toxic and non-toxic solutions. In each population 25 individual tillers were rooted in distilled water and the longest root of each was measured. The rooted tillers were then transferred to heavy metal solutions at different concentrations; a test sample was maintained in distilled water. After 5 d the longest root was measured again. The ratio

$$100\times\frac{\text{length of the longest root in toxic solution}}{\text{length of the longest root in non-toxic solution}}$$

is known as 'the tolerance index' of the population for a given metal at a specific concentration. The same procedure was used to study the effects of soil nutrients (Ca, Mg, K and Na added as sulphate or nitrate) on the tolerance level of plant populations.

In the samples from normal areas, we found small amounts of total Cd (1.0 mg kg^{-1} from Frasnes and 0.85 mg kg^{-1} from Trazegnies). No exchangeable or soluble Cd was found. In the contaminated soils (Table 2) Cd reached high levels, being greatest in soils from Breinig (calcareous), but the mobility of the metal was much higher in the acid soils of Plombières. Smaller amounts of Cd were found in soils from Prayon. Soils from Strempt (Germany) were rich in Zn and Pb but no significant quantity of Cd was found.

Ernst[10] considers that the amount of exchangeable metal is the maximum available to plants and that the soluble

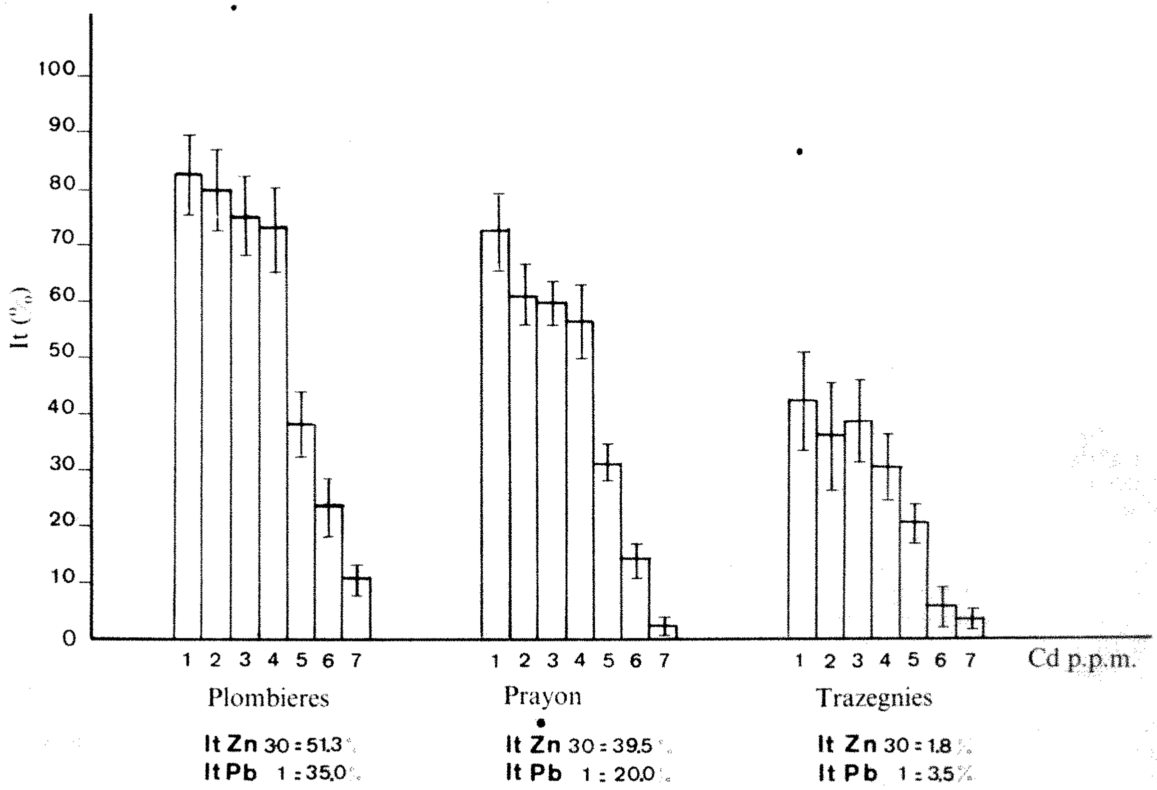

Fig. 1 Cd tolerance in *A. tenuis* populations at different concentrations of Cd. Plombières and Prayon are the contaminated areas. Trazegnies is the test population. Tolerance indices are given as percentages with standard errors. 1–7, Cd concentrations in the culture solutions: 1, 0.25 p.p.m.; 2, 0.50 p.p.m.; 3, 0.75 p.p.m.; 4, 1.00 p.p.m.; 5, 1.50 p.p.m.; 6, 2.00 p.p.m.; 7, 2.50 p.p.m. It Zn 30 is the tolerance index to Zn for the population grown on a solution with 30 p.p.m. of Zn. It Pb 1 is the tolerance index to Pb for the population grown on a solution with 1 p.p.m. of Pb.

fraction is the minimum available. Amounts of soluble Cd were very low compared with Zn (Table 2). My results for *A. tenuis, F. ovina* and some dicotyledons from Plombières and Breinig are shown in Table 3, together with values for Zn and Pb. Cd values were higher for dicotyledons than for monocotyledons. *F. ovina* from Breinig (calcareous soil) contained more Cd than did the population from Plombières. The opposite pattern was found for Zn and Pb. This relates to the differential mobility of metals in relation to edaphic conditions.

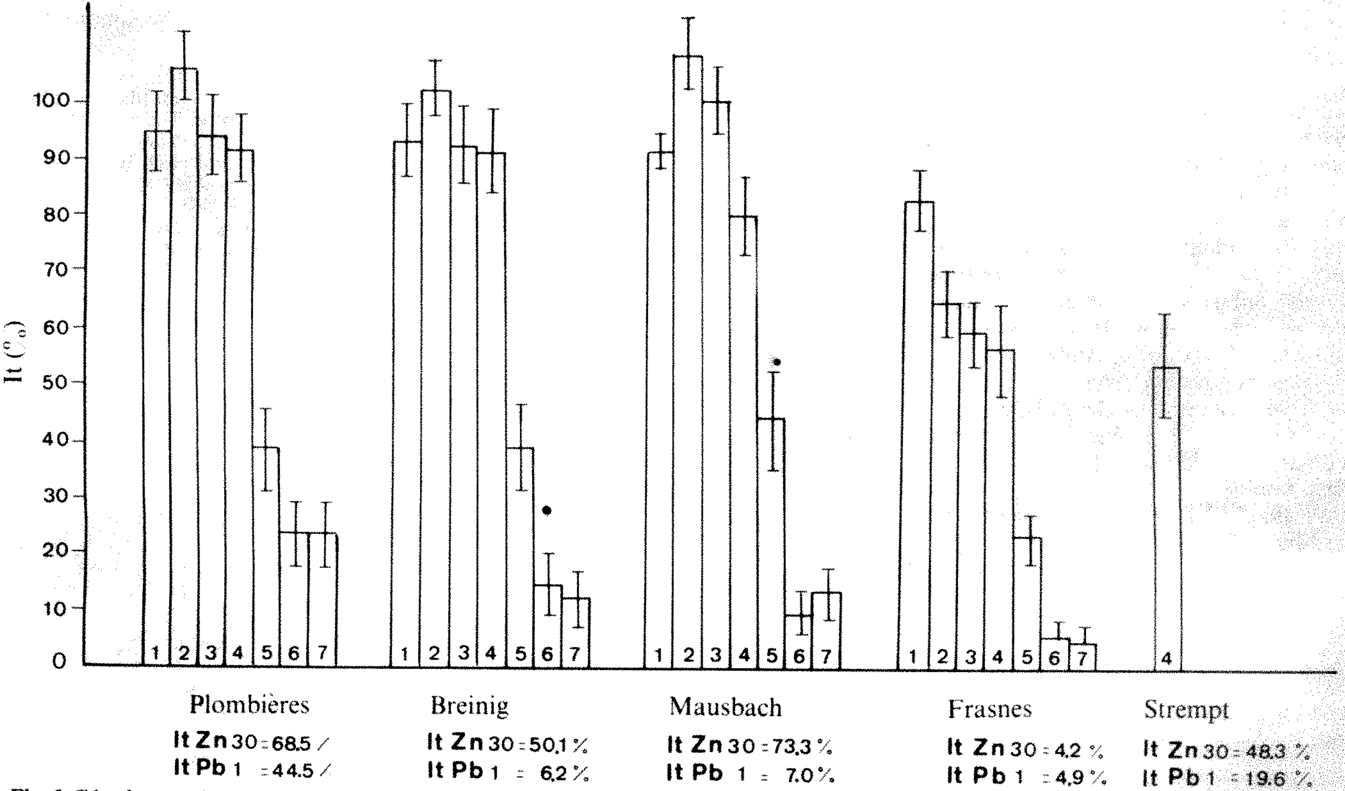

Fig. 2 Cd tolerance in populations of *F. ovina* at different concentrations of Cd. Plombières, Breinig and Mausbach are populations from contaminated areas. Frasnes and Strempt are the test population but Strempt is an area contaminated with Zn and Pb. The tolerance indices are given as percentages with standard errors. 1–7 are Cd concentrations in the culture solutions. 1, 0.25 p.p.m.; 2, 0.50 p.p.m.; 3, 0.75 p.p.m.; 4, 1.00 p.p.m.; 5, 1.50 p.p.m.; 6, 2.00 p.p.m.; 7, 2.50 p.p.m. It Zn 30 is the tolerance index to Zn for the population grown on a solution with 30 p.p.m. of Zn. Table 4 Effect of some soil nutrients on the toxicity of Cd

Species	Populations	Cd 1 p.p.m.	Cd 1 p.p.m. +Ca 5×10⁻⁴ M	Cd 1 p.p.m. +Mg 5×10⁻⁴ M	Cd 1 p.p.m. +K 5×10⁻⁴ M	Cd 1 p.p.m. +Na 5×10⁻⁴ M
	Plombières	83.2 ± 6.9	97.8 ± 6.3	84.1 ± 6.9	118.6 ± 9.5	85.2 ± 6.6
A. tenuis	Prayon	62.3 ± 6.0	99.2 ± 6.2	70.6 ± 6.2	85.3 ± 9.6	58.2 ± 4.3
	Trazegnies	41.4 ± 6.1	106.6 ± 9.0	92.8 ± 9.2	96.3 ± 7.3	70.9 ± 6.3
	Plombières	90.4 ± 5.3	96.5 ± 6.4	89.5 ± 6.3	99.4 ± 7.0	86.4 ± 6.0
F. ovina	Breinig	89.7 ± 6.0	98.4 ± 6.0	91.4 ± 6.5	88.6 ± 6.8	87.5 ± 5.5
	Frasnes	56.5 ± 6.0	85.5 ± 5.7	89.7 ± 8.0	88.0 ± 6.7	60.2 ± 5.0

Tolerance indices are reported in % with standard errors. Plombières, Prayon and Breinig are the contaminated areas. Trazegnies and Frasnes-lez-Couvin are normal areas.

I next tested for Cd tolerance in populations of *A. tenuis* and *F. ovina* from the contaminated areas of Plombières, Prayon, Breinig, Mausbach and Strempt. As Figs 1 and 2 show, the populations of the contaminated areas were more tolerant than those from normal areas. Tolerance indices were very high for *A. tenuis* from Plombières and Prayon, but much lower for this species from the normal soil of Trazegnies. *A. Tenuis* populations from Plombières and Prayon are therefore genetically adapted to Cd toxicity. With *F. ovina*, high tolerance indices were found for the populations from Plombières, Breinig and Mausbach compared, with those for the population from the normal soil of Frasnes.

Thus my work on transplanted populations shows that Cd tolerance has a genetic basis. The population of Strempt was not tolerant to Cd even though it was tolerant to Zn and Pb (Fig. 2). In *A. tenuis* and *F. ovina* populations, however, a decrease in the tolerance index was generally observed at 1.50 p.p.m. Cd. At 2.50 p.p.m. (except the population from Plombières) the plants stopped growing. In addition, in Plombières *A. tenuis* was always less tolerant than *F. ovina* to the three heavy metals tested.

The effects of some soil nutrients were studied. *A. tenuis* and *F. ovina* populations from contaminated and normal soils were grown in a solution containing Cd $(NO_3)_2$ (1 p.p.m.) and different soil nutrients $Ca(NO_3)_2$, $MgSO_4$, K_2SO_4 and Na_2SO_4 each at 5×10^{-4} M. Table 4 shows that the addition of Ca, Mg or K to the Cd solution restored normal growth to the populations of both species, even when they had been collected from normal soils. Na did not reduce the toxicity of Cd. This effect has been observed for the same populations grown on Zn and Pb solutions[8].

Cd has high mobility and is available to plants. In acidic soils solubilisation makes this availability greater than in basic soils. Plants from soils rich in Cd are genetically more tolerant to Cd than plants from normal soils. The significant differences in tolerance indexes between *F. ovira* and *A. tenuis* show that tolerance to Cd is a specific character. Apparently, cotolerance does not occur, for the *F. ovina* population from Strempt was not tolerant to Cd but it was tolerant to Zn and Pb.

Cd tolerance is probably not restricted to a few species of Poaceae and it would be interesting to test species from other families.

We thank Professor P. Duvigneaud and Professor A. D. Bradshaw for advice and criticism. I am a fellow of the Institut pour l'Encouragement de la Recherche Scientifique dans l'Industrie et l'Agriculture.

Self-thinning driven by leaf area not by weight

THE self-thinning rule is perhaps the most widely applicable principle in plant population dynamics. White[1] has shown that it applies to more than 70 species ranging from herbs to trees, in many nutrient conditions. The rule states that $W=Kp^{-3/2}$, where W is average plant weight, p is the density of plants, and K is a constant. In other words when the log of average weight is plotted against the log of average density for a crowded even-aged plant population, numbers must be lost as the individuals gain weight in such a way that the population's trajectory is held under a line of slope $-3/2$.

Why the slope should be $-3/2$ has been unclear. The dimensional explanation has been put forward[2] that the weight of a plant increases as the cube of a size dimension, while the area occupied by it increases as the square of a

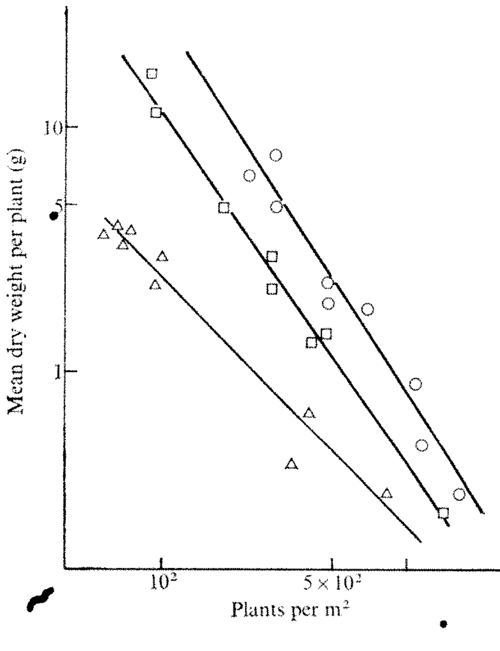

Fig. 1 Changes in density (p) and mean individual plant weight (W) of *Helianthus annuus* populations with time. The populations were grown at 100% (○), 60% (□) and 23% (△) light intensity. Data from starting densities of 1,600 and 400 plants per m^{-2} are combined. Thinning lines shown are for 100% light log $W = 3.84–1.33 \log p$, for 60% light $\log W = 3.53-1.30 \log p$, and for 23% light $\log W = 2.50-1.08 \log p$. After White and Harper[2], from data of Hiroi and Monsi[4].

size dimension. But this reasoning does not explain the only significant exception to the −3/2 slope which has been found, which is that the slope is flatter under deep shade[2,3]. This contribution shows that plants in low light develop more leaf area per unit weight, and that populations in both low and high light thin along the same slope in relation to leaf area.

I have found data where light levels were varied in studies both on self-thinning, and on the relation of leaf area to plant weight, only for *Helianthus annuus*. Self-thinning was studied by Hiroi and Monsi[4] and analysed by White and Harper[2]. The flattening of the slope of self-thinning at low light intensity is shown in Fig. 1. Blackman and Wilson[5] documented leaf area–plant weight relationships in different light intensities. Figure 2 shows that while leaf area per unit plant weight is constant at any one light level, it is greater in shade than in full light.

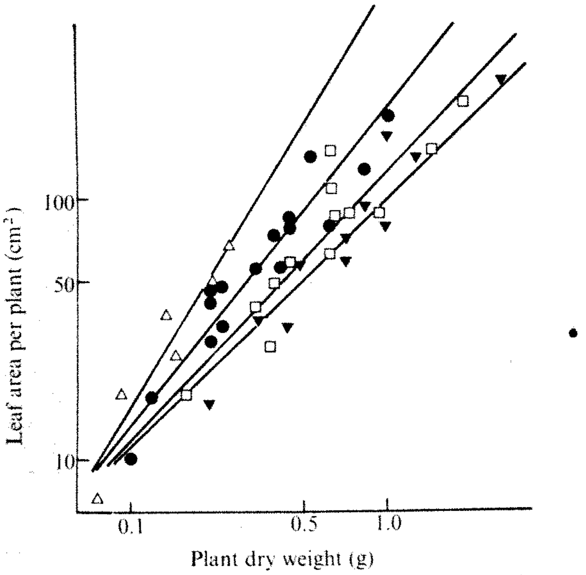

Fig. 2 Relation of leaf area per plant in cm² (L) to individual plant weight in g (W) at different light levels for *Helianthus annuus*, from data of Blackman and Wilson[5]. Data for six experiments are combined. Light intensities were 100% (▼), 50% (□), 24% (●) and 12% (△) of full daylight. Best fit equations are, for 100% light, $\log L = 2.01 + 0.98 \log W$, for 50% light $\log L = 2.11 + 1.05 \log W$, for 24% light $\log L = 2.36 + 1.24 \log W$, and for 12% light $\log L = 2.83 + 1.63 \log W$. All equations have r^2 greater than 0.9. Where there were identical data points only one, from the lowest light level, is shown here, but all were used in calculating equations.

Both the flatter thinning slope, and the higher leaf area per unit weight, under low light, are common to all plant species studied[3,5,6], though *H. annuus* seems to be the only species for which both are documented.

The equations of Fig. 2 can be used to transform the data of Fig. 1 from a plot of weight against numbers to a plot of leaf area against numbers (Fig. 3). This completely removes the anomalous behaviour of the system at low light intensities. Thus it seems that the self-thinning rule in its most general form is $L = Kp^{-3/2}$.

Now the behaviour of plant populations while self-thinning is characterised (1) by the −3/2 slope just shown to be general if leaf area rather than weight is used as abscissa, (2) by the constant K, and (3) by the speed with which the population moves along the trajectory defined by $L = Kp^{-3/2}$, and the place where it stops. Formulating the self-thinning rule in terms of leaf area allows some further deductions on the third of these points. Since Lp is equal to the leaf area index (LAI) or area of leaf per unit ground area we can write $\mathrm{LAI} = Kp^{-1/2}$. Thus we can relate the relative mortality rate $(-(\mathrm{d}p/\mathrm{d}t)/p)$ of plants to the relative growth rate of the LAI $((\mathrm{dLAI}/\mathrm{d}t)/\mathrm{LAI})$; specifically $(-(\mathrm{d}p/\mathrm{d}t)/p) = 2((\mathrm{dLAI}/\mathrm{d}t)/\mathrm{LAI})$. Thus the time dynamics of mortality are driven by the function relating dLAI/dt to LAI, a relationship which has been studied for several crops. In particular, we expect no further thinning when the canopy reaches maximum LAI[6].

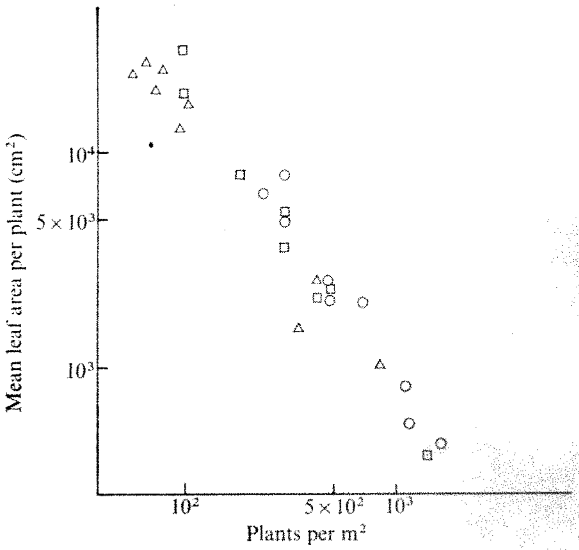

Fig. 3 Data on self-thinning in *Helianthus annuus* of Fig. 1 with average weight per plant transformed into average leaf area per plant using the equations appropriate to each light level from Fig. 2. Symbols for light intensities as in Fig. 1.

It is therefore to be hoped that future work on self-thinning will include measurements of leaf area as well as of weight and numbers of plants. As White and Harper[2] said when formulating the self-thinning rule: "It would be of great theoretical interest and of no little practical significance to determine the parameters of K for even a single species". Perhaps it will prove possible to explain K in terms of those canopy properties which determine optimal and maximum leaf area indices[6].

New structure associated with stomatal complex of the fern *Polypodium vulgare*

THE opening movements of stomata are generally considered to result from the guard cells gaining an osmotic advantage over their immediately adjacent epidermal cells resulting in the uptake of water into the guard cells and their consequent increase in volume. Fujino[1] and Fischer[2] independently proposed that active potassium transport between the guard and epidermal cells could be the mechanism by which the cationic fraction of the osmotic imbalance could be achieved. In recent years many investigators have produced corroborative evidence for this potassium shunt[3] using Macallum's histochemical stain[4]. Further support for the hypothesis has been obtained using electron probe microanalysis[5–8] and potassium-sensitive microelectrodes[9]. Despite these studies, no clear-cut picture has emerged concerning either the reservoirs of the ions at either end of the flux or the intercellular ionic pathway although the findings of Heller *et al.*[10] implicate the vacuole as the ion reservoir within the guard cells as do those of Penny and Bowling[9]. There is no current evidence of where or, indeed, whether, potassium is sequestered after it is shunted out of the guard cells during stomatal closure, but it has been suggested that the differentially thickened cell walls of the stomatal complex could serve as storage sites[11,12]. We have recently discovered some new morphological features in the stomatal complex of the common polypody, *Polypodium vulgare* L., which we believe represent the site of potassium accumulation in this species.

Using the basic Macallum stain[4] and viewing the stained epidermal strip from the side adjacent to the mesophyll under a Zeiss Photomicroscope II, distinct polar accumulations of the ion can be observed in the guard-cell complexes (Fig. 1*a*). The accumulations are commonly up to $25\ \mu m$ in diameter and can extend by as much as $5\ \mu m$ beyond the guard cell walls at the poles (Fig. 1*b*). Associated with the guard cells, and especially with the polar accumulations, are potassium-rich strands that we construe as hollow trabeculae which bridge the common anticlinal walls of the guard and subsidiary cells. The polar accumulations show a distinct bimodal staining pattern which we interpret as indicative of (1) a darker, central circular site of ion adsorption and (2) a paler, bi-lobed osmotically/imbibitionally-induced swelling. This bimodal pattern is ill-defined in many guard-cell complexes because of the dense nature of the underlying chloroplasts but, interestingly, both elements of the polar structures are present in many dead guard cells which show no trace of protoplasts (Fig. 1*c*). Light microscopy studies suggest that the ion-adsorbent sites rest immediately on the outer surface of the guard-cells walls and that the osmotically/imbibitionally-induced sacs are located between the guard-cell walls and the endocuticle (Fig. 2).

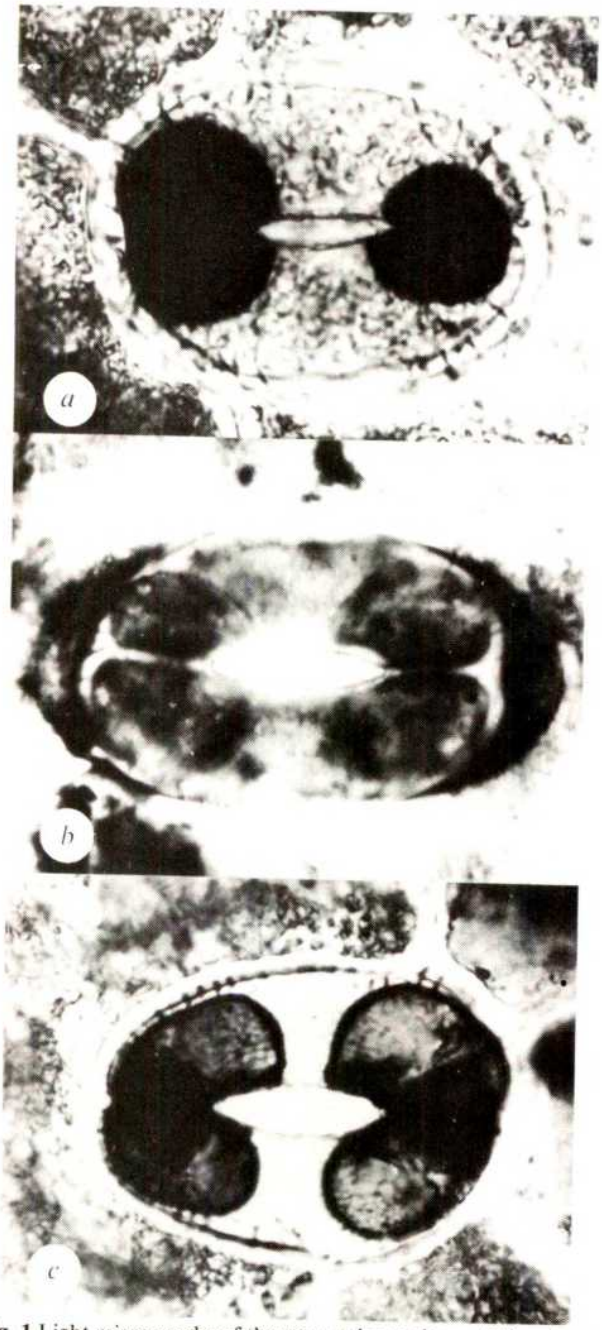

Fig. 1 Light micrographs of the stomatal complexes of *P. vulgare* stained for potassium using the Macallum technique, × 1,130. *a*, Living complex viewed from the side adjacent to the mesophyll demonstrating the polar accumulation of the ion and the ion-rich trabeculae; *b*, living complex viewed from the outer surface demonstrating the polar accumulations subtending and extending beyond the polar cell walls of the guard cell complex; *c*, dead complex viewed from the side adjacent to the mesophyll demonstrating the two elements of the polar structures.

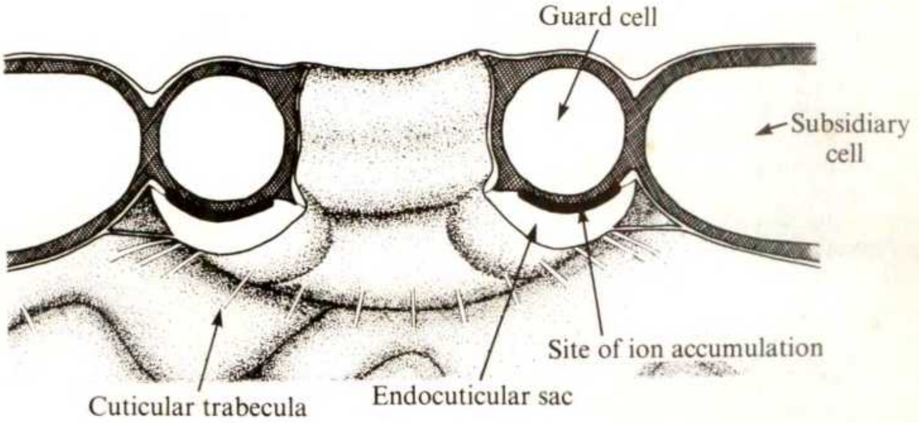
Fresh material examined in an inverted position in the cryo unit of JSM-35 scanning electron microscope clearly shows that the polar accumulations observed with the histochemical stain are compatible with discrete substomatal sacs at the poles of the guard-cell complex and that the trabeculae are formed from extensions of the endocuticle immediately above the common sutures of the guard and subsidiary cells (Fig. 3*a*). The substomatal cuticular swellings are considered to represent the osmotically/imbibitionally-inflated products of the underlying ion-adsorbent sites determined with the histochemical stain. Epidermal strips fixed in 70% ethanol and observed with the scanning electron microscope indicate the collapse of the endocuticle on to the underlying cell walls and what we believe to be the actual ion-adsorbent areas underneath the substomatal sacs (Fig. 3*b*).

Using similar techniques, we have established the presence of substomatal sacs and ion-adsorbent areas in a wide range of filicopsid species but their absence in the psilopsid, lycopsid and sphenopsid pteridophytes we have been able to examine. What seem to be identical structures have also been found in some members of the monocotyledon family Commelinaceae, namely *Tradescantia virginiana*, *T. pallidus*, *Commelina communis*, *Callisia fragrans* and *Palisota barteri* (Fig. 4).

We can find no previous report of substomatal sacs in the literature although 'polar vesicles' were reported in the guard cells of *Casuarina*[13] and analogous structures in the guard cells of *Psilotum*[14]. From these reports and our own studies on *Psilotum nudum*, it is clear that the polar vesicles are formed as a result of the dumb-bell-shaped lumen of the guard cells. Thickened common anticlinal guard-cell walls in *Vaccinium* spp. give rise to the appearance of polar pouches[15] but a re-examination of this structure in *Vaccinium myrtillus* leaves us in little doubt that they are artefacts caused by the subsidiary cells entirely subtending the guard cells except in the polar regions. Differentially thickened common guard cell walls have also been reported by Raju *et al.*[16]. We confirm the existence of these specialised regions and have found them in many of the species we have examined (including *Polypodium vulgare*) but do not believe that they are directly connected with the actual substomatal sacs we report here.

The functional significance of these new structures is difficult to determine at present owing to the subdued responses of fern stomata in general. We have been unable to produce any clear evidence that stomatal movements in *P. vulgare* are anything more than extremely limited in extent although Lange *et al.*[17] elicited responses to certain environmental conditions imposed on isolated epidermal

Fig. 2 Diagrammatic interpretation of a vertical longitudinal section through the polar structure in the guard cell complex of *P. vulgare*. The ion-adsorbent sites are represented by the solid black areas adjacent to the guard cell wall (cross-hatched) with the osmotically/imbibitionally swollen endocuticular sacs lying immediately below.



strips of this species. Meidner[12] records some inconsistencies between potassium content and stomatal aperture in the related fern, *Phyllitis scolopendrium*, a species which exhibits more typical stomatal responses[18]. We have obtained tentative evidence from scanning electron microscopy that the substomatal sacs become slightly smaller under dark conditions when compared with those under light conditions. Fern guard cells generally differ from those of typical angiosperms in having more numerous and larger chloroplasts which means that the vacuolar element of the protoplasts must be greatly reduced in volume. It could be that the substomatal sacs have been developed in *P. vulgare* and allied species to accommodate the accumulation of ions such as potassium in an extracellular position. If this is the case, it is difficult to see how the ions could have the necessary turgor effect on the guard cells required for stomatal movements. More probably, the function of the substomatal sacs is concerned with water conservation since cuticular water loss must be high in ferns because of the poor development of the cuticle in this group of plants. The inner faces of the guard and subsidiary cells are evaporative sites which make a major contribution to the water lost in

stomatal transpiration[19]. The presence of potassium-rich sacs at these evaporative sites could reduce potential transpiration losses by virtue of their low osmotic potential and could also provide the guard-cell complex with a convenient source of cations for incorporation into the complex during stomatal opening.

We gratefully acknowledge the scanning electron microscope facilities made available to us by JEOL (UK) Ltd, London and the provision of plant material by the Herbert Whitley Trust, Paignton.

Stem anatomy and sheathing mycorrhizas in the *Betula verrucosa–Amanita muscaria* relationship

Increasingly, attempts are being made to afforest difficult sites including prairie and steppe lands, peat bogs, *Calluna* heaths and industrial wastelands. In the United Kingdom the Forestry Commission is planting Sitka spruce (*Picea sitchensis* (Bong. Carr.) and Lodgepole pine (*Pinus contorta* Loud.) on land subject to periodic or protracted waterlogging and, notwithstanding the use of improved techniques of planting and site preparation, these species tend to be shallow rooted and liable to 'wind blow'[1]. In these conditions the establishment of nursery-grown seedlings is problematical. As long ago as 1917, Melin[2] noted that while *Pinus sylvestris* L. and *Picea abies* (L.) Karst. transplants, used for afforesting freshly drained peat bogs, were without mycorrhizas they remained stunted. Growth accelerated as soon as these structures began to appear, however, presumably with the development of effective amounts of fungal inocula which may have been initially absent.

Until now the benefits accruing to hosts after mycorrhizal formation—increasing root and stem production[3]—have usually been attributed to enhanced mineral nutrition[4]. Marx and Bryan found that stems of trees with mycorrhizas grew taller and wider than those of trees without mycorrhizas[5]. In recent experiments, however, with (1) seedlings of one seedlot of birch (*Betula verrucosa* Ehrh.) and (2) two isolates of one of its ectomycorrhizal associates *Amanita muscaria* (L. ex Fr.) Hooker, it was found that different stem tissues were affected differently. Inoculating 10-d-old seedlings growing axenically on modified Ingestad's medium[6] solidified with 1% agar, with isolates 1 and 2 taken from sporophores collected at Tomintoul and Penicuik, Scotland (Table 1) significantly increased stem diameters by 22 and 31% respectively when assessed 8 weeks later.

Inoculation, which resulted in the formation of mycorrhizas within 4 weeks, increased widths of epidermal layers by 400 to 500%, but those of vascular tissues by only 6 to 18%. But when transverse sections were examined microscopically, in addition to affecting the widths of differing bands of tissue, inoculation was found to have altered their nature (Table 2).

Table 2 Differences in stem anatomy of seedlings of *Betula verrucosa* with and without mycorrhizas formed with *Amanita muscaria*

Seedlings without mycorrhizas	Seedlings with mycorrhizas
Epidermis one cell thick without bark	Bark well developed, five cells thick
Lenticels absent	Lenticels developing
Cortex—small, thin-walled cells, closely adpressed, with very few intercellular spaces	Cortex—large cells with conspicuously 'thickened' walls, rounded with many distinct intercellular spaces
Phloem parenchyma—very infrequent occurrence of starch	Phloem parenchyma—most cells with starch and darkly staining substances
Xylem—secondary thickening patchily distributed	Xylem—uniform secondary thickening throughout tissue
Primary tissues—virtual absence of starch in pith	Primary tissues—most pith cells contain starch grains

Just as when pot-grown tomato plants were infected with the vesicular-arbuscular fungus *Glomus macrocarpus* var. *geosporus*[7], so inoculation of *B. verrucosa* with *A. muscaria* was similarly associated (Fig. 1) with (1) the more uniform and probably thicker secondary thickening of the xylem, (2) larger and more rounded cortical cells with conspicuous intercellular spaces, (3) the relatively advanced development of bark, which was missing from non-mycorrhizal controls and (4) increased starch content of the phloem parenchyma and pith. Where it occurred, bark was punctuated with lenticels.

What advantages do these morphological changes, probably attributable to changed hormonal balances, confer on young trees, in view of the fact that they may reflect the ability of mycorrhizas to accelerate processes which might occur inevitably with increased age? They seem to be of two kinds related to (1) gaseous exchange, and (2) structural properties.

The effect of *A. muscaria* on stem cortex development can be regarded as an extension of a phenomenon identified by Coutts (see ref. 1, page 376). They found that air spaces

Table 1 Effects of inoculating roots of *Betula verrucosa* with the mycorrhizal *Amanita muscaria* on the width of stem tissues

	Width of stem tissues (μm)			
Treatment	Epidermis/bark	Cortex	Xylem/pith	Total
Uninoculated control	16	100	514	629
Inoculated with:				
isolate 1	100 (530)	121 (22)	543 (6)	765 (22)
isolate 2	85 (430)	138 (38)	604 (18)	827 (31)

Effects were assessed after 8 weeks of growth in axenic conditions at 26 °C with continuous light (mycorrhizas appeared 4 weeks after inoculation). Measurements were made on three sections of each replicate seedling. Figures in brackets refer to percentage increases.

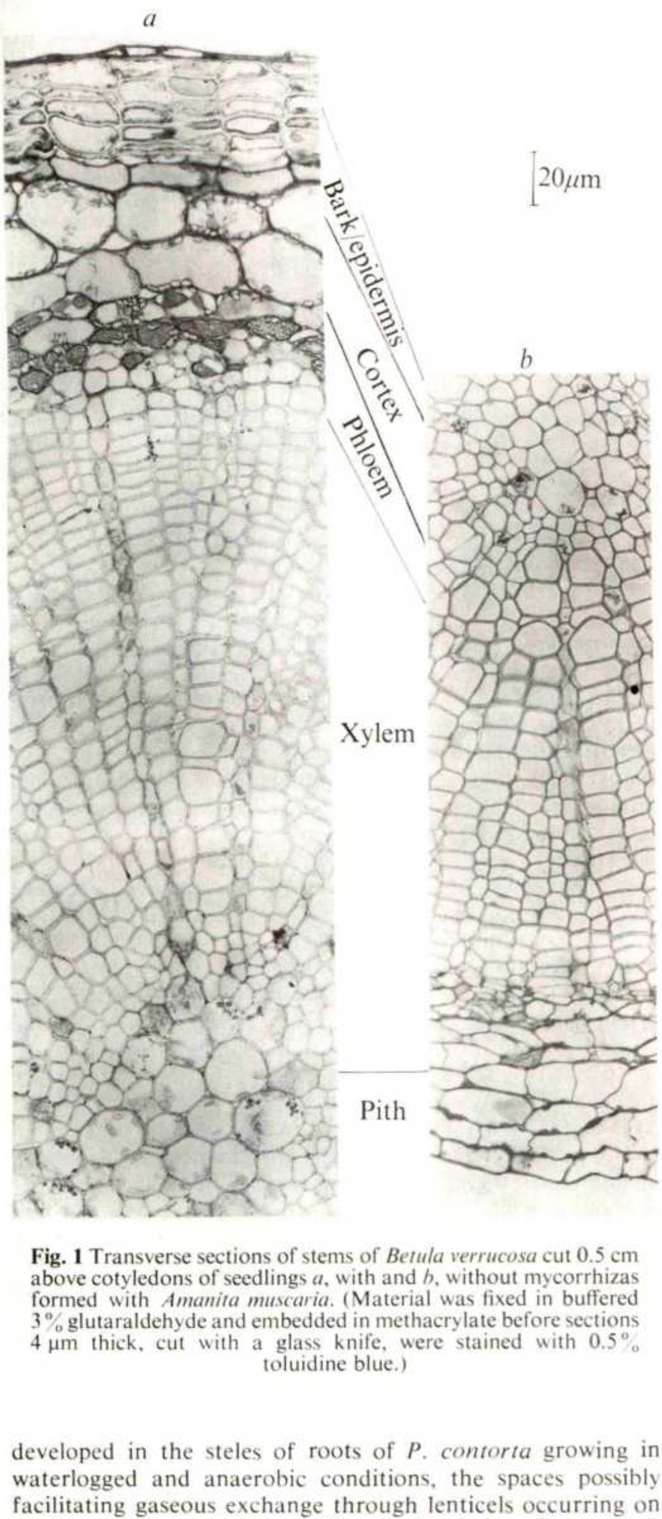

Fig. 1 Transverse sections of stems of *Betula verrucosa* cut 0.5 cm above cotyledons of seedlings *a*, with and *b*, without mycorrhizas formed with *Amanita muscaria*. (Material was fixed in buffered 3% glutaraldehyde and embedded in methacrylate before sections 4 μm thick, cut with a glass knife, were stained with 0.5% toluidine blue.)

developed in the steles of roots of *P. contorta* growing in waterlogged and anaerobic conditions, the spaces possibly facilitating gaseous exchange through lenticels occurring on sections of root and stem. The accelerated appearance of bark and lenticels and the concomitant development of a spongier cortex in stems of *B. verrucosa* may serve a similar purpose, stem changes possibly complementing cortical alterations occurring in roots with sheathing mycorrhizas.

On the other hand, accelerated bark development might hasten the waterproofing of trees which otherwise might be at risk in arid conditions. Zerling, as mentioned in a review by Meyer[8], found that sheathing mycorrhizas improved the water relations of trees in prairie and steppe regions.

Thus, while cortical changes in stems might facilitate tree establishment in 'stress conditions', whether these are associated with too much or too little water, the greater thickening of xylem elements and the early development of bark may confer structural benefits, not only increasing quality (uniformity) and quantity of yield but also possibly aiding the ability of the tree to withstand exposure.

Phytochrome-initiated fast rhythm controlling developmental response

To identify the steps controlling a developmental response, we must relate changes occurring soon after the inducing signal to responses many hours later. In higher plants exposure to red light shifts developmental patterns by converting phytochrome, a ubiquitous plant pigment, into its active form[1]. Far red light converts phytochrome back to its original form and stops the response. Red light induces changes in electrical properties of plants in 15–30 s (refs 2, 3) and within minutes ATP levels[4], NADP transport[5], and nitrate reductase activity[6] change. It requires hours or even days for phytochrome effects on circadian rhythms[7], germination, de-aetiolation, and flowering responses to appear[1]. Until now there has been no indication of the mechanism by which events immediately following phytochrome conversion determine the later development. It should be possible to probe the nature of the first controlling steps by perturbing these steps and thus affecting growth. If the steps directly following phytochrome conversion are sensitive to additional red light, then a second illumination will alter the overall growth. We have found that a brief flash of red light given to dark-grown bean seedlings starts oscillations in a temperature-compensated system. The interaction of this system with a second flash of red light showed that the oscillating system controls subsequent development.

Compared with unilluminated plants, bean seedlings (*Phaseolus vulgaris* var. Black Valentine) exposed to 10 min of white light and returned to dark have 40% greater leaf protein and leaf weight 24 h later[8]. Red illumination, 115 $\mu W\ cm^{-2}$ at 600 nm, saturated this growth response in 4 min, while our experiments used a total of 8 s of this red light. Given as a single flash, 8 s of red light increases average leaf weight by 8%. We used leaf weight increase in whole seedlings to measure the integrated phytochrome response.

To determine the effects of interference by a second red light on the reaction to the first, we kept total illumination constant and varied the interval between two 4-s flashes. For intervals ranging from 2 min 0 s to 2 min 30 s in increments of 5 s, we found that the length of the interval determined the leaf weight 24 h later. In 11 trials minimum growth occurred in the samples exposed to an interval around 2 min 15 s and maximum growth for an interval only 5 s longer. The maximum weight increase was 60% greater than the minimum. This sharp jump from low to high weight increase is an easily observable feature to use in studying the interacting response to red light.

Given the repeatable difference in growth response to intervals of 2 min 15 s and 2 min 20 s, does the same minimum–maximum jump occur for any other pair of intervals 5 s apart? We extended the range of intervals from 0 min 5 s to 5 min 15 s and recorded average weight as a function of interval (Fig. 1). Arrows mark every significant minimum–maximum jump where probability from analysis of variance is less than 0.05. After the jump at 2 min 15 s to 2 min 20 s, the next significant one is at 3 min 0s to 3 min 5 s, 45 s later. The likelihood of finding the next three jumps spaced at 45±5 s intervals from these is only $3^3(3!\,24!)/27! = 0.009$. The part of the curve between the significant transitions shows hints of repetition but no outstanding features. Autocorrelation shows pronounced periodicity for 45 s, $P<0.05$, and 90 s, $P<0.01$. The 45-s periodicity persists at least 20 min. For intervals as long as 20–22 min, the minimum–maximum jump in the response appears at 20 min 20 s to 20 min 25 s and 45 s later at 21 min 5 s to 21 min 10 s.

Apparently red light shifts some system closely associated with controlling the growth rate into a rapidly oscillating state. If the changing sensitivity to a second illumination started by the initial red light is part of the phytochrome response, then far red light given immediately after the first red should eliminate the minimum–maximum jumps in response to the second red. There is no minimum–maximum jump at any interval when 4 s far red immediately follows the first red (Fig. 2). Far red light must either be damping the oscillations or desynchronising the plants so that the minimum–maximum jumps are no longer distinct. Variations among individual plants for any interval is no greater for initial red–far red than for red light alone, indicating that far red damps or stops the oscillations.

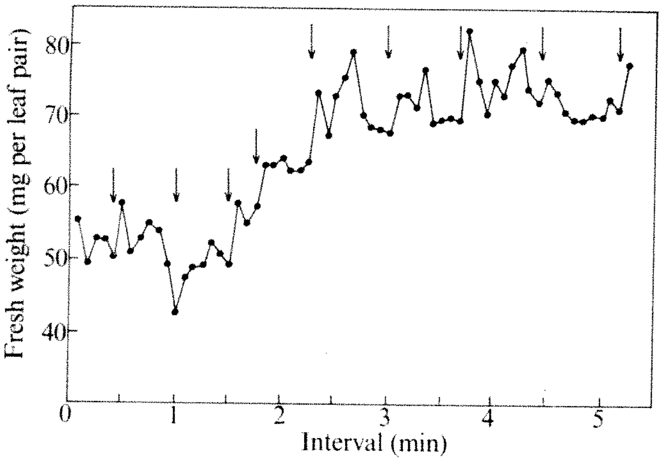

Fig. 1 The effect on leaf growth of the interval between two 4 s red illuminations. Average weight of primary leaf pairs from 8-d-old seedlings 24 h after red light. Arrows mark all the intervals where the second red light significantly suppresses growth compared to the interval 5 s longer, the minimum–maximum jumps. Plants were grown in the dark with standard nutrient: 5 mM $Ca(NO_3)_2$, 5 mM KNO_3, 1 mM KH_2PO_4, 1 mM $MgSO_4$. Six pots of 15 seedlings each were given two 4 s red light pulses, 115 µW cm^{-2}, with a measured dark interval between. The standard deviation among the samples for each interval ranges from 3 to 13%. For comparison, % std average fresh leaf weight: 7 d unilluminated, 9%; 8 d unilluminated, 5%; and 8 d with 10 min red light on day 7, 6%.

To prove that the rapidly oscillating system is phytochrome dependent, we must show repeated reversibility, with red light reversing the damping effect of far red. When red immediately follows far red it re-establishes the minimum–maximum jumps in response to the final red signal (Fig. 3). Arrows mark the significant jumps at 2 min 5 s to 2 min 10 s and 3 min 15 s to 3 min 20 s in two replicate experiments. The shape of the curve is unlike the shape with red alone, but minimum–maximum jumps in the response are clearly not damped out as they are by far red light.

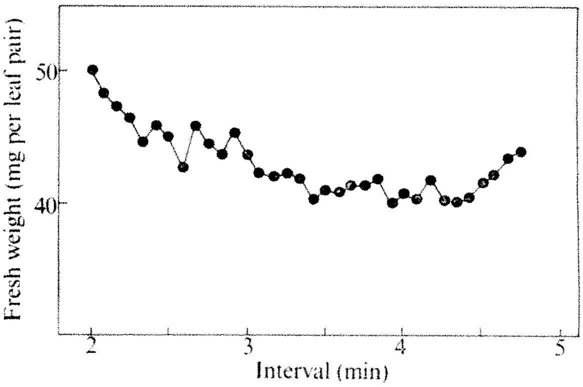

Fig. 2 Far red reversal. The effect on leaf growth of the interval between 4 s red light followed immediately by 4 s far red light, 2500 µW cm^{-2}, and another 4 s red illumination after the dark interval. Other conditions as in Fig. 1.

The period of the oscillation is independent of temperature between 15 and 30 °C. The seedlings were grown, and experiments described previously were carried out at 22 °C. To avoid the possibility that a temperature shift itself might produce time-dependent effects, we moved seedlings into the 15 or 30 °C room at random times with respect to illumination. At 15 °C, the entire plants equilibrated to 15 °C. Minimum–maximum jumps in the response occurred 40 or 45 s apart between 3 min 0 s and 6 min 0 s. At 30 °C, hypocotyls equilibrated to 30 °C, but transpiration and evaporation lowered the leaf temperature to 25 °C. For intervals ranging from 2 min 0 s to 4 min 0 s, there were three minimum–maximum jumps in the response, 45 and 40 s apart. The period of the oscillation is unchanged, but the phase of the oscillation is affected by the temperature during the illumination.

The results demonstrate that we can study the system controlling the phytochrome response by perturbing it with additional red light. The presence of oscillations shows that previous models[9], which give the developmental response as a monotonically increasing function of the inducing red light, must be revised for subsaturating amounts of light. Initiation of these oscillations is among the first consequences of phytochrome conversion. The system is active

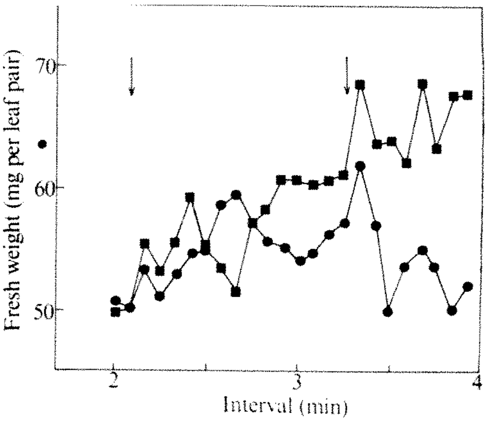

Fig. 3 Red reversal of far red. The effect on leaf growth of the interval between 4 s red light, 24 s far red, and 4 s red, followed by the dark interval and then another red illumination. Arrows mark the minimum–maximum jumps. Other conditions as in Fig. 1.

within 10 s, since growth responses to the second flash of red light at 5 and 10 s are significantly different, $P<0.01$. It is certainly functioning within 25 s, even though it does not reach stable oscillations for 2 min. The temperature independence of the system implies that it is in some organised structure. The system must be linked to, but is probably not identical to, the phytochrome binding sites in the membranes. Since circadian rhythms in plants are sensitive to phytochrome and are temperature compensated, this oscillating system may be the mechanism by which red light interacts with those rhythms. The growth response to two red light signals shows that phytochrome conversion rapidly activates a new type of control linking early events to later development through an oscillating system.

Two previously undescribed potato viruses from South America

THE proneness of potatoes (*Solanum* spp.) to virus diseases is well known, and about 20 viruses are recorded in naturally infected potatoes in Europe and North America[1,2]. Many of these viruses also occur in the Andean region of South America. For example, in Peru several well known viruses were detected[3] in 'basic seed' stocks by inoculating sap to a range of indicator species and by serological tests. Some indicator plants in these tests, however, developed symptoms unlike those typical of previously described potato viruses. These symptoms were of two main types, necrotic local lesions and systemic necrosis in *Chenopodium quinoa*, and systemic necrosis and shoot distortion in *Phaseolus vulgaris* cv. Pinto or Sanilac. We describe here the characterisation of the virus isolates producing these effects. Two previously undescribed viruses were identified: we call them potato black ringspot virus (PBRV) and potato virus T (PVT).

The stock culture of the first virus, PBRV, is an isolate obtained from a plant of the cultivar Antarqui (*S. tuberosum* subsp. *tuberosum* × *S. tuberosum* subsp. *andigena*) growing at Huasa Huasi, Junin, Peru and showing necrotic spotting on the tip leaves. In glasshouse conditions at Dundee, PBRV produces local lesions in inoculated *C. quinoa* leaves in 4 d and systemic necrosis in 6–8 d. Necrotic local lesions develop in 6 d in *P. vulgaris* cv. The Prince; systemic necrotic spotting is produced in 7–8 d and ultimately the growing point of the main shoot is killed. Potato plants (*S. tuberosum* subsp. *tuberosum* cv. Maris Bard) infected by inoculation of sap develop black rings and spots in systemically infected leaves. PBRV has a very wide host range, which will be described in detail elsewhere, occurs in moderate concentration in sap and is moderately stable (Table 1). Purified virus preparations, made from systemically infected *Nicotiana clevelandii* leaves by the method of Murant *et al.*[4], contain numerous isometric particles which measure about 25 nm in diameter in electron micrographs of samples negatively stained with phosphotungstate. Gel-diffusion serological tests indicate that PBRV is distantly related to tobacco ringspot virus (Table 2) and therefore belongs to the nepovirus group[5], other members of which have soil-inhabiting nematodes as vectors and are transmitted through the true seed of many plant species.

Table 1 Some properties of PBRV and PVT

Properties in sap*	PBRV	PVT
Dilution endpoint	10^{-4} to 10^{-5}	10^{-4} to 10^{-5}
Thermal inactivation point (10 min exposure)	58–60 °C	55–60 °C
Longevity at 20 °C	9–10 d	2–4 d
Particle shape and size (nm)	Isometric (25)	Flexuous filament (640 × 12)

*Source and assay plants respectively were *N. clevelandii* and *C. amaranticolor* for PBRV, and *C. quinoa* and *P. vulgaris* cv. Pinto for PVT.

Table 2 Serological relationship between PBRV and tobacco ringspot virus

Antiserum	Antigen* PBRV	Antigen* Tobacco ringspot virus
PBRV	1/2048	1/32
Tobacco ringspot virus	1/16	1/512

*Figures are antiserum reaction end-points in gel-diffusion serological tests.

The stock culture of the second virus was also obtained from potato cv. Antarqui growing at Huasa Huasi, but the source plant showed no obvious symptoms of infection. This culture was passed through a series of local lesions, which develop in heavily shaded inoculated leaves of *P. vulgaris* cv. The Prince in 6 d; systemic vein necrosis is produced in 10 d, and leaves formed subsequently show a distorting mosaic. In *C. quinoa* PVT is much less virulent than PBRV, producing no symptoms in inoculated leaves and a mild systemic mottle after 10 d. Typically, no symptoms develop in potato cv. Maris Bard infected by inoculation of sap. PVT is less stable than PBRV in sap at 20 °C (Table 1) and has a narrower host range. Infective *C. quinoa* sap, negatively stained with uranyl acetate, contains flexuous filamentous particles measuring about 640 × 12 nm. Serological tests made by the tube precipitin method, using virus particles purified by a technique similar to that of Lister[6], and antisera to purified virus, indicate that PVT is related to apple stem grooving virus (Table 3) but not to potato viruses S or M. Significantly PVT is frequently seed-transmitted in various solanaceous species; for example, of 18 progeny seedlings derived from experimentally infected *Datura stramonium* mother plants, 13 were infected.

Our report is intended to alert potato pathologists to the occurrence of PBRV and PVT, and to indicate how

Table 3 Serological relationship between PVT and apple stem grooving virus

Antiserum	Antigen* PVT	Antigen* Apple stem grooving virus
PVT	1/256	1/64
Apple stem grooving virus	1/32	1/128

*Figures are antiserum reaction end-points in tube precipitin tests, after incubation for 5 h at 37 °C.

they can be detected. Both viruses seem to be widespread in Peru. Our findings also support the idea that the Andean region of South America can be considered the main centre of diversity not only of tuber-bearing species of *Solanum*[7] but also of their viruses. Early export of infected potato tubers from South and Central America to various other countries is probably responsible for the present worldwide distribution of many potato viruses. Other viruses, which did not occur in the originally exported material or did not spread in the new country, are likely still to be confined to the Andean region. Indeed we have evidence of viruses in addition to PBRV and PVT that occur in South American potatoes but have not been reported elsewhere.

We thank Dr M. F. Clark for apple stem grooving virus and its antiserum. L. F. Salazar is on secondment from the International Potato Center, Lima, Peru.

Control of inner cell mass development in cultured mouse blastocysts

THE mouse blastocyst consists of a group of cells, the inner cell mass (ICM), attached to a small area of the inside surface of a sphere of trophectoderm cells. The trophectoderm gives rise to the extraembryonic regions of the conceptus while the ICM forms the embryo proper[1]. At implantation trophoblast cells invade the uterine epithelium. Those overlying the ICM proliferate to form the ectoplacental cone and the extraembryonic ectoderm and the remainder undergo transformation into giant cells[2]. The cells of the inner cell mass divide further, and, together with the extraembryonic ectoderm, give rise to a column of cells, the egg cylinder, that extends into the blastocyst cavity (blastocoele). Lactic dehydrogenase A subunits (4A, LDH-5) appear at this time[3], and may be synthesised first in tissue deriving from the ICM[4]. Subsequently LDH-4 (3A1B) and LDH-3 (2A2B) appear as the contribution of B subunits to the pattern increases. If implantation is prevented, further development of the blastocyst is arrested[5] and LDH-5 fails to appear[3]. Implantation therefore seems to act as a trigger, not only for trophoblast proliferation, but also, directly or indirectly, for further development of ICM. In the work reported here we have varied the conditions of culture of isolated blastocysts and have elicited alternative forms of development that mimic those observed *in vivo* when implantation occurs or is prevented. We have shown further that the triggering of ICM development *in vitro* may represent the release from an inhibitory effect of trophectoderm.

Blastocysts flushed from the uteri of Q strain mice on the fourth day of pregnancy were cultured in supplemented Eagle's minimal essential medium with 20% foetal calf serum[4] in various conditions intended to favour or inhibit attachment of the blastocysts to the substratum. The results obtained are summarised in Table 1 and illustrated in Fig. 1. On Falcon dishes, attachment and outgrowth begin asynchronously on the second day of culture and all blastocysts are outgrown by the third day, showing giant cell mass grew vigorously. Such clumps of blastocysts were neighbouring trophoblast cells. As shown in Table 1 (group *A*) such outgrowths synthesise substantial amounts of LDH-5. Groups *B–D* give the results obtained with three different suspension culture conditions intended to inhibit blastocyst attachment. These were the use of substrata unfavourable to blastocyst attachment and outgrowth (bacteriological or agar-coated dishes), and hanging drop culture of single embryos, either on plastic cover slips suspended in oil, or in inverted Falcon microtest plates with the wells filled to capacity (15 μl) with medium. In each case synthesis of LDH-5 is greatly reduced. None of these conditions was completely reliable in preventing attachment during 3 d of culture. Blastocysts did eventually attach to the bacteriological dish or agar surface, and, in hanging cultures, to the oil–medium interface or to the air–medium interface. In all cases such attachment led to the disappearance of the blastocoele cavity and, rarely, to some increase in the mass of cells. Such 'collapsed' blastocysts often contained some LDH-5, presumably depending on the time of blastocyst 'attachment' and/or collapse relative to the time of collection. Attachment to the agar surface was undoubtedly responsible for the three batches of embryos in group *B* (Table 1) that synthesised significant amounts of LDH-5. Even more strikingly, if groups of blastocysts were cultured together in a hanging drop, they always coalesced rapidly, their blastocoele cavities disappeared and the total cell transformation and proliferation of the ICM and invariably found to be positive for LDH-5 (gel 4, Fig. 1). When blastocysts that had remained in suspension for 3 d were transferred to Falcon dishes, attachment and outgrowth began within 15 min in a very synchronous fashion and significant amounts of LDH-5 were synthesised by the following day (gel 6, Fig. 1).

Since these results suggested that further development is related in some way to a collapse of the trophectoderm, we

Table 1 LDH-5 synthesis in blastocysts and ICMs after 3 or 4 d of culture in different conditions

Group	Culture conditions	No. of batches of embroyos*	No. of batches with LDH-5 band

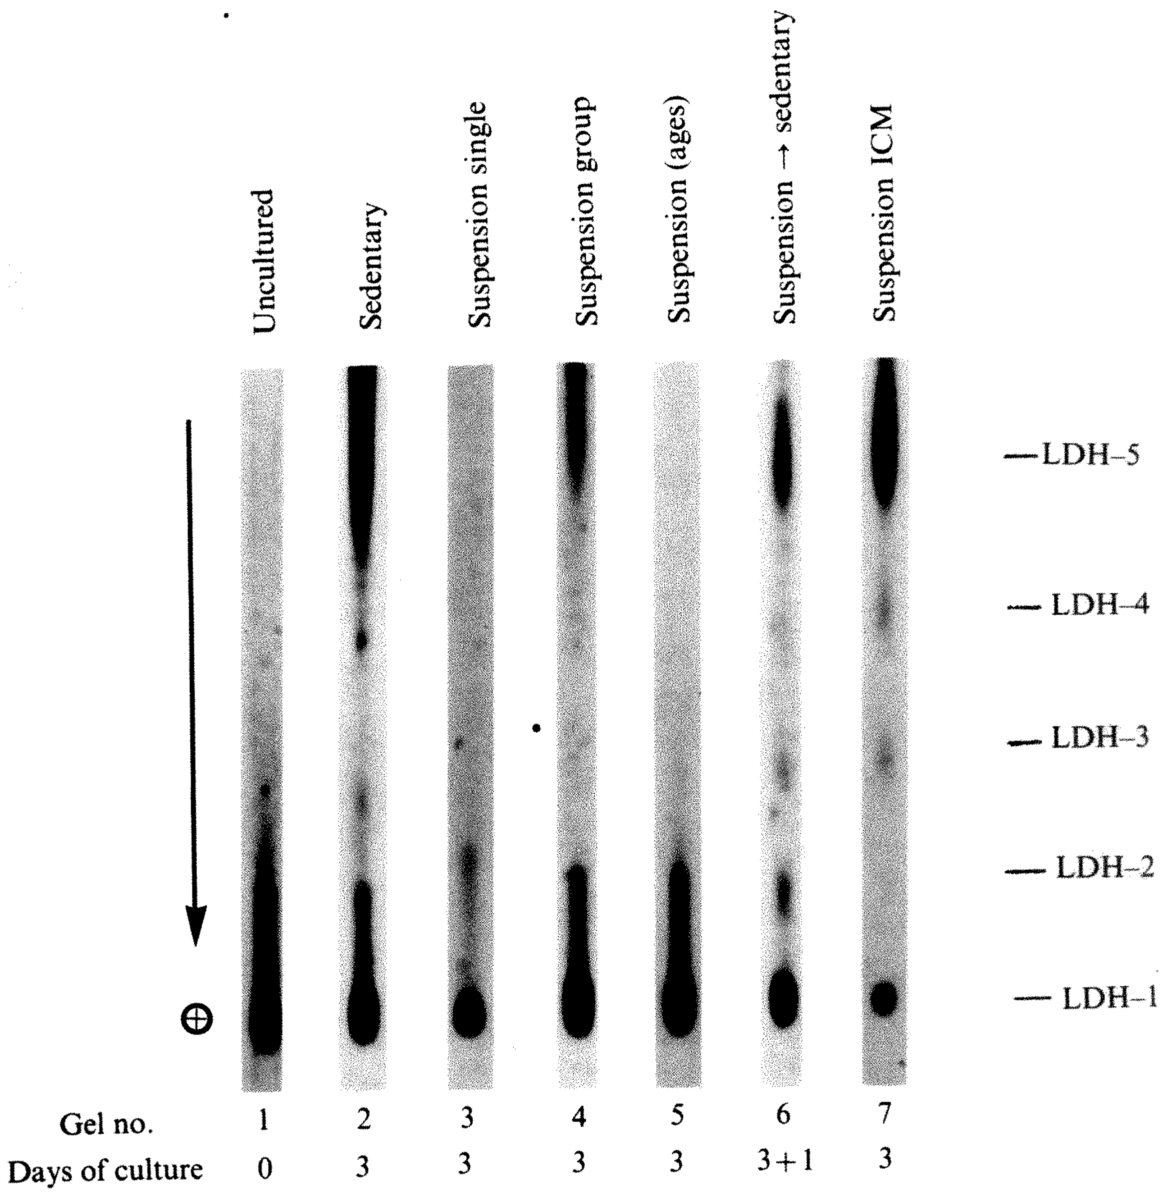

Fig. 1 Microdisk electrophoresis showing LDH isozymes in extracts of embryos after sedentary and suspension culture from the blastocyst stage. Isolation of blastocysts on the fourth day of pregnancy, media, and LDH staining were as described before[4]. Zonae pellucidae were removed before culture by 5 min of incubation in pronase. Polyacrylamide gel electrophoresis in 5-μl Drummond caps was performed as described before[7]. Approximately 10 embryos were applied to each gel as follows: (1) uncultured blastocysts, (2) outgrowths from blastocysts after 3 d of sedentary culture on a Falcon dish, (3) blastocysts after 3 d of suspension culture singly in hanging drop, (4) blastocysts after 3 d of suspension as a group in hanging drop, (5) blastocysts after 3 d of suspension culture on an agar-coated dish, (6) outgrowths from blastocysts cultured for 3 d on an agar-coated dish followed by 1 d of culture on a Falcon dish, (7) inner cell masses after 3 d of culture in suspension on a bacteriological dish. All extracts contain residual maternally-inherited LDH-1 (ref. 4).

analysed isolated ICMs in suspension culture. Trophectoderm was removed immunosurgically[6] by treatment of zona-free blastocysts with rabbit anti-mouse serum followed by guinea pig complement. Trophectoderm cells are lysed; ICMs, because they are not directly exposed to the anti-mouse serum, survive. Such ICMs grow and develop in suspension culture, forming a layer of primary endoderm cells on their surface after 2 d. In contrast to whole blastocysts, they synthesise LDH-5 in the absence of attachment and outgrowth (Fig. 1 and Table 1, groups *E* and *F*). This result suggests that implantation relieves an inhibitory effect of trophectoderm on ICM development. This inhibition could be due to a restriction on free access for some nutrient(s), or to a more subtle contact effect.

β-retinoic acid inhibits and reverses testosterone-induced hyperplasia in mouse prostate organ cultures

CERTAIN human prostatic cancers are associated with abnormalities of testosterone metabolism and/or increased sensitivity of prostatic epithelial cells to testosterone[1,2]. Most treatments, (oestrogen therapy, orchiectomy and radiation therapy) for these diseases are designed therefore to reduce the levels of testosterone or its active metabolites in the patients[3]. Recently, however, studies with

non-hormonal chemotherapeutic agents for the treatment of prostate cancer have been initiated[3-5]. In mouse prostate organ cultures, we and Lasnitzki have shown that vitamin A and several synthetic analogues (retinoids) inhibit and reverse carcinogen-induced epithelial lesions[6-8]. Since testosterone has been linked with human prostatic cancer and induces hyperplastic lesions of the prostatic epithelium *in vitro*[2,9], it prompted us to start investigating the effects of β-retinoic acid (RA) and other retinoids on testosterone-induced lesions in the mouse prostate system. Preliminary results presented in this report show that RA inhibited and reversed testosterone-induced lesions in mouse prostate organ cultures.

Ventral prostate from 8- to 10-week-old C3H mice were removed aseptically and teased into approximately 1.5×1.0-mm explants. The explants were arranged on strips of lens paper and were placed on stainless steel grids. Six to eight explants were placed on each grid that were contained in 35 mm plastic Petri dishes. Petri dishes were filled up to the level of the grids with CMRL 1066 medium (~2.5 ml) supplemented with 10% horse serum, 3% chick embryo extract, 100 U ml^{-1} each of penicillin and streptomycin and 25 μg ml^{-1} amphotericin B. The cultures were incubated at 37 °C in an atmosphere of 50% O_2+45 N_2+5CO_2. Culture medium was renewed every 48 h.

Two series of experiments were carried out. In the first, explants were incubated simultaneously with testosterone (1.8×10^{-5} M) and different concentrations of RA to determine if the development of hyperplasia could be prevented. In the second, the reversal of hyperplasia was examined. In these experiments, explants were first allowed to develop hyperplasia by treatment with the testosterone for 8 days, after which time, these hyperplastic explants were simultaneously treated with testosterone and different concentrations of RA for an additional 96 h. The changes in rates of cell proliferation caused by testosterone or RA were determined by the colcemid metaphase arrest technique[6]. The explants were fixed in buffered formalin, processed for histology, serially sectioned, and the mitotic index and standard deviation (m.i.±s.d.) determined as previously described[6]. The significance of the difference between two groups was determined by Student's *t*-test, and a value of $P<0.05$ was considered significant.

Since the mitotic indices in different groups of explants were variable, the data presented in each table represent one experiment. Table 1 shows that testosterone stimulated cellular proliferation in the epithelium of prostate at 4 or 8 days after treatment, but that this stimulatory effect was prevented in explants that were simultaneously treated with testosterone and RA. For instance, at 4 d after treatment, the m.i. in the control explants was 148±59, whereas the corresponding value in testosterone-treated explants was 647±261. The m.i. in explants simultaneously treated with testosterone and RA were 147±45, 148±25 and 389±87 at 1.7×10^{-5} M, 3.3×10^{-6} M, and 6.6×10^{-7} M, respectively. A similar mitotic inhibitory effect by RA was observed at 8 d.

The morphology of prostate explants incubated in control media for 8 d showed little alteration from the *in vivo* structure. The alveolar epithelium remained 1–2 cell layers thick and exhibited little mitotic activity. Occasionally some Periodic-Acid Schiff (PAS) positive secretory material was present in the alveolar lumen of the control explants. Treatment of explants with testosterone produced hypertrophy and hyperplasia of the alveolar epithelium. The epithelium of these explants was tall, contained many mitoses, and showed a significant increase in the PAS positive material in the alveolar lumen. When, however, explants were treated simultaneously with the testosterone and RA (1.7×10^{-5} M), the degree of hypertrophy and hyperplasia was significantly less than that of explants that received the hormone only.

Table 2 shows the data on the reversal of testosterone-induced hyperplasia by RA and indicates that testosterone stimulated proliferation in the prostatic epithelium at 8 d, and that the values of m.i. in the testosterone-treated

explants remained significantly higher than the corresponding control values for at least 12 d. But when explants were first treated with testosterone for 8 d followed by simultaneous treatment with testosterone and RA at 1.7×10^{-5} M, 3.3×10^{-6} M, and 6.6×10^{-7} M for an additional 48 or 96 h, the hyperplasia was reversed.

The mechanism of inhibition and reversal by RA of testosterone-induced hyperplasia in the mouse prostate is not known. It has been shown that steroid hormones interact with their specific proteins in the target tissues. In testosterone-dependent tissues for instance, the prostrate gland of experimental animals[10–12] and humans[13], the existence of proteins with a pronounced affinity for the hormone has been documented. Furthermore, for its biological activity, testosterone must be metabolised (mediated by the enzyme 5α-reductase) to 5α-dihydrotestosterone, the form that appears to be responsible for the stimulation of proliferation of the prostatic epithelium[3,14–16]. Thus the inhibition of binding of testosterone and/or its metabolism to 5α-dihydrotestosterone would result in its failure to cause stimulation of proliferation. Sandberg *et al.*[3] suggested that oestrogens, which have a remarkable efficacy in alleviating human prostatic carcinomas, act by reducing the testosterone titres directly via the pituitary[17–19] and/or indirectly by inhibiting the enzyme 5α-reductase[20,21]. Since the prostate organ culture model used in the present investigation does not involve the pituitary, the inhibition of testosterone-induced hyperplasia by RA may be accomplished by inhibition of the binding of testosterone to the specific protein and/or by inhibition of the metabolism of testosterone. However, the antihyperplastic activity of RA can also be explained by several other mechanisms.

We thank Dr Michael Sporn for his helpful discussions. This work was supported by a contract from the Lung Cancer Segment, National Cancer Institute. RA was obtained from Hoffmann La-Roche, Nutley, N.J.

Virulence and toxicity of axenic *Entamoeba histolytica*

The ability of cultured *Entamoeba histolytica* to cause ulcers in the caecum of guinea pigs and rats or abscesses in the liver of the Syrian hamster decreases rapidly on elimination of the accompanying bacterial flora[1–4]. It seemed that some strains grown axenically on TP-S-1 medium[5] for many years had lost their pathogenicity entirely. When very large inocula were used, however, (10^7 amoebae), a granulomatous lesion was evoked in the hamster liver[6,7]. Our experiments with strains made freshly axenic, isolated from patients with amoebic dysentery, suggested that the number of amoebae required to induce a certain extent of pathology in the hamster liver increased with the number of transfers in axenic culture[8]. After a long period of axenic growth, strains probably maintain a very low degree of pathogenicity. Using two such strains, HK-9 and HB-301, we obtained results which may contribute to the understanding of the pathogenicity of *E. histolytica*. We were able to restore the virulence of the HK-9 strain with cholesterol and establish a higher degree of virulence by two successive passages through hamster liver (HK-9H_2). *In vitro* toxicity towards guinea pig leukocytes, and agglutinability induced by concanavalin A (con A) were markedly greater in strain HK-9H_2 than in HK-9. Antigenic analysis revealed a pattern for HK-9H_2 different from that of the HK-9 strain.

Table 1 Virulence* of *E. histolytica* HK-9H_2 to hamster liver

Time since last passage (weeks)	Size of inoculum ($\times 10^5$ amoebae in 50 μl)			
	0.5	2.5	4.5	8
4	7	49	—	—
11	—	—	—	100
17	0	8	—	—
34	—	—	8	18

*Virulence is expressed as the average extent of abscess as a percentage of the infected central liver lobe. Between five and 10 hamsters were used in each experiment. They were killed 1 week after infection.

Amoebae were injected, after laparotomy of the hamster under anaesthesia with ether, through a 20-gauge needle. The volume of the inoculum chosen was as small as possible to avoid damage of the liver parenchyma. Virulence studies are detailed in Tables 1 and 2. On intrahepatic injection of 10^7 amoebae in 150-μl-inocula, strain HK-9 showed no virulence, whereas HB-301 caused small abscesses occasionally. Two transfers on TP-S-1 medium to which cholesterol (0.35 mg per tube) was added increased the virulence of the HK-9 strain. Inocula of 5×10^6 amoebae induced small granulomatous lesions from which amoebae could sometimes be cultured axenically. The virulence of the resulting HK-9H_1 strain, that is HK-9 after one passage through hamster liver, was markedly increased. Further passages through hamster liver increased virulence even more, so that inocula as low as 5×10^4 sometimes caused abscesses. After 16 weeks virulence was reduced, however, with larger inocula required to induce lesions (Table 1).

Further experiments confirmed the effect of cholesterol on the virulence of the HK-9 strain (Table 2). Cholesterol did not further increase the virulence of HB-301 strain. Epicholesterol—the 3α-hydroxy isomer of cholesterol which, unlike cholesterol, does not induce changes in the permeability of the cell[9]—had the same effect. Although amoebae were present in the small abscesses they could be cultured on TP-S-1 medium only twice; the number of amoebae was probably too small to initiate an axenic culture in other cases. When the hamsters were not killed after 1 week, but allowed to live on their normal diet of food pellets and water, the abscesses healed and eventually disappeared. An effect of cholesterol on the virulence of axenic amoebae has not been reported before. There is disagreement on the effect of cholesterol on the invasiveness of amoebae-bacteria cultures in the rat caecum[10–11].

Virulent HK-9H_2 and non-virulent HK-9 strains were characterised by at least three clear differences—toxicity for guinea pig leukocytes, con A-induced agglutination,

Table 2 Effect of cholesterol and epicholesterol on the virulence of *E. histolytica* HK-9 and HB-301

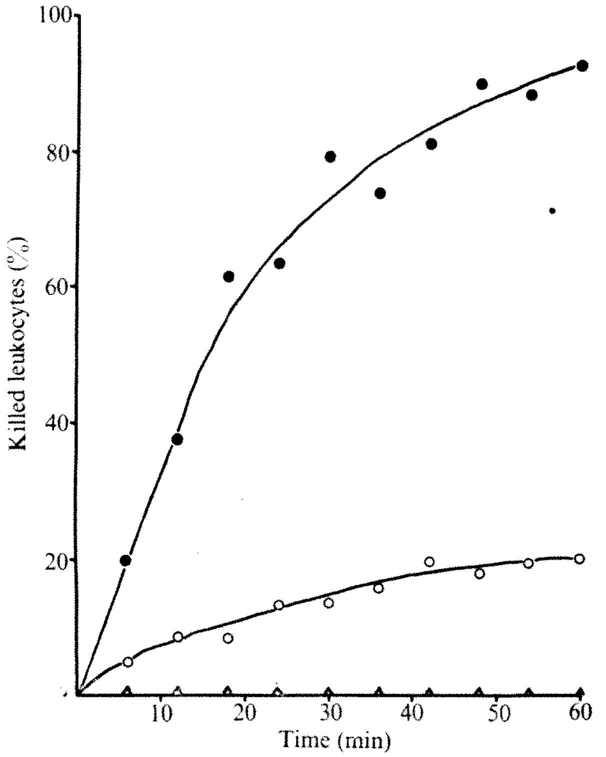
Strain	Treatment	No. of experiments	Size of inoculum ($\times 10^6$)*	No. of hamsters with abscesses per no. of hamsters inoculated	
HK-9	Untreated	3	1.1–4.8	0/12	(0%)
	Cholesterol	5	1.2–5.8	6/15	(40%)
	Epicholesterol	2	1.5–2.0	4/8	(50%)
HB-301	Untreated	2	1.7–3.6	4/6	(67%)
	Cholesterol	2	1.5	5/8	(63%)

Cholesterol and epicholesterol were dissolved in chloroform and evaporated in culture tubes (0.35 mg per tube) before adding the TP-S-1 medium.

*Amoebae in 75–150 µl. The largest inoculum tested consisted of 75 µl packed cell volume and 75 µl TP-S-1 medium. One week after infection lesions were usually more or less confluent granulomatous necrotic areas. Amoebae were demonstrated by microscopy or culture of smears, or in histological cross-sections.

and antigenic composition. Amoebae from 2- or 3-d-old cultures were washed in physiological saline twice and a suspension of 3×10^6 amoebae per ml was prepared. Leukocytes were obtained by draining the peritoneal cavity of a guinea pig of about 300 g 16 h after the injection of 55 ml of physiological saline. The suspension contained approximately 10^7 leukocytes per ml, of which half were polymorphonuclear and half mononuclear leukocytes (monocytes, macrophages and lymphocytes). On mixing leukocyte and HK-9H$_2$ amoebae suspensions, 50% of the leukocytes were killed in about 15 min (Fig. 1), so that each amoebae killed an average of about 1.7 leukocytes. The increasingly smaller chance of an amoebae hitting an intact leukocyte may explain the shape of the curve. Induction of contact-lysis by *E. histolytica* in human leukocytes and cell cultures has been reported before[4,12,13]. Amoebae of the HB-301 and HB-301H$_2$ strains showed the same degree of toxicity towards guinea pig leukocytes as HK-9H$_2$, whereas the original HK-9 strain seemed to have a very low toxicity. HK-9H$_2$ maintained its leukocytotoxicity on the same level even when its virulence decreased in the course of 34 weeks. Toxicity could not be increased in HK-9 amoebae by addition of cholesterol to the medium; at least one passage through hamster liver was required for restoration of toxicity. Interactions between amoebae and pure suspensions of guinea pig macrophages were also studied. Macrophages were separated from other cells in a peritoneal washout by using their adherence to glass. Macrophages seemed to be lysed by the amoebae just as quickly as the inflammatory exudate cells.

Fig. 1 Contact-lysis of guinea pig leukocytes by *E. histolytica* strain HK-9 (○) and HK-9H$_2$ (●). The control (△) was a suspension of leukocytes without amoebae. The ratio of leukocytes to amoebae was approximately 10:3. Samples of 15 µl of each suspension were mixed on a clean microscope slide, covered with a coverslip and sealed with vaseline. The slide was maintained at 37 °C on a heated microscope stage and observed with a ×40 phase contrast objective. The percentage of leukocytes killed (that is, showing rounding up, fusion of nuclear lobes and diminution of granules) was assessed every 6 min by counting 100 leukocytes at random. A vital stain was not used.



Martinez-Palomo *et al.*[14] reported selective agglutination of pathogenic strains of *E. histolytica* induced by con A, We did not observe a clear correlation between con A-induced agglutination and virulence towards the hamster liver with our axenic strains. Only when HK-9 was compared with HK-9H$_2$ was a marked difference found. The technique of Martinez-Palomo *et al.* was modified, using microtitre plates and stepwise increase of con A concentration. Amoebae suspension (200 µl) was put in the cups of the microtitre plate and 10-µl drops of con A solution of 200 µg ml^{-1} were added one by one. After addition of a drop the suspension was shaken on a microshaker for 15 s and agglutination was assessed (0, +, ++, and +++) at a low magnification on the stage of an inverted microscope. Immediately after the second passage through hamster liver maximal agglutination was obtained in a suspension of HK-9H$_2$ amoebae of 10^6 ml^{-1} with con A at 15 µg ml^{-1}, whereas 40 µg ml^{-1} was necessary for HK-9. After 8 weeks *in vitro* cultivation the difference between HK-9H$_2$ and HK-9 was reduced to zero. Another passage through hamster liver restored the difference. HB-301 and HB-301H$_2$ both agglutinated at a con A concentration of approximately 20 µg ml^{-1}.

Antigenicity was analysed by immunoelectrophoresis (IEP) using human and rabbit anti-*E. histolytica* sera, and gel chromatography on Ultrogel AcA 34 and AcA 44 (LKB). The IEP pattern of HK-9H$_2$ showed at least one more precipitation line on the cathodal side than that of HK-9. Gel chromatography revealed a greater absorbance at 280 nm in the fractions with a molecular weight between 150.000 and 400,000. This will be investigated further.

We conclude that an increase of virulence in an attenuated axenic strain is involved with some, more or less stable, characteristics, such as toxicity towards host cells, of the surface membrane and antigenic make-up. The stability of these characteristics may depend on the homogeneity of genotypes within the population of a strain, which are constantly submitted to selective forces. In particular, the degree of toxicity towards leukocytes seems to be a vital characteristic of a virulent strain. *In vitro* toxicity against guinea pig leukocytes provides a convenient, quantitative test, which may prove useful to assess the pathogenic potential of a strain. Treatment with cholesterol or epicholesterol may be a useful way to adapt a non-virulent strain to hamster liver passage.

E. histolytica HK-9 and HB-301 were provided by Dr L. S. Diamond, of NIH.

Failure of BCG to protect calves against *Babesia divergens* infection

The possible use of nonspecific immunity to control *Babesia* infections has not been much examined. Cattle treated with *Escherichia coli* lipopolysaccharide (1.25 μg per kg live weight) immediately before infection with *B. argentina* (=*B. bovis*) were slightly more resistant than controls[1]. An interferon inducer, a double stranded RNA, slightly delayed death in mice infected with *B. rodhaini*[2]. The question has been reopened by some work with *B. microti* and *B. rodhaini* in which mice injected intravenously (i.v.) with 2×10^7 *Mycobacterium bovis* strain BCG (Glaxo strain) became completely immune to intraperitoneal challenge with 10^6 *Babesia* parasites[3]. These remarkable results suggested that the method should be examined in domestic animals. We decided to assess it in calves and report here that BCG fails to protect against infection with *B. divergens*, the common cause of redwater in the UK.

In a preliminary trial two splenectomised Friesian bull calves were used; one was inoculated i.v. with 50 ml of BCG suspension (a fresh, wet preparation, Glaxo) containing an indicated 3 mg ml^{-1}. Thirty-four days later both calves were challenged by the i.v.. inoculation of 0.1 ml of a *B. divergens* stabilate (Eire 2 strain). Both calves became infected and reacted similarly. This result was disappointing but because the use of splenectomised calves might have affected the outcome a second experiment using intact animals was carried out.

Glaxo provided 300 ampoules of lyophilised BCG vaccine, each ampoule containing 10^8 viable units. We dissolved the contents of each ampoule in approximately 0.5 ml of phosphate-buffered saline (PBS), the ampoules were thoroughly rinsed with PBS and the final suspension measured 200 ml. This was divided into three equal parts each of which contained approximately 10^{10} viable units. Each aliquot was inoculated immediately i.v. into a calf (K81, K82 and K84); no adverse side effects were noticed. Four weeks later these calves, together with three control animals (K56, K625 and K628) were challenged i.v. with 3.1×10^{10} parasitised erythrocytes (*B. divergens*, strain Eire 2). All the calves became infected; their reactions are summarised in Table 1. There was no indication that inoculation with BCG had suppressed the multiplication of *B. divergens*.

Table 1 Summary of results of challenge with *B. divergens*

Calf no.	Maximum parasitaemia (per 1,000 RBC)	Duration of parasitaemia (d)	Maximum temperature (°C)	Minimum RBC count ($\times10^6$ mm^{-3})
K81 : BCG	5	3	40.4	6.7
K82 : BCG	98	6	40.3	3.9
K84 : BCG	5	4	40.0	5.6
K56	5	3	39.7	7.1
K625	5	2	40.3	7.2
K628	3	3	40.1	6.1

One of the BCG calves (K82) reacted noticeably more severely than the others. At necropsy no macroscopic abnormalities were noted in any of the calves.

Various reasons for this failure can be adduced: one possible explanation lies in the dose of BCG. We had calculated that to repeat the work in mice as closely as possible it would be necessary to give 10^{11} *M. bovis* organisms to each calf but it was clearly impracticable to administer more than 10^{10} organisms.

We thank Mrs M. N. Hoare and Mr D. C. Davies for splenectomising the calves, and Dr I. A. Clark for prepublication notice of his work. Dr R. Curtis of Glaxo supplied BCG.

Development of resistance to cytotoxicity during aflatoxin carcinogenesis

It is now some time since Haddow first suggested that an early stage in chemical carcinogenesis might involve the induction of cells resistant to the toxic action of the carcinogen[1]. Although it seems that many carcinogens also have acutely toxic properties, the relationship between these activities is largely unknown. We have investigated this relationship by using the mycotoxin aflatoxin B_1, and shown that resistance is linked with proliferation of specific hepatocytes.

Aflatoxin B_1 is a potent hepatotoxin and hepatocarcinogen in many animal species including the rat[2]. Feeding young adult male Fischer rats a diet containing a low concentration (4–5 p.p.m.) of aflatoxin B_1 for 6 weeks, followed by return to control diet, results in 100% incidence of hepatocarcinoma[3]. During the first 3 weeks of the 6-week feeding regime, histological examination of the liver indicates an acutely toxic response, accompanied by depressed nucleic acid synthesis[4]. If toxic feeding is stopped at this stage an insignificant incidence of neoplasia results. The acutely toxic action results in the death of a considerable proportion of the hepatocytes at the end of the 3 weeks. The second 3 weeks of the 6-weeks feeding regime, during which the carcinogenic response is initiated, is accompanied by a proliferation of both parenchymal and nonparenchymal cells[3,4]. Nucleic acid synthesis also recovers[4]. The cells which proliferate to replace those killed by the acutely toxic action of the first 3 weeks feeding do so in the presence of a continuing supply of the toxin, showing that they possess a mechanism which makes them resistant to the acutely toxic, but not to the carcinogenic, actions of aflatoxin. The diet-induced resistance of the rats to the acute toxicity of aflatoxin is shown by the results in Table 1. The LD_{50} is increased at least 2–3-fold. This increase in the LD_{50} is paralleled histologically, by resistance to the hepatonecrotic effect of the toxin.

The possibility that the resistance of the liver cells in the whole animal to the acutely toxic action of aflatoxin B_1 could also be demonstrated *in vitro* was examined. Hepatocytes were isolated, and subsequently cultured, from livers of control animals (BL8) and livers of animals which had received the aflatoxin-contaminated diet (BL7) for 6 weeks. Morphologically, BL7 and BL8 cells appeared similar, but when treated with aflatoxin, BL7 cells survived and BL8 cells became structurally disorganised and detached from the dish (Fig. 1). Thus the resistance to the acutely toxic action of aflatoxin B_1, which was observed in the hepatocytes of intact animals which had received the toxic diet for 6 weeks, was also displayed by cells isolated from those livers and subsequently maintained in culture *in vitro* for 4 d. The isolated cells were not dividing at this time. In further experiments, cells isolated from control animals (BL8) or animals fed the toxic diet (BL7) were cultured with the medium being changed at approximately weekly intervals. After several weeks, or much sooner in cells isolated from rats fed the toxic diet, certain of the cells in the cultures started dividing, and numerous individual colonies were formed. Colonies were removed from the dish by trypsinisation and the dispersed cells were reseeded to establish rapidly dividing epithelial cell lines from each of the original maintenance cultures (BL7L and BL8L). These cell lines were indistinguishable morphologically. After several passages, the sensitivity of the cells to aflatoxin B_1 was again determined. Resistance of the original hepatocytes in the case of the aflatoxin-fed rats was still present in the cell lines derived from them. These results demonstrate that the resistance to the acutely toxic action of aflatoxin B_1, once established in the cells, is stable. Although most BL8L cells were killed when treated with aflatoxin B_1, a few survived. Dishes were washed with fresh medium 3 d after treatment with the toxin to remove dead cells, and returned to the incubator. Several weeks later colonies were observed to be growing from these surviving cells. These cells were then subcultured, after becoming confluent, and were subsequently passaged several times. Their response to the addition of aflatoxin B_1 to the medium was then determined. Cells derived from the susceptible cell line (BL8L) were now as resistant to the acutely toxic action of aflatoxin B_1 as the BL7L cells which had survived treatment *in vivo*. It therefore seems that resistance to the acute toxicity of aflatoxin B_1 depends on the proliferation of certain hepatocytes with either an inherent resistance to aflatoxin toxicity or the capacity for the induction of that resistance by aflatoxin B_1, either in the whole animal or in culture.

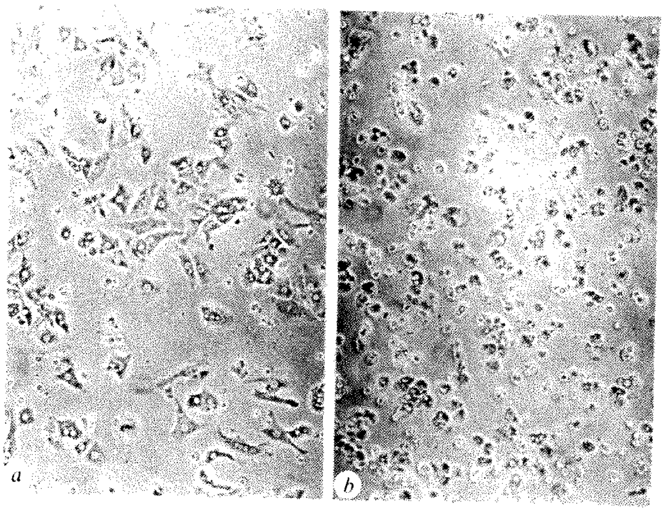

Fig. 1 Hepatocytes were isolated by perfusing liver excised from young adult male Fischer rats through the portal vein with collagenase solution (0.5% w/v) using a modification of the technique of Seglen[5]. The cellular suspension was further dissociated by agitation as described by Drockmans *et al.*[6]. Approximately 3 × 10^8 cells were obtained from each liver, with 80% viability assessed by exclusion of Trypan blue. Gross contamination was reduced by centrifugation twice at 50*g* for 2 min, and remaining cell clumps, broken cells and reticulo-endothelial cells were removed by sedimentation at 1*g* in a 1–4% Ficol gradient at 4 °C in a modification of the apparatus described by Tulp and Bont[7]. This process also yielded final cultures free of fibroblasts. 8 × 10^7 cells were layered on to a gradient. After collection by low-speed centrifugation, cells were suspended in Williams E medium containing 10% foetal calf serum (Flow Laboratories, Irvine, Scotland) at 1 × 10^6 cells per ml and 3 ml was seeded per 60 mm plastic Petri dish. Medium was changed after 1 d. After 3 d, medium was again changed and cells were treated with aflatoxin B_1 (0.3 μg ml^{-1} medium) in DMSO (6 μl ml^{-1} medium). Control dishes received DMSO alone. Appearance of cells after 2 d treatment with aflatoxin: *a*, cells isolated from rat which had received the toxic diet (see Table 1) for 6 weeks (BL7); *b*, cells isolated from control-fed rat (BL8). Cells receiving DMSO alone appeared as in (*a*).

Table 1 Effect of feeding a low level of aflatoxin B_1 on its acute toxicity

	Surviving after 7 d

0.75	0	3
0.5	3	3
0.25	3	3
0	3	3

Control diet: 50% non-toxic peanut meal/50% powdered MRC 41 B diet plus 3.3% Arachis oil. Toxic diet: 25% toxic peanut meal (naturally contaminated with 16 ppm aflatoxin B_1), 25% non-toxic peanut meal, 50% powdered MRC 41B diet, 3.3% Arachis oil. Diets were fed for 6 weeks to young adult male Fischer rats (150–200 g body weight). Groups of three animals were injected with aflatoxin B_1 dissolved in dimethylsulphoxide (DMSO), all animals receiving a total injection volume of 200 μl. All deaths occurred within 3 d of the injections. No further deaths occurred until 3 weeks from time of injection, when the experiment was terminated.

The basis for the resistance is not known. It is not due to an overall failure of the cells to metabolise the toxin, for examination (thin-layer chromatography on silica gel G plates developed in chloroform–methanol, 9:1, (v/v, viewed under ultraviolet light) of a chloroform extract of the medium and cells, after incubating resistant cells (BL7L) in the presence of aflatoxin B_1 for 2 d, showed a considerable decrease in the concentration of residual aflatoxin B_1 compared with that found in control dishes which contained medium and aflatoxin B_1 but no cells. The resistance of the isolated cells and of the liver *in vivo* could be associated with a failure of the new cell population to metabolise aflatoxin B_1 specifically to an active metabolite. Such metabolism seems necessary for the inhibition of hepatic nucleic acid synthesis in *in vitro* systems[8], which correlates with the toxic effect of aflatoxin *in vivo*[4]. The results given in Table 2, however, show that neither the capacity of the microsomes to activate aflatoxin B_1, nor the susceptibility of nuclear RNA polymerase to the active metabolite, is affected by feeding the toxic diet. Other possibilities are that the resistance could be associated with the rapid repair of nuclear lesions, or with detoxification by other cellular factors. Our observation that the reduced glutathione content of the liver doubles as a result of 6

Table 2 Activation of aflatoxin B_1 *in vitro* to a form inhibitory to RNA polymerase *in vitro*

Source of fraction			RNA polymerase activity (d.p.m. incorporated per mg DNA)
Nuclei	Microsomes	NADPH	
CON	CON	–	55,500
CON	CON	+	19,200
CON	TOX	+	19,500
TOX	TOX	–	52,800
TOX	TOX	+	21,700
TOX	CON	+	19,700

TOX, animals fed toxic diet for 6 weeks (see Table 1): CON, animals fed control diet for 6 weeks. Assays carried out as described by Godoy and Neal[9]. Fractions were used in two successive incubations. First incubation, for activation of aflatoxin B_1: medium contained 50 μmol KCl, 150 μmol Tris-HCl *p*H 7.4, 12.5 μmol $MgCl_2$, 20 μl DMSO containing 10 μg aflatoxin B_1, 0.4 ml microsomal suspension (3.2 mg microsomal protein in 0.15 M KCl) and 1 ml nuclear suspension containing 150–200 μg DNA (in 0.44 M sucrose/1 mM $MgCl_2$). 0.75 μmol NADP, 10 μmol glucose-6-phosphate and 0.5U glucose-6-phosphate dehydrogenase were added to incubations as indicated. After 10 min incubation at 37 °C in air, nuclei were spun down at 4 °C and supernatant was decanted. Second incubation: Mg^{2+}-primed RNA polymerase activity of nuclei was determined as incorporation of label from ^3H–UTP during 10 min at 37 °C. Results are means of triplicate assays, variation < ± 10% of mean.

weeks of feeding with aflatoxin (unpublished) could be relevant to the detoxification process. •

We thank Dr Alan Paine for advice on cell culture techniques.

H–2 compatibility requirements for T suppressor cell functions induced by Friend leukaemia virus

GENE products of the major histocompatibility complex (H–2 in the mouse) regulate cellular interactions between various immunocompetent cell types[1–4] as well as interactions between thymus-dependent (T) killer cells and chemically altered or virus-infected target cells[5,6]. Identity of certain determinants of H–2 seems to be necessary for effective interaction between any two participating cell types. We have investigated the H–2 compatibility requirement for the suppressive interaction between T suppressor cells and mitogen-responsive cells in cultures infected with Friend leukaemia virus and find that there is an H–2D compatibiilty requirement. However, the H–2 restriction we observe is mediated by a third cell type which we term an 'interfering cell'. The two principal cell types, that is, T suppressor cells and mitogen-responsive cells, can interact even if they do not share any H–2 determinants provided that the interfering cells are functionally absent. This may provide an alternative explanation for the role the major histocompatibility complex in regulating other immune cellular interactions.

Friend leukaemia virus complex (FV) induces erythroleukaemia and causes severe immunosuppression in genetically susceptible adult mice[7]. FV mediates immunosuppression, at least in an *in vitro* model, by activating T suppressor cells[8,9]. The T suppressor cells prevent T and bursa equivalent-dependent (B) cells from responding to a variety of mitogens in the presence of FV. The population size and/or function of these T suppressor cells in the body are under the regulatory influence of marrow-dependent (M) cells, since treatment of genetically resistant C57BL/6 mice with ^{89}Sr to destroy M cells induces the generation or appearance of T suppressor cells. T suppressor cells are also present in thymuses of infant C57BL/6 mice before the maturation of M cells. Mixtures of spleen cells from normal C57BL/6 mice, which have no detectable T suppressor cells, with spleen cells from ^{89}Sr-treated C57BL/6 mice are suppressed by FV *in vitro*[9]. We have taken advantage of such a mixture protocol to determine the H–2 compatibility requirements between T suppressor cells and mitogen-responsive cells.

Spleen cell suspensions containing mitogen-responsive cells (but not suppressor cells) from 'resistant' B10.D2, B10.A, and C57BL/6 mice responded well to the mitogen, concanavalin A, in the presence of FV (Table 1). Addition of small numbers (10^5) of H–2-identical or semi-allogeneic 'susceptible' spleen cells, containing T suppressor cells, to the 9×10^5 spleen cells of 'resistant' mice resulted in suppression of mitogenesis by FV. The suppressor cells functioned after exposure to 800 R of γ rays *in vitro*.

However, suppression across the H–2 barrier was not effective. Adult DBA/2 (H–2^d) spleen, marrow or thymus cells failed to suppress C57BL/6 (H–2^b) spleen cells. The data of Table 1 and Fig. 1 clearly indicate that donors of cell suspensions containing T suppressor cells and the mitogen-responsive cells must share the same H–2D determinant for FV to induce immunosuppression *in vitro*. The critical experiment was the differential ability of 129 and DBA/2 spleen cells to suppress HTG lymphocytes (Fig. 1).

One explanation for the H–2 compatibility requirements for cytolytic T cells and target cells has been that T cells react to 'altered self'[5,6]. Indeed, antibodies directed against H–2D determinants inhibited cytolysis of syngeneic tumours by sensitised T cells[10,11], and an H–2D compatibility requirement for cytolytic T cells against Friend virus-induced tumours was observed[12]. An H–2D-end compatibility requirement for T suppressor cells has also been previously described[13]. In the AKR leukaemia model, T suppressor cells were restricted both by H–2 and non-H–2 differences because of an 'allogeneic effect'[14]. Another explanation for H–2 restriction has been the 'clonal selection' of T cells reactive to antigens presented on cells of a given H–2 type[15].

The H–2 compatibility requirement does not exist for

Fig. 1 H–2D compatibility requirements for mitogen-responsive cell-T suppressor cell interaction. See Table 1 for details of protocol. Open squares are H–2^d determinants; solid squares are H–2^b determinants; hatched squares are H–2^k determinants.

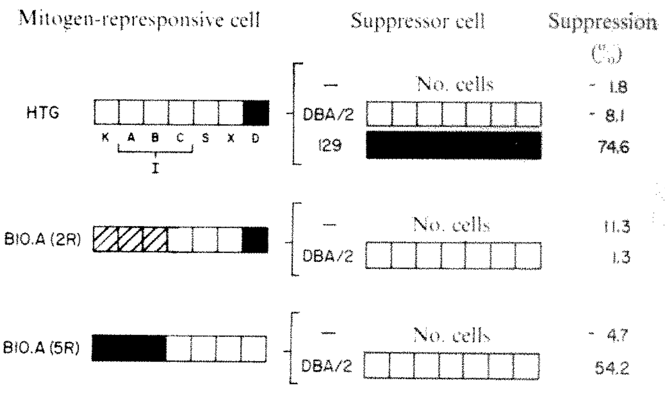

Table 1 H-2 compatibility requirements for Friend virus-induced suppression of mitogen-responsive cells by T suppressor cells

§The lower case refers to the H-2 determinants K, IA, IB, IC, S and D.

cellular cooperation in antibody responses[16–18] or in T cell-mediated lysis[19] when the cell donors are tolerant to the antigens of the target cells. Even H-2-less cells can be lysed if concanavalin A is added to the reaction mixture, presumably to overcome a deficiency in 'recognition' of the target cell by the killer T cell[20]. In appropriate conditions *in vivo*, that is, transfer of 'resistant' marrow cells into irradiated 'susceptible' infant mice previously infected with FV, we had not observed any H-2 restriction for immunosuppression in the FV model[21]. Therefore, we considered the possibility that a third cell type, other than the T suppressor cell or the mitogen-responsive cell, was responsible for the H-2 restriction. If that were true, one may be able to overcome the H-2D compatibility requirement by treatments *in vitro* and *in vivo* which would eliminate the interfering cell.

We were able to overcome the H-2D restriction simply by irradiating the cell suspension containing T suppressor cells (Table 2). Moreover, spleen cells from an unhealthy DBA/2 donor mouse with a tiny thymus were capable of suppressing C57BL/6 mitogen-responsive cells. This alerted us to the possibility that adrenal steroids may remove the interfering cell, since steroids do cause severe hypoplasia of the thymus. Indeed, spleen cells from DBA/2 mice injected 2 d earlier with 2.5 mg cortisol were able to suppress mitogen-responsive cells of C57BL/6 mice in the presence of FV. Spleen cells from infant DBA/2 donors also suppressed H-2-incompatible C57BL/6 cells. To complete the analysis, we were able to 'reconstitute' the H-2 compatibility requirement by mixing adult untreated DBA/2 spleen cells containing the interfering cell with DBA/2 spleen cells devoid of such cells (Table 2).

We considered the possibility that an 'allogeneic effect' produced by interaction between interfering cells and H-2D-incompatible mitogen-responsive cells[14] might have been responsible for these findings. However, semi-allogeneic F1 hybrid spleen cells from susceptible donors were able to suppress parental-strain spleen cells from resistant donors (Table 1). This result indicates that allogeneic effect could not be responsible for failure of H-2-incompatible cells to interact in this system.

The complex immune cellular interactions so far detected

Table 2 Effect of source of DBA/2 spleen cell suspension on suppression of C57BL/6 mitogen-responsive cells

*Adult, 12 weeks of age; infant, 3 d of age. Spleen cells were exposed to 1000 R of ^{137}Cs γ rays *in vitro* just before initiation of culture. 10^5 DBA/2 cells were added to 9 × 10^5 C57BL/6 spleen cells from adult mice with con A and/or FV as described in legend for Table 1. Adult DBA/2 mice were injected with 2.5 mg cortisol (or saline vehicle) 2 d before the spleen cells were collected. DBA/2 mice are susceptible to FV and were the source of T suppressor cells.

†,‡See Table 1.

in the Friend leukaemia virus model are depicted in Fig. 2 and are summarised as follows. Marrow-dependent cells of genetically resistant mice, but not of genetically susceptible mice, restrict the numbers and/or functions of T suppressor cells *in vivo*[8,9] (Fig. 2*a* and *b*). T suppressor cells, even in the presence of syngeneic interfering cells, inhibit the proliferation of H-2D-identical mitogen-responsive cells in cultures infected with FV (Fig. 2*c*). Interfering cells, syngeneic with the T suppressor cells, prevent the suppression of H-2-incompatible mitogen-responsive cells (Fig. 2*d*). T suppressor cells, in the absence of syngeneic interfering cells, are quite capable of inhibiting the proliferation of H-2D-incompatible mitogen-responsive cells (Fig. 2*e*). Finally, mitogen-responsive cells of genetically resistant or susceptible mice proliferate well when exposed to FV, if no T suppressor cells are present in the mixture[8,9].

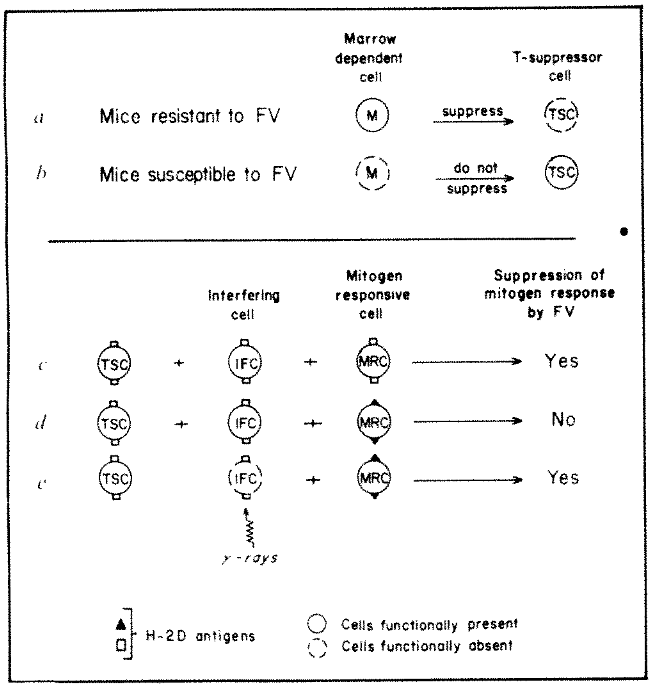

Fig. 2 Immune cellular interactions in the Friend leukaemia virus model. *a*, *b*: *in vivo*. *c*, *d* and *e*: *in vitro* cultures containing con A and FV.

One does not have to invoke 'altered self' or 'dual recognition' hypothesis to explain the H-2 compatibility requirements, at least in this instance. It is conceivable that the use of 'tolerant' cell populations to overcome the H-2 compatibility requirements in other studies[16-19] could be explained by the elimination of an interfering third cell. The mechanism of interference by the third cell type has yet to be determined, but the release of receptors for alloantigens[22] is a hypothesis worth testing.

Sister chromatid exchanges induced by mutagenic carcinogens in normal and xeroderma pigmentosum cells

XERODERMA pigmentosum (XP) is a human disease characterised by sensitivity to sunlight[1], a high incidence of skin cancer[1] and a deficiency in DNA repair[2]. Investigations of DNA damage and repair in XP cells exposed to chemical carcinogens[3-8] had led to the classification of these agents in two groups: those in which damage can be repaired by apparently normal levels of excision repair (for example, monofunctional alkylating agents) and those in which it cannot (for example, 4-nitroquinoline-1-oxide) (Table 1). In XP cells, normal excision of MMS[9] or MNNG[10] damage is correlated with normal levels of chromosome aberrations, and reduced excision repair of 4NQO damage is correlated with high levels of chromosome aberrations[9], indicating that unrepaired damage is correlated with high levels of aberrations. It has recently been found that although sister chromatid exchanges (SCEs) differ from aberrations in many ways, they are far more sensitive indicators of chromosomal damage[11]. We therefore considered that a comparison of excision repairability with the yields of SCEs induced by chemicals might be informative in elucidating mechanisms of SCE formation. The results indicate that, contrary to the results with aberrations, the frequency of induced SCEs is higher in XP cells than in normal cells whether or not XP cells can perform normal amounts of excision repair of the chemically-induced damage. The data indicate that the lesions and/or subsequent events that give rise to chromosome aberrations are different from those leading to sister chromatid exchange and that SCE formation in XP cells

Table 1 Relative levels of excision repair (damage excision, unscheduled synthesis, or repair replication)* in xeroderma pigmentosum cells damaged by various chemicals or ultraviolet light

Mutagen	Level of excision repair in XP cells (group A) (% of normal)	Reference
Ultraviolet light	<5%	2
4-nitroquinoline-1-oxide	<5%	4,6,7
Mitomycin C	reduced	20
Dimethyl sulphate	100%	30
Methyl methane sulphonate	100%	3,8
Ethyl methane sulphonate	100%	8,30
N-methyl-*N*-nitro-nitrosoguanidine	100%	3,6,7
Ethyl nitrosourea	100%	30

*These measurements of repair replication and unscheduled synthesis were all made during the first hours after exposure and represent measurement of the more rapidly repaired damage.

is the most sensitive mammalian system yet described for detecting possible genetic effects of chemicals.

Human fibroblasts from a normal donor (GM637, Human Genetics Cell Bank, Institute for Medical Research, Camden, New Jersey) and from an excision-repair deficient xeroderma pigmentosum patient (XP12RO, Complementation Group A, donated by A. Veldhuisen, TNO Rijswick, The Netherlands) were treated with various concentrations of the chosen chemicals.

So that we could see sister chromatid exchanges, the cells were then grown for two rounds of DNA replication in the presence of 5-bromodeoxyuridine (BUdR) to produce "harlequin chromosomes" (ref. 12) in which the sister chromatids stained differentially.

The control yields of SCEs in normal and XP12RO cells are similar to one another (Table 2) and fall within the range previously reported for many cell types[13–16], with the exception of the very high spontaneous yields in cells from patients with Bloom's syndrome[14]. The control yields in the present experiments, in which the cells were exposed to 20 μM BUdR, are somewhat higher than the yields found after exposure to 10 μM BUdR (ref. 15), which is consistent with the observation that some of the SCEs are caused by the BUdR itself[17]. Once exposed to the chemicals, however, XP12RO cells contain higher numbers of SCEs than normal cells. This occurs even at concentrations too low to have detectable effects on normal cells (Table 2). The difference between normal and XP cells is most striking when MNNG (Fig. 1) is used, but is clearly evident for all the chemicals (Table 2). Kato noted that MNNG did not increase SCEs in normal Chinese hamster cells[31].

Since XP cells cannot perform excision-repair of damage induced by 4NQO, the elevated levels of SCEs, as well as the elevated levels of chromosome aberrations[9,10], and increased cell killing[6] observed after 4NQO treatment can be correlated with unrepaired damage. Such correlations also exist for ultraviolet damaged XP cells[18,19].

The same correlation cannot be made with damage induced by MMS, EMS, ENU, DMS, and MNNG, however, because XP and normal cells seem to undergo similar amounts of excision repair after exposure to these agents (Table 1). Nor can the correlation be made with damage induced by MMC because XP cells, which have been reported to be defective in unscheduled synthesis[20], respond as repair proficient cells for the induction of chromosome aberrations[20].

If XP12 cells are defective only in excision repair, then

The cell lines were both transformed by SV40 and were chosen because of their high rate of cell division; previous studies[19,28] have demonstrated that transformation does not alter the DNA repair characteristics of human fibroblasts, although it does slightly increase the spontaneous frequency of sister chromatid exchanges in various cell types (normal, galactosaemic, Lesch–Nyhan and XP)[15]. Cells were grown in 75-cm^2 plastic flasks containing Eagle's minimum essential medium (MEM) with Earle's salts and 15% foetal calf serum. Twenty-four hours after the cells were recultured, BUdR (final concentration 20 μM) and the carcinogens were added to the flasks. The cells were then grown for two rounds of DNA replication (48 h) so that both strands of one chromatid and one strand of its sister would contain BUdR. Once BUdR had been added, the cells were kept in total darkness except during handling procedures, which were carried out in subdued light from incandescent bulbs to minimise any effects caused by the photolysis of BUdR-containing DNA. The yields of SCEs under these conditions were no higher than those obtained under total darkness. The carcinogens used included ethyl methane sulphonate (EMS), methyl methane sulphonate (MMS), *N*-methyl-*N*-nitro-nitrosoguanidine (MNNG), ethyl nitrosourea (ENU), dimethyl sulphate (DMS), 4-nitro-quinoline-1-oxide (4NQO), and mitomycin C (MMC). These were dissolved in medium (EMS, MMS), in phosphate-buffered saline at *p*H 7.2 (MNNG, DMS) or at *p*H 6.0 (ENU), in ethanol (4NQO), or in water (MMC) and then diluted with MEM to obtain the final concentrations that were to be added to cells. Colcemid (final concentration 2×10^{-6} M) was added to each flask for the final 6 h of exposure of BUdR. The mitotic cells were then shaken off the flasks, centrifuged and treated with a hypotonic solution (0.075 M KCl) for 6 min to spread the chromosomes. The cells were centrifuged, and the pellet was fixed and washed twice in 3:1 methanol/acetic acid. The fixed cells were concentrated by centrifugation and dropped on to dry microslides. The slides were stained in 5 μg ml^{-1} of Hoechst 33258 in phosphate-buffered saline at *p*H 6.8 (ref. 29) and then washed in distilled water, thoroughly dried, and mounted with a drop of Sorensen's buffer (*p*H 6.8) and a coverslip. They were then exposed to light one and a half inches from a high pressure mercury lamp (625 J m^{-2} s^{-1}) for 45 s to 5 min to allow the photochemical reaction to take place. The coverslips were then removed and the slides washed in distilled water, drained and then stained in 4% Giemsa (Gurr's R66) in M/15 Sorensen's buffer at *p*H 6.8, dried, and mounted in DePeX.

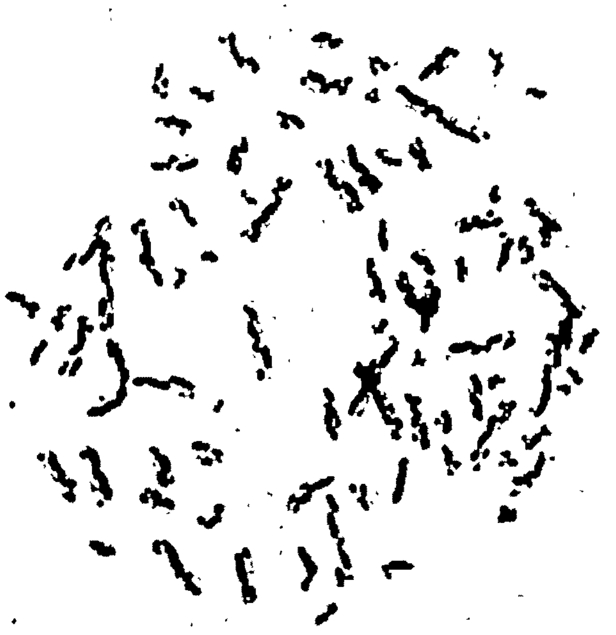

Fig. 1 A polyploid XP cell showing many SCEs after exposure to MNNG.

the increased yield of SCEs in such cells would be caused by unexcised damage in DNA. According to such a hypothesis, the results obtained with the alkylating agents would indicate that there is a minor fraction of the total damage remaining unexcised in each case. This fraction would be too small to be resolved by the usual measurements of repair replication or unscheduled synthesis, which have been made immediately after exposure to mutagens[3-6], as well as too small to give rise to higher than normal amounts of chromosome aberrations[9,10], or cell killing[8]. An increase in SCEs, however, is induced since they are very sensitive indicators of unexcised damage in DNA.

These observations, and the apparent lack of correlation between SCE frequencies and either chromosome aberration frequencies or cell killing (in the case of the alkylating agents) raise questions about the biological significance of SCE formation. SCEs differ in many respects from chromosome aberrations: SCEs are induced at high frequencies by chemicals at concentrations that induce few aberrations[11]; SCEs are not markedly increased by low doses of ionising radiations[21], whereas aberration frequency is; SCEs saturate with increasing doses of ionising radiation[22], and with tritiated thymidine[23]; SCEs react differently to treatments with caffeine than do chromosome abberrations[24,25]; SCEs are not correlated in any consistent fashion with the increased aberrations seen in the human diseases, Bloom's syndrome[14] ataxia telangiectasia[18] and Fanconi's anaemia[26], since SCE levels are very high in Bloom's, normal in ataxia telangiectasia, and reportedly low in Fanconi's anaemia.

SCEs may thus be the result of fundamentally different cellular events and lesions than are chromosome aberrations. Since the latter are associated with cell death, SCEs may be more representative of events compatible with cell survival, including mutagenesis. Although the majority of SCEs are probably genetically neutral because equal amounts of homologous chromatids are exchanged, some could conceivably be involved in deletion, insertion or frame shift mutagenesis because of a slight inequality of the exchanged material. Indeed, Magni and von Borstel[27] have found that mutation in yeast is correlated with meiotic exchange.

The sensitivity of XP cells we have observed indicates that whatever may be the genetic significance of SCEs, their measurement in XP cells is the most sensitive indicator yet found for detecting chromosomal effects of potential mutagens and carcinogens in mammalian cells.

This work was done under the auspices of the US Energy Research and Development Administration.

Drugs which disrupt microtubules do not inhibit the initiation of lymphocyte activation

LYMPHOCYTES are activated to grow and divide when mitogens such as plant lectins bind to surface receptors. Several hypotheses have been advanced to explain how a signal which results from the interaction of an activating ligand with its receptors, may be transduced across the membrane to initiate cell activation[1]. Recently Edelman and co-workers proposed a model in which a complex, composed of receptor, microfilaments and microtubules serves as a regulator for lymphocyte mitogenesis[2-4]. From experiments in which colchicine, when added to stimulated cultures at various time intervals, gradually lost its capacity to suppress subsequent DNA synthesis over 30–40 h, it was concluded that drugs which disrupt microtubules block lymphocyte activation at the point at which a lymphocyte becomes committed to undergoing growth and division[5,6]. However, other similar experiments[7,8] showed that colchicine was effective in suppressing DNA synthesis up to 48 h after the addition of mitogen. If indeed the microtubules are involved in the initiation of lymphocyte activation, then the disruption of these cytoplasmic structures should also affect cellular events which occur before DNA synthesis[9].

Here we report that two microtubule active drugs, colchicine and vinblastine, failed to affect events which occur early in stimulated lymphocytes, namely the increased RNA synthesis, the synthesis of a specific protein, lymphotoxin, and the increased turnover of membrane phospholipids. These results strongly suggest that microtubules are

Table 1 The effect of colchine or vinblastine on the concanavalin A-induced incorporation of ^{3}H-thymidine into DNA*

Concentration of drugs (M)	c.p.m. (10^{-3}) per 4 × 10^5 lymphocytes†

10^{-5}	13.0±5.4	16.9±5.6
10^{-6}	18.3±0.9	17.7±5.1
10^{-7}	29.4±2.1	35.5±10.2
10^{-8}	39.8±7.9	52.3±3.5

* Incorporation into unstimulated lymphocytes: 0.6±0.2.

† Data given are means of triplicates ± s.d. 4 × 10^5 lymphocytes were cultured in microplates in 0.2 ml DME supplemented with 10% FCS in a water-saturated air–CO_2 atmosphere to maintain a *p*H of 7.2–7.4. Concanavalin A (2 μg) and the microtubule active drugs were added at the beginning of the experiment. After 54 h of culture 1μCi ^{3}H-thymidine (specific activity 1 Ci mmol^{-1}) was added and the lymphocytes were incubated for further 16 h. DNA was collected with an automated sample harvester and the radioactivity retained on the glass filters was measured by liquid scintillation counting.

not involved in the process which is responsible for the commitment of lymphocytes.

The experiments were performed with lymphocytes from the mesenteric lymph nodes of 8–12-month-old rabbits which were grown under SPF conditions. For measuring DNA synthesis, cells were cultured at 2×10^6 ml^{-1} in Dulbecco's modified Eagle's medium (DME) supplemented with 10% calf serum (FCS) in microtitre plates. To determine RNA synthesis, lymphocytes at 1×10^7 ml^{-1} were cultured under similar conditions. The incorporation of phospholipid precursors into lecithin was measured in lymphocytes, cultured at 10^7 cells ml^{-1} in DME supplemented with 2.5 mg ml^{-1} defatted albumin. Lymphotoxin was tested in supernatants from lymphocytes cultured at 10^7 ml^{-1} in DME+10% FCS for 24 h. In all experiments the microtubule active agents were added together with concanavalin A at the beginning of each experiment.

Table 1 shows that colchicine and vinblastine suppressed the incorporation of ^{3}H-thymidine into DNA of lymphocyte cultures stimulated with concanavalin A. Concentrations of 10^{-8} M and higher proved to be active. At concentrations of 10^{-5} the suppression of DNA synthesis ranged between 57 and 78% (mean 67%) with colchicine and between 63 and 82% (mean 72%) with vinblastine. In a concentration range up to 10^{-5} M both drugs were not toxic for lymphocytes after 4 and 20 h of culture, as assessed by the exclusion of trypan blue. At concentrations of 10^{-4} M, vinblastine started to be cytotoxic which was also found with colchicine at concentrations higher than 10^{-3} M.

The incorporation of ^{3}H-uridine into RNA becomes measurable early in the course of activation. From measurements taken at 4 or 22 h, neither drug, at concentrations up to 10^{-5} M influenced the uptake of ^{3}H-uridine into RNA of stimulated lymphocytes (Table 2). A remarkable suppression of ^{3}H-uridine uptake was, however, always observed in unstimulated lymphocytes after 22 h. These data would favour the notion that colchicine as well as vinblastine acts on the permeation of ^{3}H-uridine into the cell, which is overcome in stimulated lymphocytes.

Table 3 The effect of colchicine and vinblastine on the secretion of lymphotoxin

Concanavalin A	Colchicine (10^{-5} M)	Vinblastine (10^{-5} M)	Inhibition of cell growth (%)
—	—	—	0
—	+	—	9.5±0.5
—	—	+	10.3±0.5
+	—	—	20.4±1.0
+	+	—	25.3±1.3
+	—	+	28.9±1.5

Data are means of quintuplicates ± s.d. Lymphocytes were cultured at cell densities of 10^7 cells ml^{-1} in DME supplemented with 10% FCS. Con A (10 μg ml^{-1}) and microtubule-disrupting drugs were added at the beginning of the experiments. After 24 h the lymphocytes were removed by centrifugation for 10 min at 350*g* and the cell-free supernatants (containing lymphotoxin) were collected. As target cells for the action of lymphotoxin a permanent cell line F1 (derived from the human placenta) was used. Lymphotoxin activity was determined by the inhibitory effect on the ^{3}H-thymidine incorporation into the target cells.

Lymphocytes which are activated by plant lectins are able to mimic the immune functions which are physiologically expressed after antigenic stimulation. In T lymphocytes, which are activated by concanavalin A, this includes the synthesis of biologically active proteins, the lymphokines. The secretion of one of the lymphokines, namely lymphotoxin, which causes impairment of cell proliferation or cell death was therefore measured in supernatants of lymphocytes stimulated with concanavalin A. After a culture period of 24 h lymphotoxin was present in stimulated cultures but not in controls (Table 3). The addition of colchicine or vinblastine at concentrations of 10^{-5} M only marginally affected the production of lymphotoxin, when measured by its capacity to suppress cell growth. Control incubations cultured in the presence of the microtubule active drugs alone also caused some reduction of target cell proliferation which, however, was much less apparent than those caused by the lymphotoxin. The measurement of growth reduction through biologically active substances in the presence of drugs which themselves inhibit proliferation may be difficult to interpret. Therefore the direct lytic effect of lymphokines (measured

* Data are given as means of triplicates ± s.d.

† Data given are means of three separate experiments ± s.d.

Lymphocytes (2 × 10^6) were incubated in 0.2 ml DME, supplemented with 10% FCS under conditions described in Table 1. After 2 or 20 h, 1 μCi ^{3}H-uridine (50 mCi mmol^{-1}) was added and the cells were cultured for additional 2 h. The cells were then collected as described in Table 1.

by the release of ^{51}Cr) was analysed with lymphotoxin preparations, after separation by chromatography on Sephadex G-150. The lytic effect of partially purified lymphotoxin from lectin-stimulated lymphocytes, which was eluted with 70,000–90,000 molecular weight substances, cultured with or without 10^{-5} M colchicine or vinblastine, was identical (18±5% after 4 h).

Very early in lectin-activated lymphocytes, the turnover of phospholipid fatty acids increased (10–12). Concentrations of 10^{-4} M of colchicine or of 10^{-5} M of vinblastine were unable to suppress the incorporation of ^{14}C-oleate into lecithin of con A-stimulated lymphocytes when measured after 4 h of incubation (Table 4). In four separate experiments, where colchicine or vinblastine were present at concentrations of 10^{-5} M, the incorporation of ^{14}C-oleate into lecithin of con A-stimulated lymphocytes reached 99±11 (colchicine) or 98±7 (vinblastine) percent of controls (data given with standard deviation). The turnover of the phospholipid fatty acids may also be followed by labelling the long chain fatty acids biosynthetically with ^{14}C-acetate[10]. As shown in Table 4, colchicine at a concentration of 10^{-4} M, or vinblastine at a concentration of 10^{-5} M caused no decrease of the ^{14}C-acetate uptake into lecithin of con A-stimulated lymphocytes. However, at concentrations higher than 10^{-5} M, vinblastine markedly decreased the incorporation of ^{14}C-acetate into lecithin of resting lymphocytes. These findings suggest that vinblastine in high concentrations primarily interferes with the permeation of acetate into lymphocytes.

Lymphocytes (10^7) were incubated at 37 °C in 1 ml HEPES-buffered DME supplemented with 2.5 mg defatted albumin.

^{14}C-oleate (10 nmol) or 25 nmol ^{14}C-acetate were added at the beginning of the experiment. After incubation the lipids were extracted, separated by thin-layer chromatography as described previously, and incorporation into lecithin was measured by liquid scintillation counting[10].

When lymphocytes are activated by mitogens as the lectin concanavalin A, a sequence of metabolic events is initiated which finally leads to cell division. Our results confirm earlier reports that colchicine or vinblastine at concentrations which disrupt the microtubular system suppress incorporation of ^{3}H-thymidine into lectin-stimulated lymphocytes. Addition of colchicine 30 h after the mitogen proved to suppress subsequent DNA synthesis to the same degree as when concanavalin A and colchicine were added together at the beginning of an experiment (data not presented). Cellular changes, which occur before the initiation of DNA synthesis were not affected in stimulated lymphocytes in the presence of colchicine or vinblastine. The incorporation of ^{3}H-uridine into stimulated lymphocytes was not suppressed at concentrations of 10^{-5} M. Similar results have been reported recently by Betel *et al.*[8]. Furthermore, the secretion of lymphotoxin which is induced in activated lymphocytes, was not decreased in a similar concentration range. In addition, cellular changes which are induced very rapidly after the binding of a mitogen to the surface receptors, that is, the increased turnover of the membrane phospholipids, were similarly not inhibited by concentrations of colchicine as high as 10^{-4} M or 10^{-5} M vinblastine. Thus our data are not compatible with the concept that microtubule-disruptive agents prevent the initiation of lymphocyte activation. It therefore seems unlikely that the putative association of receptor molecules with microtubules plays a large part in the signal transmission in concanavalin A-activated lymphocytes.

Habitat values and endemicity in the vanishing rain forests of Sri Lanka

TROPICAL forests are among the most seriously threatened terrestrial environments, and while biologists and conservationists argue for preservation, the plunder continues virtually unabated[1]. In Sri Lanka (Ceylon), for example, the southern rain forests and montane forests contain a rich assemblage of endemic animals, but despite the protestations of the local conservationists, deforestation is rapidly destroying these habitats. One reason for govenment inaction in Sri Lanka, as elsewhere, may be the inability of conservationists to make an objective case for the value or uniqueness of these forests. In this paper, we propose some new approaches to this old problem.

Habitat value judgments must be quantitatively expressed if they are to seem credible in this technological age. The dilemma is that all estimates of quality or value are inextricably rooted in cultural, ethical and aesthetic assumptions, which are themselves value judgments. So-called objectivity in such matters is obviously impossible even though agreement is often achieved, at least within a culture. The logical and epistomological problems notwithstanding, we suggest in this paper some indices of habitat value that have the virtues of simplicity, flexibility and (to us, at least) intuitive appeal. The simplest and most general form of the index is

$$V_i = (Q_i/A_i)\,1{,}000 \qquad (1)$$

when A_i is area of the *i*th habitat and Q_i is the number if species in

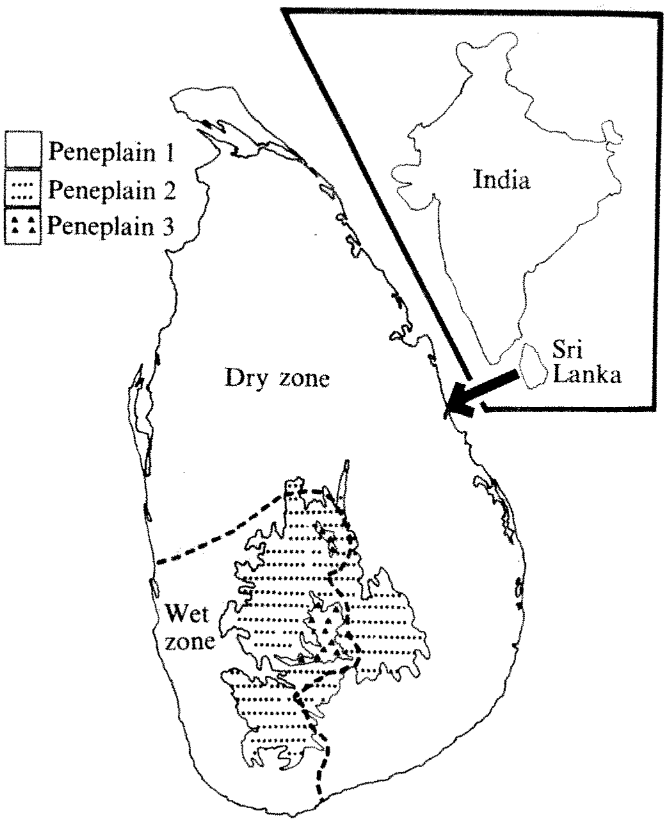

Fig. 1 The island of Sri Lanka showing the three peneplains and the dry and wet zones. The dashed line encloses the wet zone. The dry zone of peneplain 1 corresponds to region A; the wet zone of peneplain 1 to region B; peneplain 2 corresponds to region C; peneplain 3 corresponds to region D.

the *i*th habitat which have some quality deemed desirable. Depending on the location and purpose, "desirable" species could be those that are endemic, rare, large, or ancestors of cultivars, to list a few examples.

Under some circumstances, it would be appropriate to replace Q_i with a term that is the sum of desirability rankings. For example, endangered species occurring nowhere else might receive a rank of 10; an endangered species that occurs in the other habitats or regions might receive a rank of 5; rare species, but not officially endangered species, might receive a rank of 1. A similar but less arbitrary procedure is to employ the index

$$V'_i=\left(\Sigma\frac{1}{A_j}\right)1{,}000 \quad . \qquad (2)$$

when A_j is the area of the total geographic range of the *j*th species occurring in habitat *i*. This index has the advantage of being free of official judgments about the status of species and incorporating the commonest criterion for concern, namely, geographically restricted distribution. This approach would not be as appropriate as the ranking method for organisms, like some birds, which can simultaneously be both rare and widespread.

An important feature of index (1) (but not index (2)) is that the value of a habitat increases as the area it occupies decreases, even when there is no change in the number of species. Therefore, this index will be especially useful in comparing large areas with smaller, putatively more valuable ones. Conversely, it will not be very helpful when considering a large chunk of undifferentiated wilderness. Conservation arguments for the latter will often need to stress other considerations, including the space requirement of large, migratory species, the advisability of preserving large amounts of genetic variation in some species[2], and the needs of present and future generations for wilderness.

Figure 1 is a map of Sri Lanka showing the major biogeographical regions as defined by altitude, rainfall, and flora[3–8]. The island has been divided into three 'peneplains'. This term refers to well-marked plains of erosion. The lowest peneplain is by far the largest and surrounds the south-central hill country. The average elevation of this area is around 30 m, but hills within it reach 125 m. The second peneplain rises as a steep step from the first and averages around 400–500 m. The third peneplain is around 1,650 m.

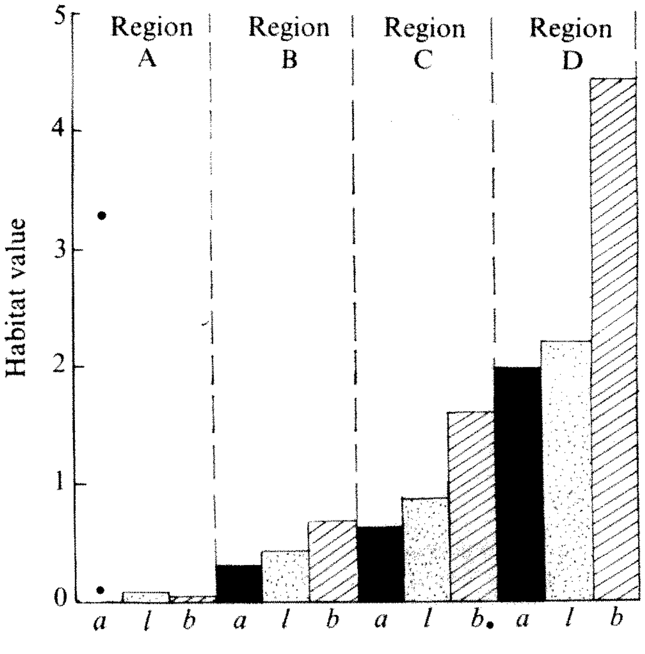
Precipitation is dependent on the trade winds and is seasonal. Two monsoons (rainy seasons) occur in Sri Lanka, the south-west (May to September) and the north-east (November to February). The rains of the south-west monsoon tend to be contained in the southern and south-western part of the island by the central mountain massif, while the north-east monsoon brings rains to both areas. As a consequence, two humidity 'zones' can be distinguished: the dry zone, that part of the island that receives only the north-east monsoon rains and an annual rainfall of under 190 cm; the wet zone which receives both monsoons and has an annual rainfall of over 190 cm. The second and third peneplains lie within the wet zone while the first peneplain is represented in both zones.

Based on the above geological and climatic zones, most authors have subdivided Sri Lanka into four biogeographic regions. We refer to these as follows: region A, the dry northern and eastern areas of the first peneplain or the dry zone; region B, the humid south-western part of the first peneplain; region C, the second peneplain; and region D, the third peneplain. Botanists have recognised floristic groupings that tend to reinforce this classification.

Recently, one of the authors (F.R.S.) spent 18 months on the island studying the distribution of reptiles and amphibians. The data indicate that the rain forest areas together with the montane regions in the south contain more endemic forms than any other part of the island. A similar pattern was observed in the avifauna. Cursory investigation of the insects and fishes seems to demonstrate a parallel distribution pattern.

Table 1 gives a list of endemic amphibians, lizards, and birds of Sri Lanka tabulated according to their occupation of the above defined regions. The methods on which the taxonomic decisions are based will be described elsewhere. We have chosen birds, lizards and amphibians as examples because information on their distributions is superior to that of other groups; for

Fig. 2 Habitat values (index (1)) of the four biogeographic regions in Sri Lanka: *a* indicates amphibia; *l* indicates lizards; *b* indicates birds.



example, Carl Gans, in the course of his work on the uropeltid snakes, is finding the published distributions for snakes to be very inaccurate. The available data[9–13] suggest that the patterns observed for the lizards, amphibians and birds ought to be reflected in the freshwater fishes and mammals.

In Table 2, we apply the habitat value indices to the Sri Lanka data; we consider only the species that occur nowhere else but on Sri Lanka. These endemics have considerable biogeographic and ecological significance because most of them are phylogenetic relicts whose closest relatives occur in South Africa, Madagascar, the Comoro Islands, Malaysia, and Sumatra. In employimg V_i' we should, strictly speaking, base our calculations on all the species on Sri Lanka, whether endemic or not. We chose not to do this for two reasons: first, the distributions of many forms is poorly

known; and second, the results would not be changed significantly because of the very small value of $1/A$ for non-endemic species relative to endemic species.

For the amphibians and lizards, the two indices give nearly identical results. For the birds, however, the V_i' values are relatively small because of the wider distributions of the birds compared to the amphibians and reptiles. In Fig. 2, we illustrate the V_i values for the regions described above. In words, the meaning of the figure is that the highlands are approximately 50 times more valuable than the lowlands because the area available is so small and the number of desirable (endemic) species in the highlands is so high. The pattern of distribution we have illustrated for the endemic species also holds true at the generic level. Of the nine endemic genera of lizards and amphibians, eight were confined to the moist or montane zones, while only one genus occurs in all zones. Current data[9,14,15] on the freshwater fishes and mammals indicate a similar trend at the generic level in these groups.

The data in Table 2 reinforce the opinion held by many biogeographers' that the southern forests and highlands of Sri Lanka are a unique biological treasure trove of evolutionary relicts[16]. The habitat values tell the story. Darlington[17] suggested that the number of relict forms on the island may be no more than occur in the southern part of India, but our recent studies on the reptilian and amphibian fauna and published data[9,10] seem to indicate that Sri Lanka does indeed have a much higher number of relict forms than continental south India. Birds may be an exception, however, because of their greater mobility and corresponding higher rates of gene flow and colonisation.

The affinities of the endemic genera of reptiles and amphibians (some have congeners in Malaysia and Sumatra, others have their closest relatives in Africa and Madagascar) are noteworthy in light of recent attempts to interpret biogeographic patterns in terms of continental drift[18]. While the majority of total faunal representation is markedly Indian in origin, the percentage representation of the Indian element is much lower in the montane areas than in the lowland dry zone. Cruz[15], in our opinion, rightly argues that the montane zones represent the most conservative elements of the Sri Lankan fauna, those that have been least influenced by recent invasions from the Indian mainland.

The habitat values of the wet, montane regions, while relatively high, are quite conservative because the percentage of land that remains forested in the wet, montane regions (B, C, and D) is only 9% compared to over 30% of the total area of region A. It should be emphasised that the paucity of endemics in the lowlands is in large part a consequence of periodic land bridge connections to South India in the Pleistocene and the episodic exchanges of lowland biotas.

Sri Lanka, like most tropical developing countries is today faced with rapid population growth and the problems associated with the cultivation of agriculturally marginal lands and the intensified exploitation of natural resources. The forests are now being cleared for the production of plywood and pulp. Extinction of many animals will inevitably occur because the ecological successional process that follows deforestation leads to the development of habitats unsuitable to most of the endemic forms (to be discussed more fully elsewhere). Even nationally accredited areas of unique habitat have recently been brought under the axe and plough[15]. Biologists, geographers and conservationists should accomplish what research they can there before it is too late.

We thank Michael Gilpin, Jack Bradbury and Bruce Wilcox for their comments on the manuscript.

Immunosuppression by mouse sialylated α-foetoprotein

AFP is the dominant serum protein in early embryonic life. It is considered also to be a tumour-associated antigen because it appears in the sera of patients and animals with primary liver cancer[1]. The function of AFP in the foetus remains unknown. Tomasi *et al.*[2] have demonstrated that mouse AFP has an immunosuppressive effect on antibody synthesis both *in vivo* and *in vitro*. Similarly, human AFP has been reported to have immunosuppressive properties[3]. One of us (E.F.Z.) has shown that mouse AFP is heterogeneous, consisting of five components (Fp1–Fp5)[4], which differ in the amount of sialic acid attached to the molecule: Fp1 contains no detectable sialyl residues while Fp5 has four per molecule[5]. We have now demonstrated that the presence of sialic acid residues in the AFP molecule is essential for the immunosuppressive activities of this glycoprotein.

The individual components of AFP were isolated as described before[6]. Briefly, mouse amniotic fluid or foetal plasma from days 15.5–16.5 of gestation were used as sources of α-foetoprotein. Components Fp1 and Fp5, respectively, were purified by electrophoresis on long preparative polyacrylamide gels at low amperage for 65 h in the cold room. Wedges were removed, the locations of AFP components were determined by fluorescence with ultraviolet-activated acidified anilino-naphthalene-sulphonic acid reagent, and the wedges were aligned with the untreated gels. Portions of the untreated gels corresponding to Fp1 and Fp5 were cut out and eluted with 0.05 M Tris-0.1 M NaCl, pH 7.0. Fp1 and Fp5 components were used in tests for immunosuppressive properties because they have no residues and four residues, respectively, per molecule. Because of the possibility that Fp1, derived from amniotic fluid, might lack internal sugars, Fp5 was treated with neuraminidase. The glycoprotein lacking the terminal sialic acid, designated Fp1^{n}, should now have its penultimate sugars on the oligosaccharide. Fp1^{n} was separated from the neuraminidase-resistant Fp3 and as indicated later it migrated to the same position as that of Fp1.

The immunosuppressive activity of the components was determined in mouse splenic lymphocyte cultures in which the primary immune response to sheep erythrocytes was measured. Female BDF$_1$ mice, 10–12 weeks old (Jackson Laboratory) served as the source of splenic lymphocytes. Splenic cultures were prepared as described by Mishell and Dutton[7]. Spleen lymphocytes were cultured with sheep erythrocytes for 5 d in the presence or absence of AFP components. The number of antibody-forming cells to sheep erythrocytes on day 5 was determined by Jerne's plaquing technique[8]. As established by the Trypan blue dye exclusion test, AFP components were not cytotoxic for splenic lymphocytes. Figure 1 illustrates AFP components as identified before and after electrophoretic purification. Electrophoretic analysis of Fp5 after treatment with neuraminidase indicates that it now is very closely related or identical to the Fp1 component. Furthermore, no apparent contamination of each purified AFP component was observed.

Figure 2 shows precipitin analysis of the AFP components by double diffusion technique in agar gel. Goat antiserum prepared against components Fp1–Fp3 was tested against homologous and heterologous AFP components. A total identity band between the various AFP components is evident indicating that all AFP components possess a common structure. Mouse serum from adult animals did not show a precipitin band formation with anti-AFP antiserum indicating that our AFP preparations were not contaminated with other serum proteins.

The immunosuppressive effects of AFP components are shown in Table 1. Mouse amniotic fluid (MAF) and component Fp5 were significantly immunosuppressive: MAF (100 μg), $P < 0.05$; Fp5 (1 μg), $P < 0.0005$. Components Fp1 and Fp1^{n}, however, exerted no effect on antibody formation to sheep erythrocytes. In addition, the acrylamide gel eluate, from which these AFP components were isolated, showed no immunosuppressive properties. Normal serum obtained from adult mice (NMS) was quite immunosuppressive although it contained no AFP (Fig. 2). Apparently additional immunosuppressive factors are present in normal animal sera as demonstrated before[9].

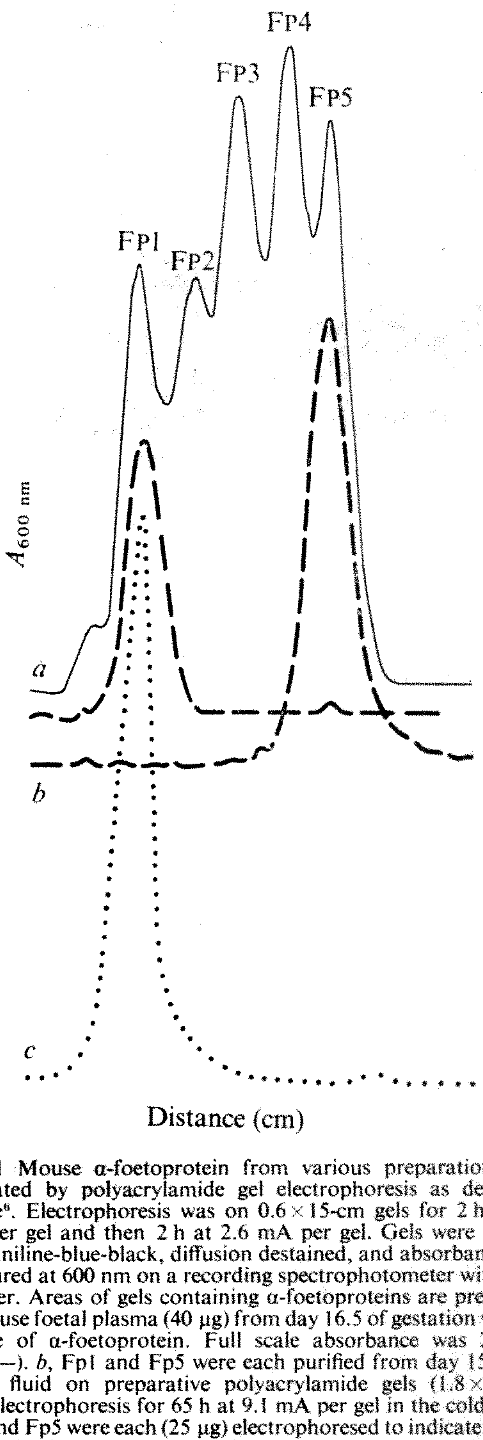

Fig. 1 Mouse α-foetoprotein from various preparations was separated by polyacrylamide gel electrophoresis as described before[6]. Electrophoresis was on 0.6 × 15-cm gels for 2 h at 3.5 mA per gel and then 2 h at 2.6 mA per gel. Gels were stained with aniline-blue-black, diffusion destained, and absorbance was measured at 600 nm on a recording spectrophotometer with a gel scanner. Areas of gels containing α-foetoproteins are presented. *a*, Mouse foetal plasma (40 μg) from day 16.5 of gestation was the source of α-foetoprotein. Full scale absorbance was 2 units (———). *b*, Fp1 and Fp5 were each purified from day 15.5 amniotic fluid on preparative polyacrylamide gels (1.8 × 44 cm) with electrophoresis for 65 h at 9.1 mA per gel in the cold room. Fp1 and Fp5 were each (25 μg) electrophoresed to indicate purity. Full scale absorbance was 3 units (— — —). *c*, Fp1^{n} was derived by treatment with *V. cholerae* neuraminidase from Fp5 purified from newborn plasma. Fp1^{n} was then separated from Fp3^{n} on a preparative gel, as described above, and Fp1^{n} electrophoresed on an analytical gel to indicate purity. Full scale absorbance was 3 units (·····).

Table 1 Effect of AFP components on the *in vitro* primary immune response to sheep erythrocytes

Preparation		PFC per 10^6 viable cells ± s.e.
Control		597 ± 135
Gel eluate		530 ± 132
MAF	(200 μg)	271 ± 82
MAF	(100 μg)	365 ± 368
MAF	(10 μg)	567 ± 8
Fp5	(10 μg)	284 ± 19
Fp5	(1 μg)	248 ± 96
Fp5	(0.1 μg)	506 ± 86
Fp1	(10 μg)	648 ± 168
Fp1	(1 μg)	467 ± 137
Fp1^{n}	(10 μg)	579 ± 228
Fp1^{n}	(1 μg)	709 ± 130
Fp1^{n}	(0.1 μg)	588 ± 134
NMS	(1%)	521 ± 150
NMS	(5%)	168 ± 38
NMS	(10%)	130 ± 104
NMS	(15%)	66 ± 11

The values were derived from at least two experiments, each of which contained triplicate determinations.

The apparent requirement for sialyl residues on the AFP molecule to achieve immunosuppressive properties parallels observations made in other biological systems. Remold and David have demonstrated[10] that macrophage inhibitory factor (MIF) which is produced by sensitised lymphocytes requires the presence of terminal sialyl residues for its inhibitory activity. It is conceivable that sialyl residues, which are quite often found on the surface of cellular membranes and serum proteins, may have an important role in the regulation of various biological properties. Because we used a primary lymphocyte culture for antibody

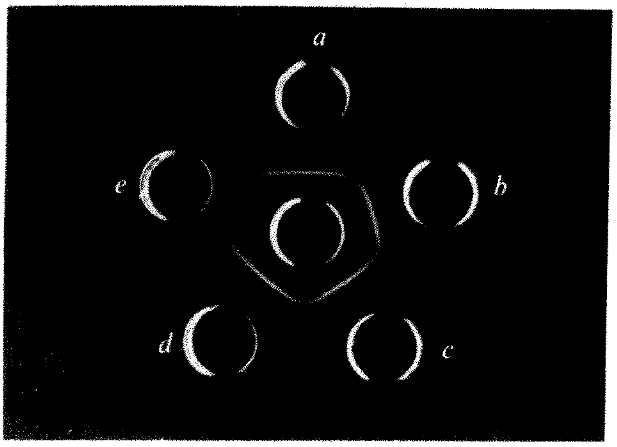

Fig. 2 Ouchterlony double immunodiffusion on an agar plate (Hyland) of α-foetoprotein preparations against anti-Fp1-3 (ref. 4). Source and purity of isolated α-foetoprotein preparations are indicated in Fig. 1. Outside wells contained: *a*, Fp5 (600 μg ml^{-1}); *b*, Fp1 (675 μg ml^{-1}); *c*, Fp1^{n} (550 μg ml^{-1}); *d*, day 14.75 mouse amniotic fluid (2.2 mg ml^{-1}), and *e*, mouse adult serum (undiluted). The centre well contained the antiserum.

formation to sheep erythrocytes, it can be assumed that in our experimental conditions IgM immune response was suppressed. Dattwyler *et al.*[11] have reported that AFP binds specifically to T lymphocytes and therefore this type of lymphocyte (or perhaps a subpopulation of T lymphocytes) may carry on its surface receptors for sialyl residues. The mechanism of immunosuppression by AFP or other serum factors remains unknown. It has been reported that immunosuppressive properties of mouse AFP are affected by binding of oestrogen[12]. It remains to be determined whether this binding is dependent on the presence of sialyl residues on AFP and whether the immunosuppression may involve more than one reactive substance. It is hoped that, as the structures in the lymphocyte membrane which can interact with sialyl residues are identified, the understanding of immunosuppressive processes will improve.

Immunocytochemical studies of cells in the rat adenohypophysis containing both ACTH and FSH

STUDIES by Siperstein *et al.*[1,2] first described the cytology of the adrenocorticotropin (ACTH) cell in the rat adenohypophysis. This cell is stellate and contains peripherally organised granules averaging 220 μm in diameter. Their cytological work was confirmed in later immunocytochemical studies in our laboratory[3–5], in which ACTH was localised in the secretory granules of cells of this type. In our recent immunocytochemical studies of follicle-stimulating hormone (FSH) cells, however, FSH was found in a cell which resembled the ACTH cell. We termed this cell the Type III gonadotroph[6,7]. Here we describe studies designed to test the specificity of the reaction for FSH in this cell type, and the relationship between the Type III gonadotroph and the cell containing ACTH.

The immunocytochemical technique used was the unlabelled antibody peroxidase–antiperoxidase complex (PAP) technique of Sternberger *et al.*[8], as modified in our laboratory for the ultrastructural localisation of ACTH[3,4]. Pituitaries were fixed in picric acid formaldehyde and embedded in Araldite 6005. Ultrathin serial sections were mounted on nickel grids, etched in 10% H_2O_2 for 5–10 min, and then stained immunocytochemically.

The specificities of the immunocytochemical stains were determined by the absorption of each antiserum with ACTH or FSH for 2 d before its use in the stain. Table 1 lists the results of specificity tests of the anti-ACTH$_{17-39}$ sera and anti-rat FSHβ sera. Only previous absorption with ACTH abolished staining in the ACTH cell with the anti-ACTH$_{17-39}$ serum; previous absorption with FSH had no effect. Similarly, FSH absorption abolished FSH staining in the Type III gonadotroph; however, absorption with ACTH had no effect.

Other specificity tests included the substitution of antiserum to luteinising hormone (LH) or thyroid-stimulating hormone (TSH) for the anti-FSH or anti-ACTH sera. Cells resembling the Type III gonadotroph were not abundant in either the LH cell population[6,7] or the TSH cell population in normal male rats or cycling female rats. The omission of the goat anti-rabbit IgG from the staining sequence abolished staining completely.

After proof of specific staining was established, the next phase of the study was designed to test if the ACTH cell and the Type III cell were the same cell. For this purpose, the stains for ACTH$_{17-39}$ and FSHβ were used on serial sections of oestrous female rats (1300 h on day of oestrous), which have an abundance of Type III gonadotrophs. Twenty serial cells were collected and analysed for their hormone content. Of the group of cells collected, nine stained for ACTH alone (Fig. 1). The other eleven cells stained for both FSHβ and ACTH (Figs 1 and 2). Out of the cells analysed, we have yet to find a Type III gonadotroph which contains only FSHβ.

The insets and arrows in Fig. 2 indicate that we have serially sectioned some of the granules. An analysis of the staining pattern of each of 26 granules in 5 areas of the cell depicted in Fig. 2 shows that 12 contain only ACTH, 8 contain both ACTH and FSH, and 6 are negative. No granules were found which stain for FSH only.

In summary, it is evident that one of the FSH cell types is a cell morphologically identical to the ACTH cell, and the serial sections collected thus far indicate that this cell contains ACTH as well. Our findings are difficult to explain. The staining for FSHβ in a stellate cell can be explained from the standpoint of morphological differentiation. For example, in a particular physiological state, such as enhanced secretion, FSH gonadotrophs may become stellate following stimulation as an aid or adjunct to their activity. The finding that these cells contain ACTH as well is however, somewhat surprising since there is no known chemical homology between ACTH and FSH.

Sectioning 220–250-μm granules serially is difficult, and we were fortunate to obtain such a serial for the cell in Fig. 2. Our results show that when FSH staining is exhibited by a granule, it is found in a granule which also contains ACTH. If this staining simply reflected a subpopulation of antibodies to ACTH found in the anti-FSH serum, then one might expect that ACTH absorption would abolish it. The results in Table 1 show that ACTH absorp-

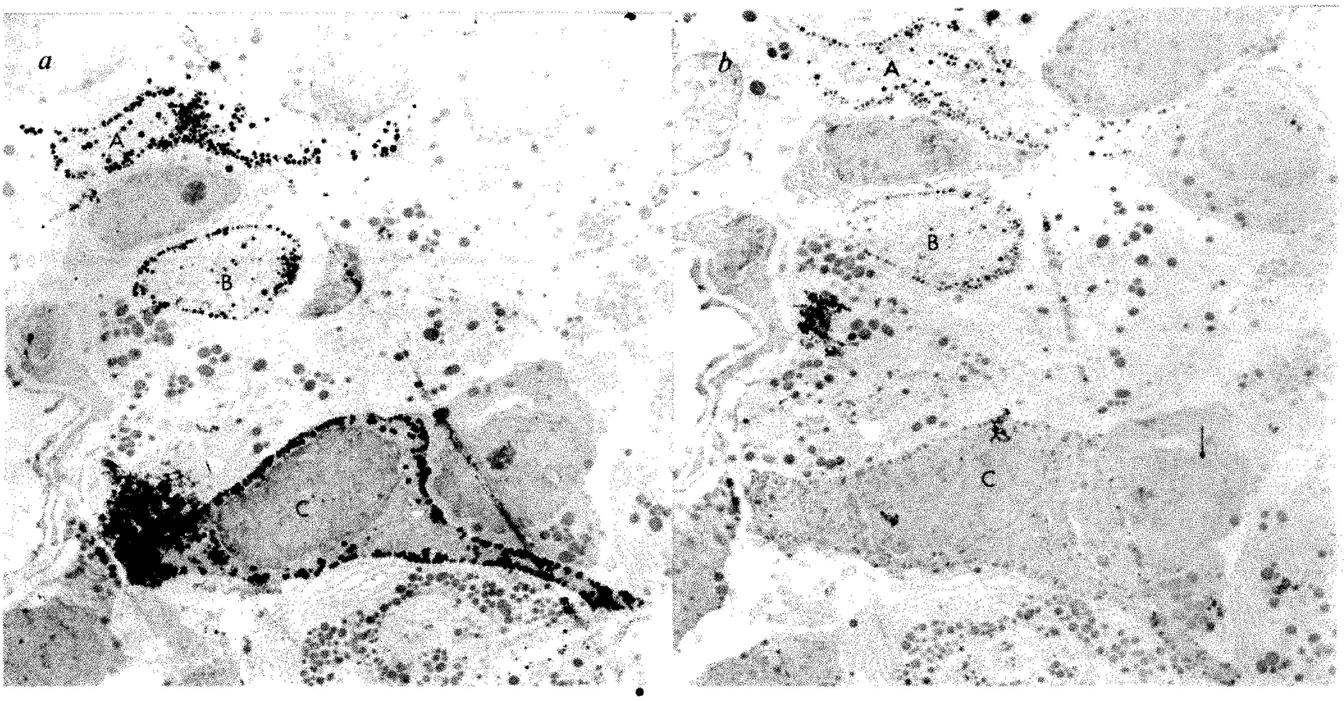

Fig. 1 *a*, Ultrathin section of rat pituitary stained immunocytochemically with 1:5000 dilution anti-ACTH$_{17-39}$ serum (48 h, 4 °C) followed by 1:100 dilution goat anti-rabbit IgG, (3 min) followed by 1:100 dilution PAP solution (3 min) and the histochemical reaction for peroxidase 3, 4. *b*, Section serial to that in *a*, stained with 1:2000 dilution anti-rat FSHβ followed by the same sequence of solutions as in *a*. Cell A stains intensely for ACTH and weakly for FSHβ. Cells B and C stain intensely for ACTH alone. Cell A resembles a gonadotroph (Type II)[7]. Only a few granules in Cell B stain for FSHβ; cell C clearly does not react with anti-FSHβ. Fixation: picric acid formaldehyde; embedded in Araldite 6005. Magnification: ×4500.

tion had no significant effect on anti-FSH staining, however. Therefore, this suggests that the staining reflects the presence of FSH or a molecule with some amino acid sequences identical to those in FSH.

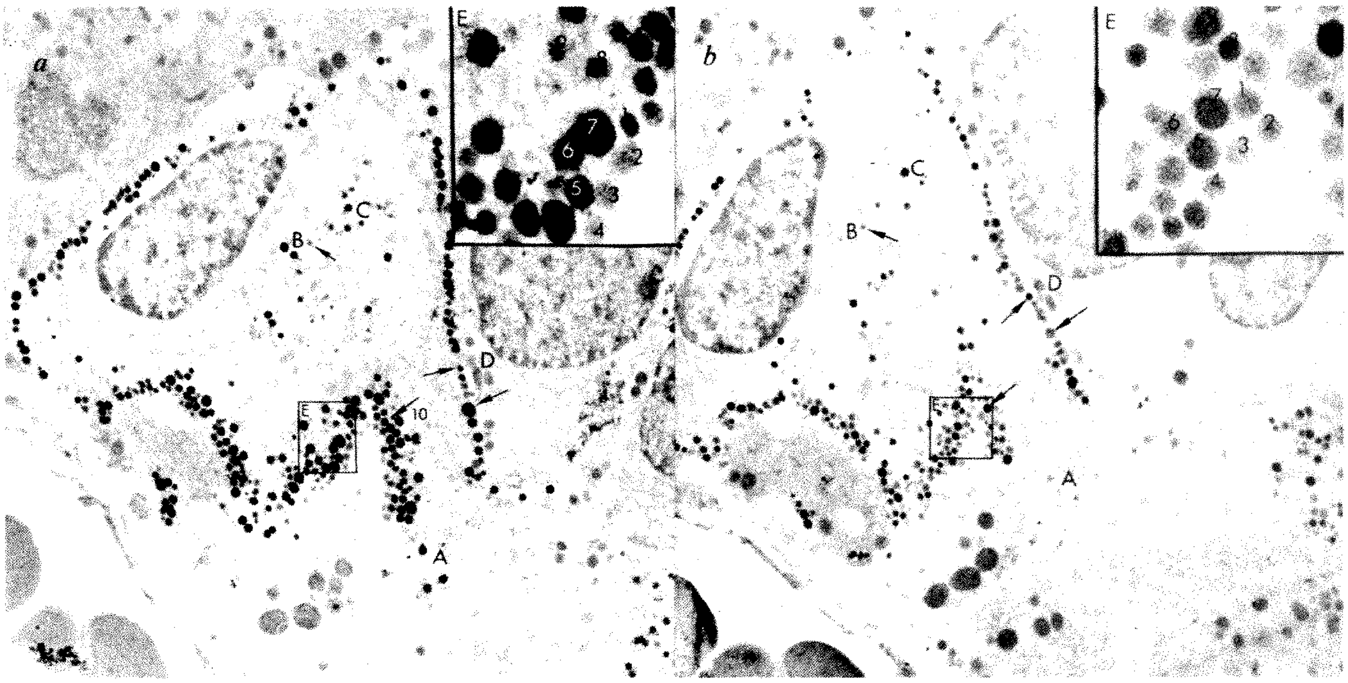

Fig. 2 *a*, Ultrathin section of female rat pituitary stained, immunocytochemically, with anti-ACTH$_{17-39}$ serum. *b*, Section serial to that in *a*, stained with anti-rat FSHβ. Cell A is stained with both antisera, although stain is weaker with anti FSHβ serum. The areas designated contain some of the same granules. Areas A and B show staining for ACTH on five granules. In area A of the cell stained for FSHβ, granules are faintly visible. No stain is evident on them, nor on those in Area B. One granule in Area B stains for neither ACTH or FSH (arrow). Area C contains two granules which stain for ACTH and FSHβ. Area D contains only one granule which stains for both hormones (arrow). The granule below it stains only for ACTH, as does the largest granule in the area (arrow). Area E was blown up as the inset. Granules 5, 7, 8, 9, and 10 stain for FSHβ and ACTH. Granules 1 and 6 stain only for ACTH. Granules 2, 3, and 4 do not seem to contain either hormone. Granule 10 is not shown in the inset in *a*; it is designated by an arrow in *a* and *b*. Magnifications: ×4500, inset ×20,000.

Table 1 Densitometric analysis of specificity of the reaction with the anti-FSHβ and the anti-ACTH sera

Antiserum*	Normalised staining intensity† of secretory granules
Anti-FSHβ‡	0.20±0.002 s.e.m.
Anti-FSHβ + 1 ng FSH ml^{-1}	0.15±0.01
Anti-FSHβ + 10 ng FSH ml^{-1}	0
Anti-FSHβ + 10 μg ACTH ml^{-1}	0.18±0.02
Anti-ACTH$_{17-39}$ sera§	0.30±0.01
Anti-ACTH$_{17-39}$ sera + 10 ng ACTH ml^{-1}	0.18±0.008
Anti-ACTH$_{17-39}$ sera + 100 ng ACTH ml^{-1}	0
Anti-ACTH$_{17-39}$ sera + 1 μg FSH ml^{-1}	0.32±0.13

*1:2000 dilution anti FSHβ, 1:5000 dilution anti-ACTH$_{17-39}$. Antigen added to 1 ml of diluted sera 2 d before its use in the stain.

†Normalised staining intensity values are optical density measurements of 50–75 granules per sample. Nuclear chromatin used as background to correct for section thickness 4.

§Produced in this laboratory. ACTH antigen-III World Standard.

There is little evidence for a functional relationship between FSH and ACTH. There is evidence for adrenal control of gonadal cycles[9] and oestrogen stimulation of ACTH release[10,11]. As discussed in a recent review[9], however, there is more evidence for a functional link between ACTH and LH than ACTH and FSH. Yet our studies show that Type III LH cells are infrequent. They comprise only 4–7% of the total LH cell population, compared with 20–30% of the FSH cell population in cycling female rats[7].

Recent studies by Pouplard *et al.*[12] have shown that human pituitary ACTH cells bind Fc fragments in a manner similar to that exhibited by mast cells and basophils. It is possible that the staining in rat ACTH cells represents a similar nonspecific affinity for immunoglobulin molecules. If this were the case, however, the controls in our study would have shown staining; for example, we would not have abolished staining by previous absorption with the antigen. Therefore, our tests show that the staining is more likely to be a specific immunochemical reaction for FSH and ACTH.

In conclusion, it seems that the old system of identification of pituitary cell types (based on granule size, distribution, cell shape) does not provide accurate information about a cell's hormone content. This is certainly true for the gonadotrophs[6,7], and as we have shown in this study, it is true for ACTH cells as well. One cannot distinguish an ACTH cell from an ACTH–FSH cell solely on the basis of morphology. We recognise the need for studies of animals in different physiological states before further conclusions are drawn. In fact, the relationship between the two hormones may become clearer as more animals in different physiological states are examined. We also recognise the need for further purification of the antisera.

We thank Dr A. F. Parlow for providing the FSH antiserum and antigens, and Ms Virginia Crain for secretarial assistance. This work was supported by a grant from the National Institutes of Health.

Stress-induced parallel changes in central opioid levels and pain responsiveness in the rat

THE isolation and identification of endogenous opiate-like peptides from mammalian brain[1,2], and from pituitary[3–5] has led to an active investigation of their pharmacological properties. These peptides—the enkephalins and endorphins—have been shown to produce naloxone-reversible analgesia[6,7], tolerance, and withdrawal[7]. While these effects seem consonant with those of morphine and other exogenous narcotics, little is yet known about the intrinsic, physiological functions of the opioid peptides. Since powerful analgesia is a prominent and reliable phenomenon associated with the administration of both narcotic alkaloids and brain opioid peptides, it seems reasonable to suggest that the opioid peptides may normally function to modulate pain responsiveness. Furthermore, work with stimulation-produced analgesia has suggested the existence, in mammalian brain, of a pain-inhibitory system with an opiate-like link[8,9]. We have, therefore, hypothesised that such an endogenous system may be engaged by either environmental, sensory, or other physiological events which lead to adaptive changes in pain responsiveness. For example, noxious or stressful stimuli may recruit pain-inhibitory mechanisms in the central nervous system, bringing about alterations in enkephalins and endorphins, with concurrent or subsequent changes in responses to pain. Consistent with this hypothesis, we now report that inescapable acute stress causes a significant increase in levels of opioid peptides with a concurrent decrease in pain responsiveness in the rat. Furthermore, both the biochemical and behavioural changes are "reversed" by repeated exposure to stress. A preliminary report of this work has been made[10].

To assess the effects of either acute or repeated exposure Sprague–Dawley rats (400–450 g) were initially tested in the tail-flick procedure on each of two occasions: immediately before the first 30 min stress session (day 1), to obtain a baseline latency, and immediately following this stress session. Thereafter, these experimental animals were re-exposed to the 30 min stress session, once daily, for a total of 13 consecutive sessions. On day 13 the animals were again tested in the tail-flick procedure for pain responsiveness on each of two occasions in the manner previously outlined. Comparable numbers of non-stress controls were, likewise, tested for pain responsiveness at appropriate times on both days 1 and 13.

Stress was produced by a 30-min period of intermittent, inescapable foot shock. During each session, rats were individually placed on the grid of an operant chamber, where a 3-mA scrambled shock stimulus was delivered for 1-s duration, every 5 s.

The pain responsiveness test was a modification of the tail-flick measure of D'Amour and Smith[11], and is described elsewhere[12]. Briefly, it involves focusing radiant heat on the tip of the rat's tail, and measuring the latency of the withdrawal reflext. The radiant heat source was adjusted such that the majority of the animals responded between 3.5 and 4.0 s during baseline testing. A cut-off point of

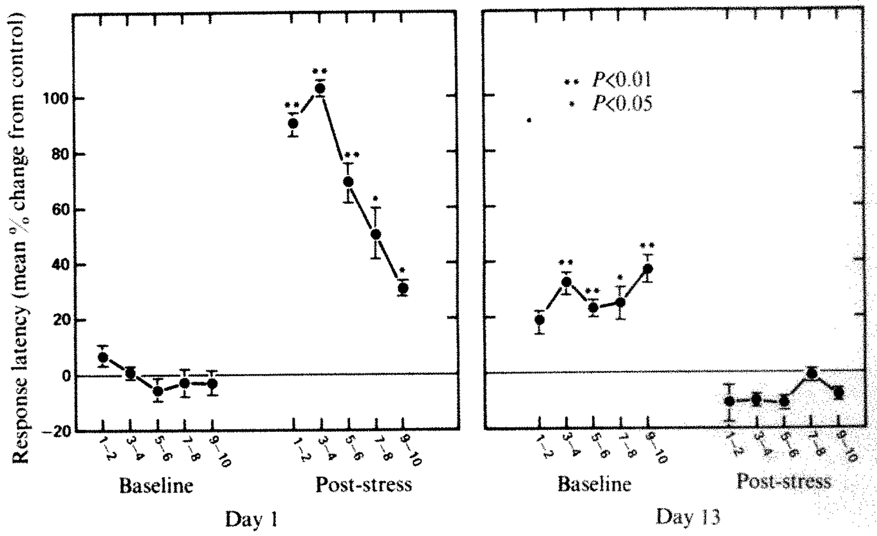

Fig. 1 Effect of acute and repeated stress on tail-flick latencies. Pain responsiveness was measured before (baseline) and after 30 min of stress (post-stress) on days 1 and 13. Response latencies of experimental animals ($n = 4$) were transformed into percentage change from control ($n = 5$) for each time point. Each point and corresponding bar represents mean ± s.e. for each pair of successive trials. Asterisks indicate significant differences from corresponding control trials.

6 s was imposed to prevent tissue damage. Ten trials were conducted during each test session, with 60–75-s intervals between trials.

To determine the possible effect of stress on endogenous opioid peptides, the levels of these peptides were measured in three separate experiments employing 33 animals. Since the results of these studies were internally consistent, they were subsequently pooled. The opioid levels were determined at four different time points. The initial two points were obtained by killing animals either before an acute stress session in order to measure control basal levels, or immediately following that stress session. The remaining two time points involved animals which had been subject to the repeated stress paradigm. These animals were killed on day 13 either before the stress session, in order to measure their resting levels, or immediately following stress. Endogenous opiate-like activity was measured using a ^{3}H-naloxone membrane binding assay[13,14]. A P_2 fraction was prepared from whole brain, and the peptides were then extracted by hypotonic lysis (10 mM Tris-HCl, *p*H 7.7, at 25 °C), boiled for 15 min, and centrifuged for 1 h at 100,000*g*. Extracts from 40 mg of tissue (wet weight were added to the binding preparation, and the inhibition of stereospecific opiate binding measured. Since we did not separate enkephalins from possible larger peptides, endogenous opiate activity was expressed in units, with one unit being defined as the amount which yields 50% receptor occupancy. All samples were assayed in duplicate; duplicate pairs differed by less than 10%. The endogenous opiate activity was abolished by treatment with carboxypeptidases, or by preincubation at 37 °C in the whole brain homogenates. Also, the effect of endogenous factors on stereospecific binding was enhanced by manganese and inhibited by sodium, indicating their specific and agonistic nature[13].

Acute stress (30 min) results in a significant increase ($P<0.001$) in tail-flick latency. As can be seen in Fig. 1 (day 1) analgesia is most dramatic during the first few trials immediately following foot-shock, with all experimental animals reaching the cut-off point (6-s response latency) on one or more of the initial trials. The pain responsiveness gradually recovers with successive trials. Nonetheless, these animals still remain significantly analgesic relative to non-stressed controls through the end of the testing.

Daily re-exposure to the 30-min stress session results in a significant elevation ($P<0.001$) in baseline response latencies when tested before the stress session on day 13. However, the subsequent stress session does not induce any further analgesia. On the contrary, it brings about a hyperresponsiveness to noxious inputs, such that post-stress latencies are significantly shorter than their pre-stress baseline responses, and significantly shorter than the response latency of non-stress controls.

Figure 2 displays the parallel changes in opioid peptides and pain responsiveness measured at various times throughout the stress paradigm. Opioid peptides are significantly elevated after a 30-min acute stress session (day 1) when animals exhibit profound analgesia. Daily re-exposure results in moderately elevated resting opioid levels and an intermediate degree of analgesia on day 13. However, following stress on day 13, these levels decrease, returning to control values. Similar effects are obtained with 60 min

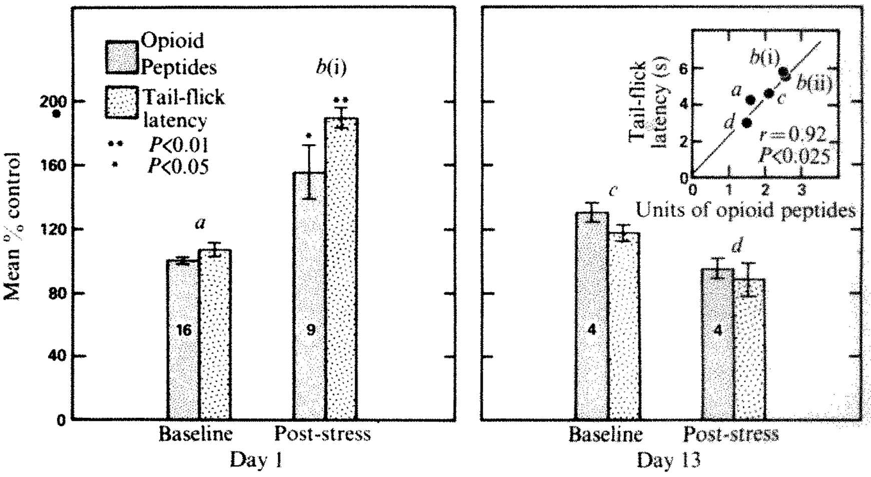

Fig. 2 Parallels between stress effects on pain responsiveness and opioid peptide levels. Opioid levels determined pre- and post-stress on days 1 and 13. Corresponding tail-flick latencies (trials 1 and 2 of each testing session, $n = 4$) for each time point are also displayed. Biochemical and behavioural data expressed as mean percentage control ± s.e. Number per group for opioid determination indicated at base of each bar. Inset demonstrates statistically significant correlation between units of brain opiate activity (per 40 mg wet weight) and tail-flick latencies (first two trials) under several stress conditions. *a*, Non-stress control. *b* (i), After 30 min acute stress; *b* (ii), after 60 min acute stress. *c*, Resting levels on day 13, after chronic 30 min stress. *d*, After 30 min repeated stress.

of acute stress, with experimental animals ($n=11$) exhibiting significant analgesia ($P<0.01$) and their brain opioid levels rising to 169% ($P<0.02$) of control levels.

The present results suggest a potential role of endogenous opiates in pain modulation and adaptive responses to stress. The levels of these peptides seem to rise with foot-shock stress, and this rise is accompanied by significant analgesia. This analgetic effect of acute stress has been independently described by other investigators[15]. While there is no *a priori* reason to attribute the full-blown analgesic effect of stress to the endogenous opiate system, it seems likely that this system may have an important role in the decrease in pain responsiveness observed after stress. Furthermore, repeated foot shock causes parallel changes in both opiate activity and behavioural responsiveness. Thus, the animals exhibit higher response latencies after chronic stress, and have slightly elevated resting levels of opiates. Yet further stress brings about a paradoxical decrease in response latencies, accompanied by a return of opiate levels to control values. It is apparent that the same stress has differential effects on behaviour and opioid levels, depending on the previous stress experience of the animal.

It should be noted that our biochemical measures involved overall opiate-like activity in the brain. While a large portion of this activity co-chromatographs with authentic enkephalins (Sephadex G-15, AG-1X2, 200–400, acetate form), it is quite possible that the larger brain opioid peptides recently described[3] may also be involved in the effects we report. Further, it would be of interest to assess the possible role of pituitary opioids—not measured here—in the stress response. While the specific interactions between brain and pituitary opiates have not been determined, their interplay may prove critical for stress adaptation and survival.

The mechanisms underlying the present findings remain to be determined; however, it seems reasonable that both physiological adaptive mechanisms and learning mechanisms may be involved in the phenomena we have observed. The biochemical events leading to increased opioid levels could involve increased synthesis, decreased breakdown, or activation of previously inactive forms. Furthermore, it is possible that different brain regions exhibit differential effects of stress. In any case, it seems likely that the rise in levels is indicative of a potentiation of the endogenous opioid system, since we have demonstrated in a separate experiment[10] that stress-induced analgesia is partially prevented by naloxone administration. This finding directly implicates opiate-receptor interactions in the change of pain responsiveness observed after stress. It therefore appears that the endogenous opiate peptides, by mediating some of the sensory changes that occur during stress, may provide an important interface between hormonal, sensory and emotional responses.

This research was supported by NIMH and NIDA Grants. H.A. is supported by a National Institutes of Health Fellowship and an Alfred P. Sloan Research Fellowship in Neurophysiology. We thank Mrs Sue Poage for preparing the manuscript.

Note added in proof: We have noted in subsequent experiments that, when enkephalins are separated from other opioid factors, specific enkephalin activity can exhibit changes which are different from those in overall opiate activity.

Rapid eye movement cycle is a sleep-dependent rhythm

NORMAL nocturnal monophasic sleep is characterised by the cyclic alternation of rapid eye movement (REM) and non-rapid eye movement (NREM) sleep, with the REM phase of this cycle recurring approximately every 90–110 min. Kleitman[1] hypothesised that an analogous 90–110 min basic rest–activity cycle (BRAC) exists during the awake state, implying a biological clock that continues to operate with the same periodicity throughout the 24-h period (that is, an activity-independent clock). We report here on the effect of altered sleep–wake schedules on the REM cycle and present evidence that the REM cycle is sleep-dependent—it operates only when the organism is sleeping and is not an expression of an activity-independent rhythm.

Several studies[2–5] have supported Kleitman's BRAC hypothesis in identifying a 90–110-min cycle during waking in arousal level, perceptual illusions, gastric motility, and in some hormone secretions. It has been suggested[2–4] that these cycles found in the awake state are expressions of the REM cycle rhythm in sleep. Under this activity-independent model, any wake time occurring within the REM cycle would not alter the REM cycle period; the time between successive stage REM onsets would remain constant, regardless of the amount of sleep or waking within the cycle.

Under the sleep-dependent model, wake time occurring between stage REM onsets should lengthen the REM cycle period, since the clock would stop on awakening. Březinová[6,7], in studying the effects of spontaneous and externally imposed waking on sleep cycle length, reported that cycles interrupted by varying amounts of waking were significantly longer than intact cycles. Feinberg[8] compared the sleep of elderly subjects, which is characterised by frequent and sometimes prolonged awakenings, with that of younger subjects. He found the REM cycles in the two groups virtually identical when the intervening wake time was subtracted. In addition, the first REM onset in normal noctural sleep is invariably preceded by 60–120 min of non-REM sleep, despite varying sleep onset times. These findings imply that it is not simply total elapsed time that determines cycle length, but sleep time.

Altered sleep–wake schedules such as in napping, or multiphasic sleep, provide an opportunity to test the sleep-dependent hypothesis (Fig. 1). We have analysed the sleep of 25 adults, aged 17–40, from three different sleep laboratories who underwent altered sleep–wake schedules. Following one baseline night of normal sleep, 8 subjects (Naval Health Research Center, San Diego)[9], underwent a 60-min sleep–160-min wake schedule for 40 h. Ten subjects (Stanford University School of Medicine)[10], had two baseline sleep nights followed by a 30-min sleep–60-min wake

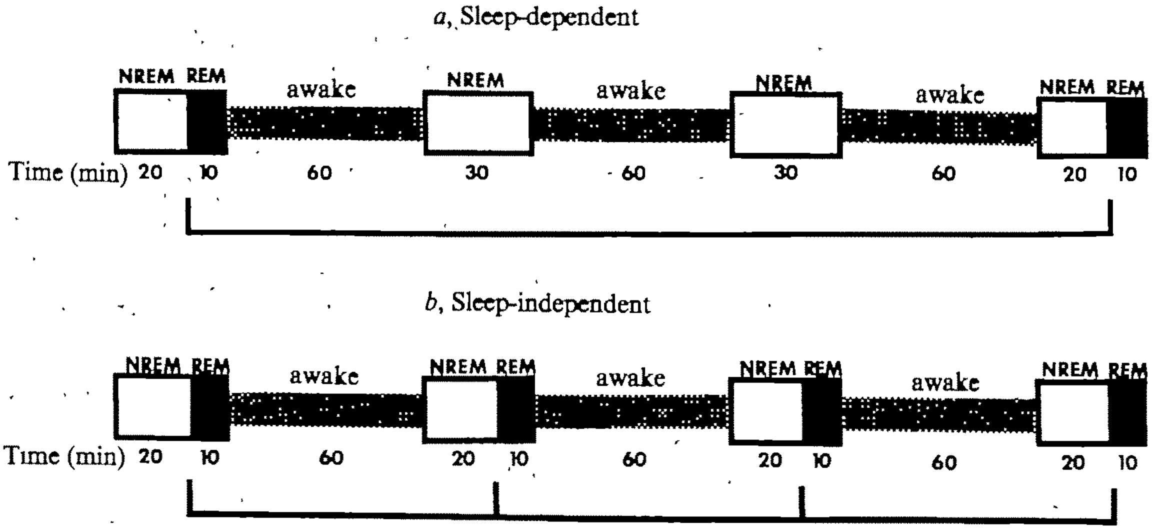

Fig. 1 Hypothetical examples of REM onsets occurring during a 30-min sleep—60-min wake schedule. *a*, Total sleep time between REM onsets is 90 min (total real time is 270 min). The 'clock' governing the time interval between REM onsets runs only during sleep; it stops on awakening and resumes at the next sleep onset. *b*, Total real time between REM onsets is 90 min (total sleep time is 30 min). The 'clock' runs during both sleep and waking. Studies of nap sleep from three independent sleep laboratories support the sleep-dependent model[1]

schedule for 5 d. Seven subjects (Montefiore Medical Center)[11], slept normally for 7 baseline nights and then were placed on a 60 min sleep–120 min wake cycle for 10 d.

Table 1 REM cycle periods for nap and baseline sleep conditions

	San Diego $N=8$		Stanford $N=10$		Montefiore $N=7$	
Nap RCP	96.6	(±20)	79.1	(±23)	119.2	(±30)
Baseline RCP	97.1	(±12)	92.0	(±12)	104.6	(±12)
Nap-Baseline RCP	−0.50	(±21)	−12.9	(±24)	14.6	(±31)
	Not significant		Not significant		Not significant	

If the REM cycle clock is sleep-dependent, stage REM onset should appear only after 90–110 min of sleep has accrued since the last REM onset, regardless of the amount of wake time between or within the scheduled sleep periods. Using the last REM onset on the last baseline night as a starting point, we 'compressed' the sleep during naps for each group of subjects by subtracting all intervening wake time, and viewed this sleep as one continuous sleep period. For both baseline and naps, a REM cycle period (RCP) was defined as the sleep time between two successive stage REM onsets

According to the sleep-dependent hypothesis, the RCP in naps should not differ significantly from the baseline night RCP. We computed the average difference between nap and baseline RCP for each subject, and the overall average difference was tested for significant (0.05 level) deviation from zero with a *t* test. None of the mean differences differed significantly from zero (Table 1).

Was this sleep-dependent rhythm only present during a specific phase of the circadian sleep–wake cycle? To answer this question, we combined the 3 studies and compared nap REM cycles starting during the time period in which sleep usually occurs (2000–0800) with those cycles starting during the normal wake period (0800–2000). An equal number of naps occurred in the two 12-h periods. The REM cycle durations for the 0800–2000 and 2000–0800 time periods were 87.3 min and 88.6 min respectively, a non-significant difference.

These findings suggest that (1) the 90–110-min cycle found in some waking activities is not an expression of the REM cycle found in sleep, but is a separate neurophysiological process, (2) the nap REM cycle period is not modulated by the circadian sleep–wake cycle, and (3) the REM cycle clock is sleep-dependent.

Endorphin from pituitary inhibits cyclic AMP formation in homogenates of neuroblastoma × glioma hybrid cells

OPIATES inhibit basal and prostaglandin E_1-stimulated formation of cyclic AMP by homogenates of cultured neuroblastoma × glioma hybrid cells[1,2]. The opiate inhibition is stereospecific and is blocked by the specific opiate antagonist naloxone. Thus, interaction of an opiate agonist with its receptor inhibits adenylate cyclase activity.

Peptides with opioid activity (endorphins) have been found in the pituitary of several species[3,4] and have been partially purified[5]. The pituitary peptide β-lipotropin (β-LPH) gives rise to biologically active fragments containing a pentapeptide sequence (methionine–enkephalin) with opioid activity at the NH_2-terminus[6], and this pentapeptide has also been found in brain[7]. In porcine pituitary, the principal opioid activity is associated with peptides that differ from all the active β-LPH fragments in that their biological activity is degraded by trypsin, as measured in the guinea pig myenteric plexus–longitudinal muscle bioassay[8]. Further characterisation of these endorphins is presented elsewhere[9]. Since endorphins derived from pituitary interact with opiate receptors in binding assays and have typical morphine-like actions in bioassays[5,10,11] it was of interest to determine if this pituitary endorphin had typical opioid effects upon adenylate cyclase activity.

The source of the endorphin was the 'MSH concentrate' from porcine pituitary described elsewhere[5]. The guinea pig myenteric plexus-longitudinal muscle[12] was used to assay all fractions during purification. A 'guinea pig unit' (GU) is defined as the amount of material giving naloxone-reversible inhibition equivalent to that produced by 1 nmol of normorphine in the 5-ml tissue bath (that is, 200 nM final concentration). Half-inhibition of the muscle twitch amplitude requires approximately 0.5 nmol normorphine (100 nM). The crude material was first fractionated on a BioRex-70 cation exchanger (BioRad Labs., Richmond, Ca, column size 4×90 cm); activity was obtained in a basic peak eluting with 0.25 M ammonium carbonate. The active fraction was passed through a BioGel P-6 column (2.5×52 cm) in Tris-HCl buffer (50 mM) at *p*H 7.4; activity was found in a peak with apparent molecular weight about 3,000. This material was refractionated on BioGel P-6 in distilled water, in order to take advantage of adsorptive properties of the column for peptides at low ionic strength. The activity peak emerging from this column had specific activity 132 GU/A_{274} Unit, whereas the specific activity of the starting material was 7.2 GU/A_{274}. (A_{274} Unit=amount of material in 1 ml solution with 1 cm light path giving absorbance 1.0 at 274 nm, the tyrosine extinction maximum.) The endorphin was concentrated on an Amicon UM05 filter (Amicon Corp., Lexington, Mass.) and portions were lyophilised and shipped in sealed tubes from Palo Alto to Bethesda.

This endorphin preparation was still impure, as evidenced by the presence of several ninhydrin spots on thin-layer chromatography plates developed in n-butanol : acetic acid : water (1 : 1 : 1, v/v/v). However, it is of interest because, as documented elsewhere[9], it represents most of the opioid activity in the pituitary, it exhibits high potency, and it is clearly different from any active fragment of β-lipotropin.

The procedure used to measure adenylate cyclase activity in neuroblastoma × glioma NG108-15 hybrid cell homogenates was as described by Sharma *et al.*[1].

Table 1 shows the effects of this pituitary endorphin on adenylate cyclase activity of the neuroblastoma × glioma NG108-15 hybrid cell homogenates. Endorphin was a more potent inhibitor of basal and PGE_1 stimulated adenylate cyclase activity than was morphine. Here the potency of the pituitary endorphin was 10 times that of morphine when the peptide concentration was calculated from absorbance at 274.5 nm, assuming one tyrosine per mole. Based upon normorphine equivalents in the guinea pig myenteric plexus bioassay, the potency inhibiting adenylate cyclase was 100 times that of morphine.

An experiment similar to that shown in Table 1 was performed also with a different endorphin preparation, containing material of about 1,750 daltons obtained from a commercial porcine crude ACTH preparation[4]. The results were virtually identical to those reported here for the 3000-dalton endorphin from MSH concentrate.

Fig. 1 shows the concentration-dependent blockade by naloxone of the inhibition of adenylate cyclase by endorphin in neuroblastoma × glioma cell homogenates. Complete antagonism of the endorphin effect could be achieved, except at the highest endorphin concentrations, and the curves are generally indicative of the expected competitive agonist-antagonist relationship. Using the method of Kosterlitz[13], K_e for naloxone can be estimated as approximately 5×10^{-8} M, in reasonably good agreement with that obtained in this system with morphine (2×10^{-8} M) or methionine-enkephalin (3×10^{-8} M) (W. Klee and M. Nirenberg, unpublished observations).

Table 1 Effect of pituitary endorphin on adenylate cyclase of neuroblastoma × glioma cell homogenates

	Addition	Cyclic AMP formed (pmol min^{-1}mg^{-1} protein) —Naloxone	+Naloxone (10μM)	% of control —Naloxone	+Naloxone (10 μM)
Basal	None	25	24	100	97
	Morphine (10 μM)	14	23	56	95
	Endorphin (0.016 μM)	18	24	72	96
	Endorphin (0.16 μM)	13	23	52	92
	Endorphin (1.6 μM)	11	18	44	72
+ PGE_1 (0.25 μM)	None	265	275	100	104
	Morphine (10 μM)	192	262	72	99
	Endorphin (0.016 μM)	263	269	99	102
	Endorphin (0.16 μM)	212	272	80	103
	Endorphin (1.6 μM)	174	256	66	97

Procedure of Sharma *et al.*[1]. Incubations were for 5 min at 37 °C with the following components in a final volume of 100 μl: 15 mM Tris-HCl (*p*H 7.5); 1 mM α-^{32}P-ATP, 10^6 c.p.m.; 1 mM ^{3}H-cyclic AMP, 10^4 c.p.m.; 5 mM $MgCl_2$; 20 mM creatine phosphate; 0.5 mM RO20–1724 as cyclic AMP phosphodiesterase inhibitor (0.1% ethanol final concentration) creatine phosphokinase, 160 units mg^{-1}, 10 units; 0.16 M sucrose; 0.097 mg NG108–15 homogenate protein (frozen cells stored at –80 °C in 0.32 M sucrose, 0.01 M Tris-HCl, *p*H 7.5). Endorphin concentrations are normorphine equivalents, according to activity assayed in the guinea pig myenteric plexus-longitudinal muscle preparation, where normorphine and morphine have equivalent potencies. Data are means of duplicates from a representative experiment that was repeated three times.

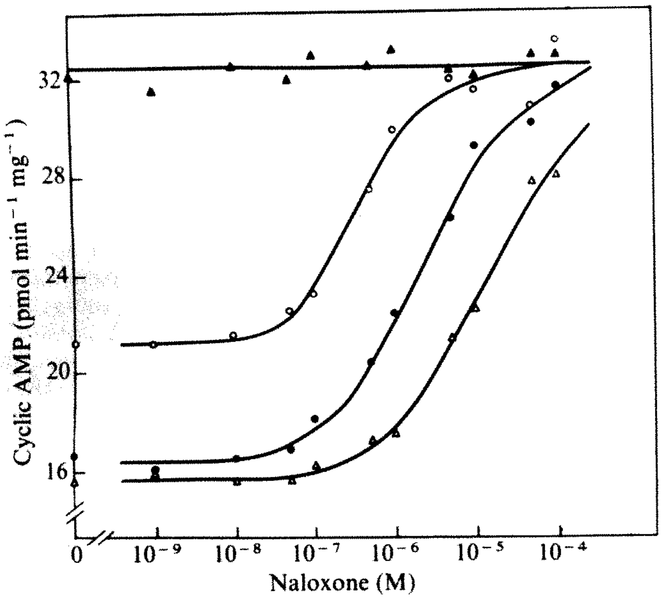

Fig. 1 Naloxone blockade of the endorphin inhibition of adenylate cyclase in neuroblastoma × glioma cell homogenates. Method as in Table 1. ▲, Control, no endorphin; ○, 0.033 μM endorphin (as normorphine equivalent in myenteric plexus-longitudinal muscle bioassay); ●, 0.33 μM endorphin; △, 3.3 μM endorphin.

Our results indicate that pituitary endorphin has typical opioid effect on adenylate cyclase of neuroblastoma × glioma NG108-15 homogenates. Since opioid peptides of molecular weight in the 3,000-dalton range, possibly identical to pituitary endorphins, are found in brain[14], it is likely that our findings have physiological significance for the function of endorphins in the nervous system.

For generously furnishing the porcine MSH concentrate we are indebted to Dr J. D. Fisher, Armour Pharmaceuticals, Inc., Kankakee, Illinois. We thank Drs Susan Gentleman and Tsung-Ping Su for the partial purification of this endorphin preparation.

Feedback loop or output pathway in striato-nigral fibres?

THE turnover of dopamine has been thought to be controlled by a 'feedback' pathway from the postsynaptic dopamine receptors in the striatum to the dopamine-containing cells in the substantia nigra[1]. This concept formed the basis of an explanation of the effects of neuroleptics on dopamine turnover[1-3]. Evidence for a striato-nigral α-aminobutyrate (GABA)-containing pathway[4,6] has supported the idea although there have been dissenting voices[7,9]. In particular, the discovery of dopamine receptors on the dopamine-containing cells themselves[8,10] has led to the suggestion that these nigral receptors might explain results otherwise explained by the feedback hypothesis[9]. Nevertheless, the existence of these receptors does not exclude the action of feedback loop in the control of dopamine turnover. We report here an attempt to evaluate the action of the striato-nigral pathway in the control of dopamine metabolism. Our results suggest that lesions in the GABA-containing striato-nigral pathway, which spare the dopamine-containing fibres of the nigro-striatal system, do not affect dopamine metabolism in the nigro-striatal dopamine neurones or the increase in dopamine turnover after administration of haloperidol.

Radioactive L-leucine, injected into the brain, is taken up rapidly by neuronal cell bodies in the region of the injection site, incorporated into proteins and transported along the axons of the cells[11]. Output fibres from a given set of neurones can thus be traced autoradiographically[12] and after injections of 4,5,^{3}H-L-leucine into the straitum the route followed by the striato-nigral fibres was traced in the brains of six albino Wistar rats. At the level of the hypothalamus shown in Fig. 1, the radioactivity marking the axons of this pathway is wholly contained within the internal capsule, well separated from the dopamine-containing fibres of the nigro-striatal system which have not entered the capsule at this level[13].

An initial series of animals with 6-mC electrolytic lesions aimed at this area could be divided into two groups (Fig. 2). One group characterised by small well localised lesions showed a marked turning response towards the lesioned side with both apomorphine (0.5–5 mg kg^{-1}) and amphetamine (2 mg kg^{-1}) in spite of intact dopamine neurones assessed both biochemically and in the fluorescence microscope. The other group of rats showed no turning response and their lesions were located outside the internal capsule.

A further 12 rats showing the turning response to apomorphine after electrolytic lesions in the striato-nigral pathway were used to assess the effect of the lesion on the biochemical parameters of dopamine turnover. Using modifications (unpublished results of N.M.N.) of the published GLC methods[14] we have measured the concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) in striatum and of GABA in the substantia nigra. The striatal dopamine concentration was also measured by a sensitive radiochemical enzymatic assay[15]. Previous experiments have shown that GABA levels in nigra drop by 50% after hemisections of brain between striatum and nigra[4]. Table 1 shows that although the lesions were as effective as complete hemisections in reducing the concentration of GABA in nigra, the response of the dopamine system to haloperidol is not substantially different on the lesioned side from that on the intact side. Indeed there are are no significant differences between the lesioned animals and normal animals in any of the measures of dopamine metabolism.

Published evidence[16] and our own studies seem to indicate only two outputs from the striatal cells as seen by autoradiography. One goes direct to substantia nigra, and the

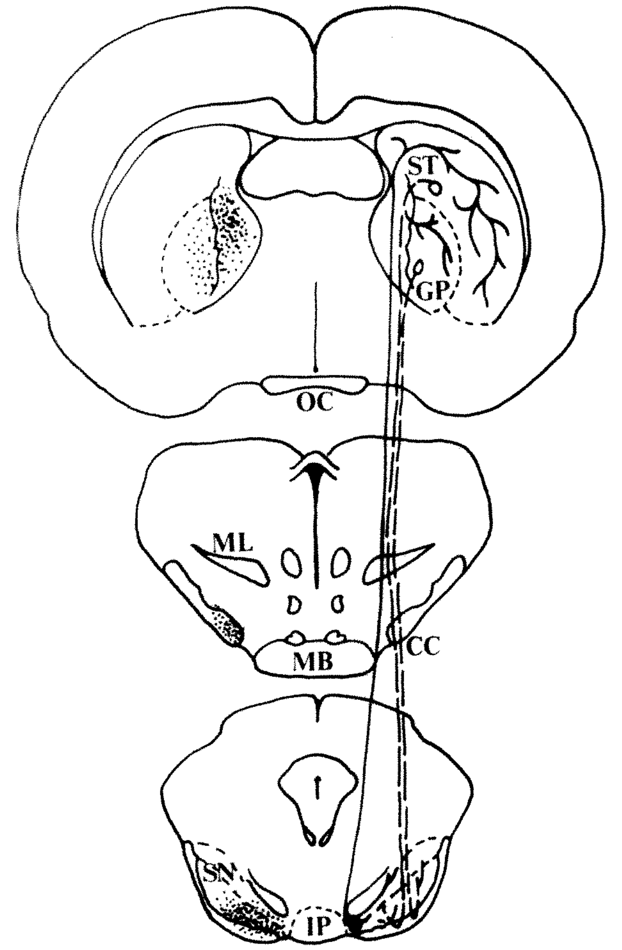

Fig. 1 The striato-nigral (GABA) and nigro-striatal (dopamine) system in rat brain. The dotted areas on the left of the sections summarise the distribution of autoradiographically localised silver grains 4 d after the injection of ^{3}H-leucine into the striatum. On the right are represented the pathways to and from striatum and substantia nigra reported in the literature[13-17]. The solid lines and filled cell body represent the nigro-striatal dopamine system; the open circles and dotted lines represent the GABA containing striato-nigral systems. At the level of the mamillary bodies represented by the middle section the GABA fibres run separately from the DA ones which enter the internal capsule at a level anterior to this. GP, Globus pallidus; CC, crus cerebri; IP, interpenduncular nucleus; MB, mamillary bodies; ML, medial lemniscus; OC, optic chiasma; SN, substantia nigra, and ST, striatum.

other synapses in the globus pallidus. There are GABA-containing fibres projecting from pallidum to nigra[16] but the pathway which they follow is very close to the site of our lesion and this, in conjunction with the fall in GABA levels, suggests that we have extensively damaged the documented pathways from striatum to nigra, with no effect on the control of striatal dopamine metabolism in either normal animals or in animals treated with haloperidol.

It is conceivable that any remaining neurones of the strial-nigral or of the pallido-nigral pathways could have functionally compensated for the reduction of GABA content in the substantia nigra by an increase in their responsiveness to neuroleptics. In addition to such a presynaptic adaptation, the GABA receptors in substantia nigra could develop denervation supersensitivity and compensate for the damage resulting from the lesions. Further work is required to demonstrate these possible compensatory mechanisms in the striato-nigral systems. Our present interpretation is that the striato-nigral pathway is not necessary for control of striatal dopamine turnover.

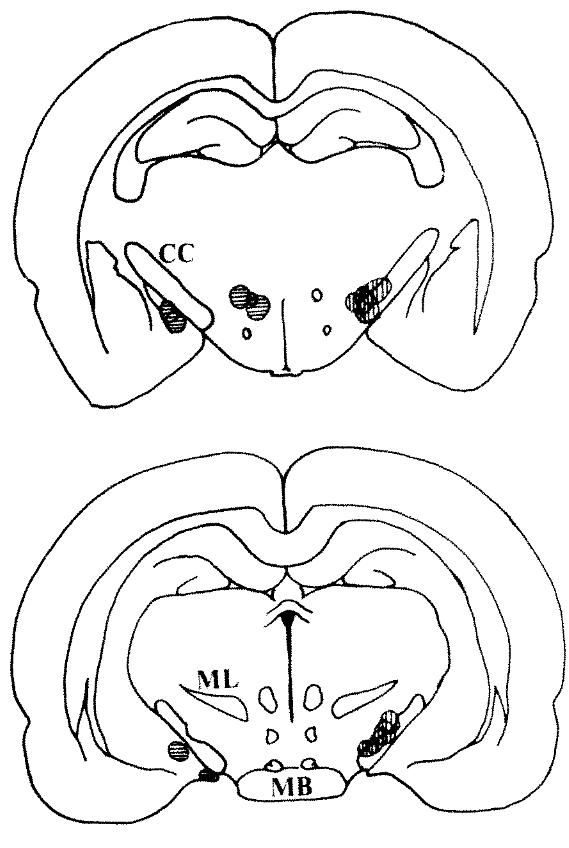

Fig. 2 Lesion sites from the first 14 rats projected on the coronal sections of the rat brain redrawn from ref. 22. The drawings represent sections 1 mm apart. The vertically-hatched lesion sites on the right are from eight rats which turned after apomorphine treatment (2 mg kg i.p.). The horizontally hatched areas on the left represent the maximal extent of lesion sites in six animals which failed to show turning behaviour in response to the same dose of apomorphine. The abbreviations are those used in Fig. 1.

Table 1 Effect of striato-nigral pathway lesions on striatal dopamine metabolism and GABA concentrations in substantia nigra in untreated and haloperidol-treated rats

		GABA substantia nigra	Concentration in stratum Dopamine	HVA	DOPAC
Untreated lesioned animals	Lesioned side	117±23 (4)*	9.4±0.49 (8)	1.2±0.11 (8)	1.1±0.06 (8)
	Intact side	236±54 (4)	9.2±0.58 (8)	1.4±0.13 (8)	1.2±0.11 (8)
Lesioned animals 30 min after 1 mg per kg haloperidol	Lesioned side	147±20 (8)*	5.2±0.46 (8)†	4.6±0.41 (8)†	3.3±0.21 (8)†
	Intact side	319±58 (8)	6.1±0.53 (8)†	4.9±0.51 (8)†	3.1±0.2 (8)†

Concentrations are given as μg per g wet weight ±s.e. (n). 2–3 Weeks elapsed between lesion induction and the death of the animal. An area of brain including substantia nigra (SN) was dissected free hand on ice and frozen in liquid nitrogen 2–4 min after the death of the animal, when the post-mortem increase in GABA should have been complete[23]. GABA concentrations in the table are uncorrected for recovery which was approximately 60%. Striata from the same brains were dissected on ice after the nigral dissection and frozen 4–8 min after decapitation. Estimates of HVA and DOPAC concentrations are also uncorrected for recovery but it was approximately 95%. Dopamine concentrations are corrected.

*GABA concentrations are significantly lower on the lesioned side, $P < 0.02$ (paired t test, two-tailed).

†These concentrations are all significantly different from the appropriate control values (in untreated animals), $P < 0.001$ (t test, two-tailed).

Speculation as to the function of the striato-nigral pathway is perhaps in order if it does not subserve the 'feedback' role usually designated to it. After induction of unilateral lesions in the nigro-striatal dopamine neurones with 6-hydroxydopamine, apomorphine in very low doses causes circling behaviour away from the lesioned side[17]. This behaviour is abolished by ipsilateral electrolytic lesions[18] located in a similar site to that shown in Fig. 2. Animals with both nigro-striatal and the striato-nigral systems lesioned unilaterally show a turning behaviour similar to that reported after the striato-nigral lesions alone[18]. The turning behaviour seen after extensive unilateral ablations of the striatum is also similar in direction and drug sensitivity[19]. That is, the induction of unilateral lesions of the striato-nigral pathway, with or without damage to the dopamine neurones is equivalent to striatal ablation in its effect on turning behaviour. We have recently found deficits in passive avoidance behaviour in animals with bilateral lesions in the striato-nigral system, which is also similar to the deficits seen after large bilateral lesions[20].

Since the striato-nigral pathway terminates predominantly within the zone reticula region of substantia nigra it seems likely that it influences neural activity within this region. The recent electrophysiological evidence for a functional connection between striatum and thalamus through zona reticulata neurones[21] suggests that the fibres which we have lesioned are a part of this system rather than a feedback loop controlling dopamine neurones in zona compacta of substantia nigra.

Can chloropractolol alkylate β adrenoceptors?

EREZ *et al.*[1] have classified chloropractolol as an irreversible, covalently-binding, antagonist of cardiac β adrenoceptors. This conclusion was based on the knowledge that similar halogen amides can alkylate sulphydryl groups[2,3] and their observation that chloropractolol produced a long-lasting antagonism of β adrenoceptors associated with a depression of the maximum response to isoprenaline.

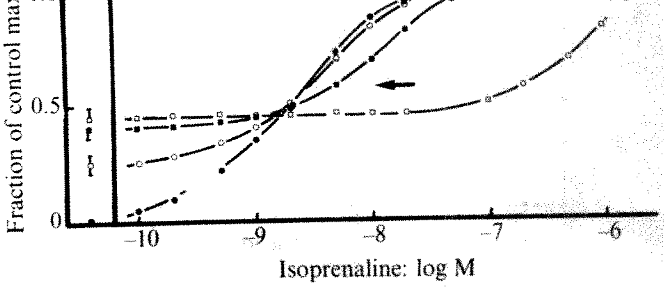
We have measured the contraction frequency of isolated rat atria, the system used by Erez *et al.*, and have found that (±) chloropractolol has agonist activity of its own with half-maximal response at 4×10^{-8} M ($n=7$) which is about five times the concentration for half-maximal response to (±) isoprenaline on this tissue. The increase in atrial frequency due to chloropractolol was not reduced by pretreatment with reserpine but was promptly antagonised by (±) propanolol, 2×10^{-8} M. The maximum agonist response to chloropractolol, however, was 0.41 ± 0.02 ($n=8$) times the isoprenaline maximum (see control value in Fig. 1 for 10^{-5} M chloropractolol alone). This compares with a maximal response for (±) practolol of 0.26 ± 0.04 ($n=4$) times the isoprenaline maximum.

We have found that chloropractolol also has antagonist properties and therefore can be classified, like practolol[4], as a partial agonist. Dextrad displacement of the isoprenaline dose-response curve, produced after equilibration for 45 min with 10^{-5} M chloropractolol, is shown in Fig. 1.

The shift of the isoprenaline dose–response curves, or dose-ratio (DR), has to be estimated for a partial agonist from the difference in the logarithms of the concentration of isoprenaline producing half-maximal responses as described by van Rossum[5]. Dose ratios for isoprenaline were obtained after equilibration with chloropractolol concentrations of 10^{-8} to 10^{-5} M. A Schild plot of log (DR-1) against log [B], the chloropractolol concentration, gave a linear regression with a slope of 0.94 (95% confidence limits 0.88–1.0), which is not significantly different from unity. The estimated dissociation constant for chloropractolol was 1.2×10^{-8} M (95% confidence limits of 8.9×10^{-9} to 1.5×10^{-8} M). No difference in the apparent dissociation constant for chloropractolol was found when comparing atria from untreated rats or rats pretreated with reserpine. Our estimate of the apparent dissociation constant for practolol, based on similar experiments, was 9.8×10^{-8} M (95% confidence limits of 2.7×10^{-8} to 1.9×10^{-7} M) derived from a Schild plot of slope 1.2. The slope for practolol was not significantly different from that for chloropractolol.

In Fig. 1, the control log dose–response curve to isoprenaline has been normalised by expressing measured increases in atrial frequency as fractions of the maximal increase in frequency. The isoprenaline log dose–response curve

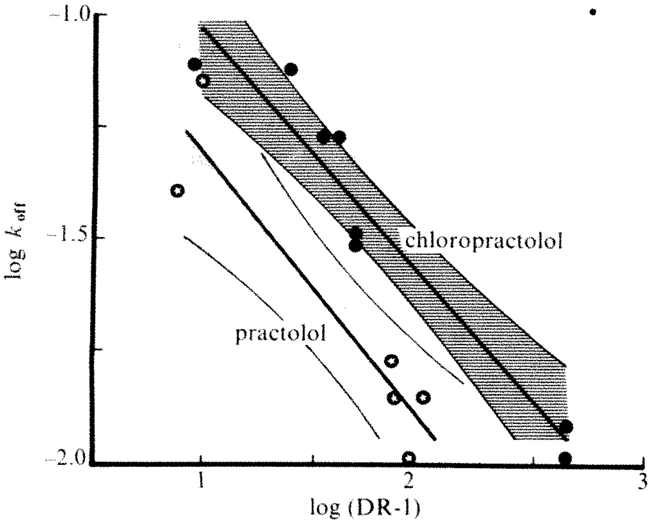
Fig. 1 Dose–response curves to isoprenaline in isolated rat atria. Ordinates: increase in atrial rate as a fraction of the maximal response to isoprenaline. Abscissae: log molar concentration of isoprenaline. The results are the average of four experiments. The curves shown are: isoprenaline alone (●); repeated after equilibration with 10^{-5} M chloropractolol for 45 min (□); repeated after four changes of bath fluid (30 ml) during 35 min (■); and repeated after another six changes of bath fluid during 90 min (○). Basal rates to chloropractolol alone are shown separately.



obtained in the presence of the antagonist was found by expressing measured increases in atrial frequency produced by the combined agonist effects of chloropractolol plus isoprenaline as fractions of the control maximum increase in frequency due to isoprenaline alone. If, instead, the increases in frequency produced by chloropractolol are ignored and the results are presented as described by Erez *et al.* (where increases in atrial frequency due to isoprenaline in the presence of antagonist are expressed as fractions of the control isoprenaline maximal increase), then a family of curves is generated with progressively reduced maxima giving a spurious appearance of non-competitive antagonism. Erez *et al.* make no reference to agonist activity of chloropractolol and their dose–response curves may have been plotted using data normalised in a misleading way. Until this problem of the agonist effect of chloropractolol altering isoprenaline dose–response curves is solved, it might be prudent to put more weight on the time-course of effect as an indicator of 'irreversibility'.

An indication of the time course of recovery from blockade can be obtained from Fig. 1. The time course of the offset of antagonism can be followed by estimating $p = \mathrm{DR}-1/\mathrm{DR}$ which is a function of fractional receptor occupancy, as defined by Paton[6] and Schild[7]. In our experiments, dose ratios were measured from complete dose–response curves, so no more than three estimates could be made in each washout sequence. Nevertheless, plots of log p against time were close to linearity in each experiment, suggesting that first-order kinetics are an adequate description of the reversal of blockade. Rate constants for recovery from blockade, k_{off}, were calculated from these plots and their relation to initial dose ratio in each experiment is shown in Fig. 2. The slopes of the log $(\mathrm{DR}-1)$ against log k_{off} regression lines for both chloropractolol and practolol are significantly different from zero; therefore k_{off}, which is apparently dependent on initial receptor occupancy, cannot be taken as an estimate of the dissociation rate constant for the drug–receptor complex. If the tissue contained other high-affinity binding sites for these antagonists so that, during washout, the receptors could be supplied with drug by slow efflux from this other pool then a similar dependence of k_{off} on concentration would be found. Although the dissociation of the drug–receptor complex is unlikely to be the rate-limiting step in our system, estimated k_{off} is useful for comparing chloropractolol with practolol. Figure 2 shows that for equiactive concentrations of the antagonists, the k_{off} is significantly greater for chloropractolol than practolol and therefore there is no support here for an alkylation hypothesis. Depending on the initial concentration of antagonist the blockade washes out at a rate between 1% and 10% per min; no conclusion about alkylation can be based on this relatively slow washout because propanolol (10^{-8} M) washes out at a similar rate of 1–2% per min from isolated guinea pig atria[8].

Fig. 2 Time course of washout of antagonism of isoprenaline (for both chloropractolol and practolol) as a function of the initial degree of antagonism. This relationship has been linearised by expressing (on the abscissa) initial antagonism as log $(\mathrm{DR}-1)$, as used in the Schild equation (where DR = dose ratio), and by expressing, on the ordinate, the rate constants for washout as log k_{off}. Each rate constant was calculated from the apparent first-order kinetics shown by the linear regression of log p on time; p was calculated from the function $\mathrm{DR}-1/\mathrm{DR}$. Analysis of variance showed that the slopes of both lines are significantly different from zero but not significantly different from each other ($t = 0.39$). Analysis of covariance showed that the data are best described by separate parallel straight lines; for vertical difference between values of Y at given x, $t = 5.52$.



Thus, we have found that chloropractolol is a partial agonist at β adrenoceptors with about 1.5 times the intrinsic activity and 10 times the affinity of practolol. We can find, however, no evidence that chloropractolol alkylates β adrenoceptors in rat atrial muscle, and it is unlikely to be any more useful than other β adrenoceptor antagonists as a tool in receptor isolation studies.

We thank Dr K. W. Bowden for synthesising chloropractolol. T.P.K. is a Canadian Medical Research Council Postdoctoral Fellow.

Histamine blocking agent in the salivary gland homogenate of the tick *Rhipicephalus sanguineus sanguineus*

STUDIES of reactivity to tick bites and tick salivary gland homogenate have revealed responses similar to those induced by histamine in the skin of lop-eared rabbits[1]. Salivary gland homogenates of the tick *Rhipicephalus sanguineus sanguineus*, however, did not cause contraction of guinea pig ileum, but blocked the action of histamine acid phosphate (HAP). We have therefore tested this extract against other drugs known to cause contraction of guinea pig ileum in order to discover the spectrum of its blocking effect on this tissue. We have found that the salivary gland homogenate of this tick antagonises and potentiates, respectively, the action of histamine and acetylcholine on guinea pig ileum.

Adult ticks at various stages of engorgement but never fully engorged were collected from dogs at a veterinary clinic and used within 18 h. They were washed in 1% merthiolate solution, dried on filter paper and stuck to the surface of low-melting-point (30 °C) wax by pressing the ventral surface down into the partially melted surface in a Petri dish and submerging the mouthparts and legs. The dish with the ticks was then placed in a deep freezer (−18 °C) for at least 1 h to harden the wax. The ticks were dissected in cold physiological saline (4 °C), and the

Table 1 Results of pharmacological tests on the salivary gland extract (SGE)

Substance	Concentration	Height of contraction of guinea pig ileum before administration of of extract (mm)	Height of contraction of guinea pig ileum after administration of 0.4 ml SGE (mm)	Reduction in contraction of guinea pig ileum (mm)	% Increase or decrease (Time)
Histamine*	$0.1\ \mu g\ ml^{-1}$	27.5	6.8	20.8	75.5
Histamine	$1.0\ \mu g\ ml^{-1}$	37.0	23.0	14.0	37.84
Barium chloride	40 mM	44.0	35.0	9.0	20.51
Acetylocholine	$0.1\ \mu g\ ml^{-1}$	25.0	31.5	6.5	26.0†

*Mean of data from two animals' tissues.

†There was an increase in contraction of the ileum following the application of acetylcholine ($0.1\ \mu g\ ml^{-1}$) after the addition of the salivary gland extract (SGE).

glands were extracted and put into a thick sterilised watch glass containing cold physiological saline. The salivary glands were freed (as much as possible) of bits of tracheae, salivary ducts and other tissues. After washing in two changes of cold physiological saline, the glands were homogenised in the watch glass with cold physiological saline by means of a sterilised glass rod with a ground end. To each pool of 25 pairs of salivary glands 0.4 ml of cold physiological saline was added. The homogenate was then removed into a sterilised Bijou bottle which was swirled gently to mix the contents. The dissection of the ticks and handling of the glands and homogenate was as far as possible carried out in sterile conditions. The homogenate was used as soon as possible.

Pharmacological testing of the salivary gland homogenate was carried out as described by Perry[5], on guinea pig ileum preparation in an organ bath containing Krebs solution at 37 °C aerated with a mixture of 95% oxygen and 5% carbon dioxide. Isotonic contractions were recorded on a physiograph (Narco Bio-Systems, Houston) using a microdisplacement transducer. Responses of the ileum to histamine acid phosphate ($0.1\ \mu g\ ml^{-1}$, $1.0\ \mu g\ ml^{-1}$), acetylcholine ($0.1\ \mu g\ ml^{-1}$) and 40 mM barium chloride were tested. The effects of the homogenate alone and against the action of histamine, acetylcholine and barium chloride on guinea pig ileum were also tested.

As before[2], 0.4 ml of salivary gland homogenate itself did not contract guinea pig ileum. But it antagonised the contraction of guinea pig ileum preparation caused by HAP (0.1 and $1.0\ \mu g\ ml^{-1}$) by 75.5 and 37.84%, respectively. Similarly, 0.2 ml of the homogenate reduced the contraction caused by HAP ($0.1\ \mu g\ ml^{-1}$) by 41.8%. The first test was reproducible (Table 1). The blocking action of the homogenate persisted for some time because the ileum did not contract after the homogenate had been washed off twice with Krebs solution and more HAP ($0.1\ \mu g\ ml^{-1}$) had been added. This indicates that the extract binds firmly to the tissues of the guinea pig ileum. After 2 h of washing, however, HAP ($1.0\ \mu g\ ml^{-1}$) produced a contraction of 35 mm. After removal of this and addition of HAP ($0.1\ \mu g\ ml^{-1}$) there was a contraction of 30 mm which was comparable to the original contraction of 27.5 mm due to the same concentration of HAP.

We showed that the agent in the tick's salivary gland homogenate was not an effective general blocking agent by its inability to antagonise substantially the contraction of the guinea pig ileum caused by addition of 40 mM barium chloride. On the contrary, the homogenate potentiated by 26% the contraction caused by acetylcholine ($0.1\ \mu g\ ml^{-1}$).

The pharmacological test showed conclusively that the salivary gland of *R. s. sanguineus* contains a histamine blocking agent. This emphasises the conclusion that the pharmacologically active substance detected in the saliva of this tick and that of *Haemaphysalis spinigera*[2] is either histamine or closely related to histamine.

The advantage to ixodid ticks in having both a histamine-blocking agent and histamine or histamine-like substance in their saliva is clear. Ixodid ticks attach to their hosts for a relatively long time and so in the absence of a histamine-blocking agent in the ticks' saliva far more pharmacologically active substance would be released into the host's tissues than necessary.

Excessive amounts of histamine in the host's tissues will endanger the life of the host to the ultimate disadvantage of the tick. On the other hand, the presence of a histamine-blocking agent in the tick's saliva implies an efficient mechanism for regulating the amount of histamine in the host's tissues at any particular moment to the advantage of the tick; perhaps small amounts being released during the first period of slow engorgement and larger amounts being released during the final period of rapid engorgement when such amounts may be required to cause a more intense reaction in the host, leading to the extravasation of a large quantity of blood.

The potentiating effects of the salivary gland extract on the action of acetylcholine on guinea pig ileum suggests that this extract would potentiate the effect of acetylcholine at the neuromuscular junction. If this effect becomes excessive at the motor end plate, it would lead to motor paralysis, which has been observed both in humans and animals after attachment and engorgement of some species of ixodid ticks[1,3]. Motor paralysis after the attachment of *Dermacentor andersoni* has been shown to be due to blockade at the neuromuscular junction[4,6].

We thank Dr S. B. Quartey for permission to collect ticks from infested dogs at the Veterinary Clinic in Accra. We also thank Miss S. Kwame for typing the manuscript.

Mutual repression of synaptic efficacy by pairs of foreign nerves innervating frog skeletal muscle

CONSIDERABLE attention has been directed recently at the proposed phenomenon of synaptic repression. In lower vertebrates experimentally crossed nerves will successfully innervate inappropriate muscles; in certain cases, it has been observed that some fibres later regrow to their original muscles, where they form functional synapses. In some instances where this occurs, the foreign innervation then seems to lose effectiveness in making the muscle contract[1-3]. Mark and his collaborators have concluded that repressed synapses of the foreign nerve remain morphologically intact[4-6] and are capable of being reactivated rapidly if the original nerve is again cut[7-9]. Although other workers[10,11] have shown persistent double innervation without apparent repression in the same or comparable preparations in fish, Yip and Dennis[12] have recently confirmed the existence of quickly reversible synaptic repression in salamander limbs. There have been suggestions that similar synaptic repression might exist in the mammalian central nervous system[13]. If this is confirmed, it could constitute an important mechanism for plasticity during development or experience[14,15]. Thus it is important to determine the mechanism of repression and to assess the reasons for the variability in the degree of competitive interaction observed in different preparations.

Yip and Dennis[12], supporting the observations of Mark[9], report a sharp drop in the quantal content of foreign nerve EPPs in salamander muscle, but no change in miniature EPP (mEPP) size. In that preparation, as in the fish muscles used, both foreign and original nerves form distributed endings along much of the length of the muscle fibres, making it difficult to identify and study the properties of individual nerve endings. In the experiments described below we find evidence of mutual repression of synaptic effectiveness by two foreign nerves innervating frog skeletal muscle, where synapses are located far apart on muscle fibres and individual synapses can be examined. In these cases the competitive interaction must be mediated somehow through the muscle fibres. The drop in efficacy takes the same form: lower quantal content without any clear-cut change in postsynaptic sensitivity to transmitter.

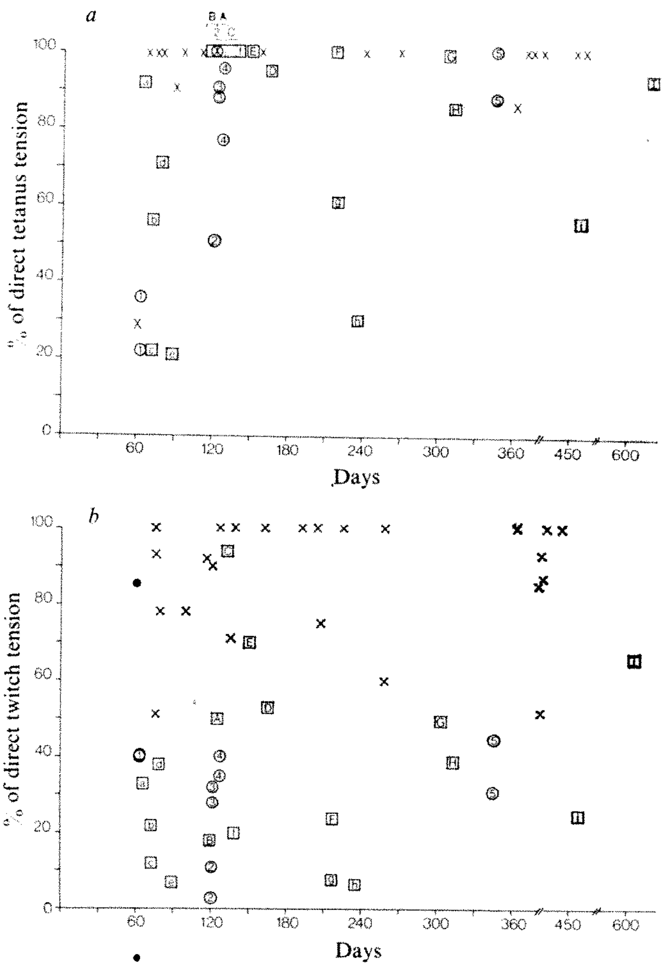
Sartorius muscles were transplanted to the lymph sac beneath the skin of the back of 3–4-inch bullfrogs (*Rana catesbeiana*) and sutured at normal rest length to the fascia of the back. One or two somatic motor nerves (spinal nerves IV and/or V) were implanted into the denervated sartorius muscle. These are mixed nerves, but those fibres forming junctions had conduction velocities characteristic of fast nerves. At different times after innervation muscles were removed to a bath of 15–18° normal frog Ringers, where measurements were made of synaptic potentials and of the contraction tensions elicited by a single stimulus (twitch) and short trains of 30–40 s^{-1} stimuli (tetanus).

When a single foreign somatic motor nerve was implanted into the muscle, it rapidly innervated most or all of the fibres in the muscle (Fig. 1a). Within 2 months, tetanic stimulation of the nerve produced 90–100% of the maximal tension that could be elicited by direct stimulation of the muscle with an electrode applied across the pelvic end (98% ± 5% s.d., $n = 17$ at innervation times greater than 2 months). Maximal direct tension is taken to be that produced when all fibres are contracting.

When two spinal nerves were implanted simultaneously, both nerves seemed to innervate most fibres in the muscle; that is, each nerve was capable of driving the muscle approximately equally well, and in most cases both elicited tetanic tensions within 80% of the maximal direct tetanus tension. Even when one nerve was implanted two or more months before the other, and would be expected to have innervated virtually all of the muscle fibres, the second was frequently able to drive many or all fibres as well (*a,d,f*). In other cases the second nerve was less effective (*b,g,h,i*), but succeeded in innervating many fibres which had presumably already been innervated by the first. The least effective nerves, *c* and *e*, had been implanted for relatively short times. In all cases the first nerve retained effective innervation on essentially all muscle fibres as judged by tetanic stimulation. The interpretation of these tension results as representing extensive dual innervating might be incorrect if strong contraction of one population of fibres could have mechanically induced antidromic action potentials in terminals of the other nerve, innervating a different population. However, no activity could be recorded on one nerve while tetanically stimulating the other, or while strongly stretching the muscle. Moreover, as will be described below, intracellular recording did show double innervation in a large fraction of the fibres.

These results indicate that the presence of one foreign nerve innervating a muscle fibre does not preclude innervation by a second. However, if synaptic effectiveness is judged by the ratio of indirect–direct twitch tension there is evidence for mutual synaptic repression (Fig. 1*b*). A

Fig. 1 Success of innervation by foreign nerves innervating transplanted sartorius muscles, as judged by measurements of the tetanic (*a*) and twitch (*b*) tensions. The tension produced by each nerve, calculated as a percentage of the maximum tension elicited by direct stimulation of the muscle, is plotted at different durations of innervation. ×, indicate success of innervation in singly reinnervated muscles. The encircled numbers represent 5 experiments in which 2 foreign nerves were implanted simultaneously. The letters inside the squares denote data from 9 experiments in which 1 nerve (capital letters) was implanted 2–3 months before the other (lower case letters).



single stimulus to either of two nerves implanted simultaneously caused only 20–50% of the fibres to twitch (mean=31±14% s.d., $n=10$). This was in marked contrast to the effectiveness of a single nerve, which, when implanted alone for 75 d or more (crosses in Fig. 1*b*), caused twitches in 70–100% of the fibres (88±16% s.d., $n=24$). The effectiveness of a nerve in producing a twitch was reduced even if it was implanted 2–3 months before the second, and was presumably able to drive virtually all of the fibres above threshold at the time when the second nerve was implanted. The proportion of fibres twitching to stimulation of the first nerve was 51±24% in nine preparations, far less than if it had been implanted alone. The proportion twitching to the second nerve was generally smaller (19±12% s.d., $n=9$). That a high proportion of junctions had subthreshold responses was also evidenced by the large tetanus–twitch ratio for each of a pair of nerves (average 6.22±4.3 s.d., $n=27$) compared with single reinnervated muscles (2.4±1, $n=21$).

Fibres that were strongly innervated by one nerve tended to be only weakly innervated by the other. Even when one nerve was implanted months before the other, each nerve seemed to have its own separate 'twitch field'. This could be seen both on visual inspection and from the observation that twitch tensions summated with little indication of overlapping innervation. Measuring overlap of functional innervation as the sum of the twitch (or tetanus) tensions to each nerve, minus the tension when both were stimulated simultaneously, divided by the smaller of the individual tensions[16,17], there was usually no more than 10–20% tension overlap of twitch populations, compared with 85–100% overlap of the populations driven by tetanic stimulation (Table 1). The arithmetic sum of the tensions produced by single stimulation of each of the two nerves, implanted simultaneously or at 2–3-month intervals (mean 67±25%, $n=14$), was approximately the same as the twitch tension to simultaneous stimulation of the two nerves (64±23%, $n=14$) and both values were clearly smaller than the average twitch tension of singly innervated muscles (88±16%, $n=24$).

As these tension measurements would predict, a large proportion of the EPPs recorded in doubly innervated muscles were subthreshold to a single stimulus. Moreover, the two nerves apparently seldom form terminals close together on muscle fibres. In approximately 80% of the fibres studied to date in which an EPP was found to stimulation of one nerve (170 of 215 fibres), the other nerve did not produce a recordable EPP at that site. The second nerve either elicited an action potential at some distant point or gave no apparent response. Figure 2*a* is a characteristic example of this group of muscle fibres. In the 20% of the fibres in which EPPs to both nerves could be seen at the same site they usually differed conspicuously in time course and amplitude, although the larger was not always the one with the fastest time course. In less than 5% of fibres were both EPPs of comparable time course, suggesting that they could have arisen close together. We conclude that on most fibres the nerves end at considerable distance from one another, and that one nerve tends to produce a much stronger synaptic response than the other.

Table 1 Overlap of innervation by pairs of nerves

Preparation	Duration of innervation	Overlap % (twitch)	Overlap % (tetanus)
1	64, 64	16	30

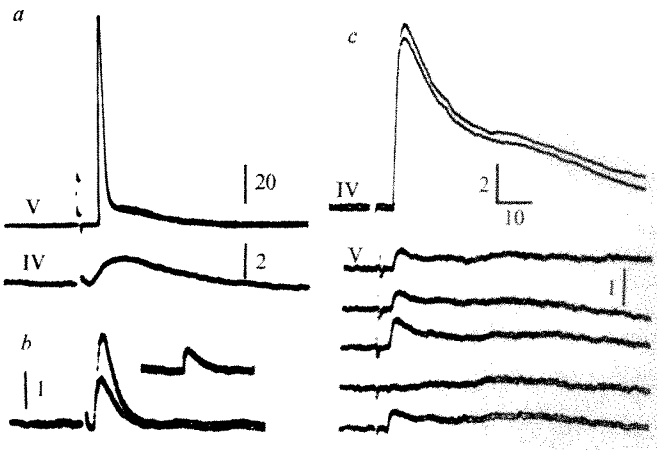

Fig. 2 EPPs from doubly-innervated muscles, all recorded in normal frog Ringer. *a*, Characteristic records from a fibre in a muscle innervated 118 days by both the IV and V spinal roots. At this recording site, nerve IV produced a small EPP, nerve V elicited a spike at some distant point in the fibre. *b*, From the same preparation, low quantal content EPP responses to two nerve V stimuli, compared with a miniature EPP from the same recording site. *c*, EPP responses to stimulation of nerve IV (superimposed top traces) and nerve V (lower series of traces) from a single recording site in a preparation innervated 320 d by nerve V, 259 d by nerve IV. Nerve IV elicited a large subthreshold EPP, nerve V a very low quantal content response that occasionally showed failures. Calibrations are in mV and ms.

EPPs from the weaker synapses (for example, Fig. 2*c*, lower traces) were typically subthreshold in normal frog ringer and showed quantal contents of 10 or less, judged by the amplitude variations of the EPPs and the ratio of average EPP to mean mEPP amplitude. This is in contrast to the EPPs at normal sartorious junctions[18] or to those in singly reinnervated muscles, where virtually all are suprathreshold with quantal contents of 75–100 or more. The dominant synapses on doubly innervated fibres were usually, but not always, suprathreshold also. Their quantal contents, therefore, probably ranged from well above to just below the number required to exceed threshold (approximately 40–50). At the weaker synapses, mEPPs were infrequent, but had rise times and mean amplitudes (range 0.3–1 mV) characteristic of control neuromuscular junctions. Figure 2*b* shows an example. The reduction in synaptic efficacy was thus primarily due to a change in amount of transmitter released, without any evidence for a change in postsynaptic sensitivity. Repression of foreign neuromuscular junctions in salamander limb reportedly takes the same form[9,12]. The reason for the lower-than-normal quantal content at certain synapses is not known but it apparently results from the influence of the other nerve innervating that fibre, and this influence can be exerted at such a distance that it must be mediated somehow through the muscle fibre.

Although the interaction observed here was between two foreign nerves rather than between the 'correct' (original) nerve and a foreign nerve, similar mechanisms may prevail in preparations showing more specificity. Indeed, although Scott[6] has concluded that there is no displacement of a foreign nerve by the original nerve in fish extraocular muscles, she too saw a diminution of effectiveness of both foreign and original nerves, stimulated tetanically, compared with a single reinnervating nerve.

It will clearly be of interest to learn more about the nature of the competitive interaction, the morphological distribution of axons from the two nerves, the interrelationships of their terminals with each other and with old endplate structures, the mechanism(s) whereby one loses influence when a second nerve grows into the muscle, and the degree to which an original (appropriate) nerve is favoured in the competition.

This work was supported by grants from the US National Institutes of Health. We thank Drs S. Hagiwara, L. T. Landmesser and M. Henkart for helpful comments on the manuscript.

Is there retrograde axonal transport of tetanus toxin in both α and γ fibres?

IT has been demonstrated by means of histoautoradiography that tetanus toxin, after injection into a muscle, reaches motoneurones in the spinal cord by retrograde axonal transport[1-3]. It was until now not known whether the labelled motor axons and motoneurones belong to the α, the γ, or to both α and γ populations. We now present evidence that tetanus toxin is selectively transported in α motor neurones.

In two cats, ^{125}I-labelled tetanus toxin was injected into one gastrocnemius muscle (4 and 5 μg toxin per kg body weight respectively; the toxin was labelled according to the method of Habermann[4,5], and contained 2 μCi and 4,500 mouse MLD. One cat MLD was equal to 5.4 μg toxin/kg body weight). Three days later the cats were anaesthetised with Nembutal, a laminectomy was performed and the ventral roots L7 and S1 were ligated on the toxin side. The cats survived for another 8½ and 3¼ hours respectively, during which time they were given intensive care[6]. The ligated roots were then excised and immersed in Karnovsky's fixative. Paraffin sections (8 μm) were cut proximal and distal to the ligature and submitted to histoautoradiography using Ilford G5 emulsion. The autoradiographs were developed with Kodak D 19b developer after 71 d and 81 d of exposure at 4 °C. Outer myelin sheath circumferences were measured at a magnification of 800 with a Kontron Manual Optic Point Counting Device (MOP/AM 01). Fibre size histograms were constructed for a representative sample of all fibres (labelled and unlabelled), and for all the labelled fibres, in each of three ventral roots. An example is given in Fig. 1. Two populations of fibres were found, with peaks at around 5 μm and 14 μm diameter. These values are very similar to those described previously for the γ and α populations of cat gastrocnemius motor fibres[7].

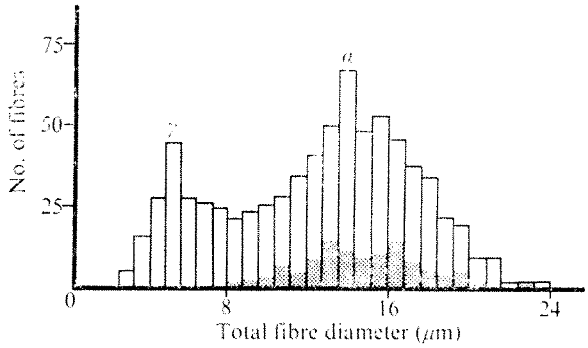

Fig. 1 Fibre size histogram from one fascicle of the ventral root L7 in a cat after injection of ^{125}I-labelled tetanus toxin into the ipsilateral gastrocnemius muscle. Open = labelled and unlabelled fibres ($n = 742$), stippled = labelled fibres ($n = 106$). n = Number of fibres measured. Total number of fibres in fascicle, ~1,500. Total number of labelled fibres, 106.

The accumulation of radioactivity at the ligature would be expected to reveal the presence even of very small amounts of intra-axonal label. Even in these conditions, radioactivity in the ventral roots was found only in fibres which, from their size, seem to belong to the α population[7].

This result is an interesting contrast to the findings of Strick *et al.*[8] who injected horseradish peroxidase into cat gastrocnemius muscle and found γ-motoneurones even more intensely labelled than α-motoneurones. Further studies are needed into the mechanism responsible for the apparent lack of tetanus toxin in the γ axons. A barrier function of structural elements of the muscle spindle or a specific feature of the γ-fibre terminal must be taken into consideration.

Moreover, the increase of γ bias in local tetanus described by Takano *et al.*[9,10] cannot be explained by assuming that tetanus toxin accumulates in γ motoneurones by intra-axonal ascent in γ-motor fibres.

This work was supported by the Deutsche Forschungsgemeinschaft. J.G. is in receipt of a Research Studentship from the Medical Research Council. We thank Professor Oksche for providing technical facilities, Professor Habermann for iodination of toxin, Dr Bizzini for tetanus toxin, and Ms Claudia Becker for technical assistance.

Modifications of nitrogen-fixing algae in lichen symbioses

THE factors responsible for the establishment of lichen symbioses involving nitrogen-fixing blue-green algae are poorly understood[1,2] and it has not been clear how the algae are modified to remain in association, virtually ceasing to grow and yet fixing N_2 at high rates. We report here that in the lichen genus *Peltigera* morphological, physiological and biochemical modifications of the algae may all be involved in this process.

Comparison of symbiotic and free-living *Nostoc* spp. by light and electron microscopy showed that with *P. aphthosa*, which also contains a green alga (*Coccomyxa* sp.) and a fungus (an ascomycete) as symbiotic partners, the heterocyst frequency of the symbiotic *Nostoc* was 21% while that of the free-living *Nostoc* was 4–5%. The symbiotic algae of *P. canina* and *P. polydactyla*, which have a fungus only as partner, showed no increase in heterocyst frequency (remaining at 4–5% when symbiotic), probably because without another photosynthetic partner overall algal metabolism could not be sustained if more than a fifth of the cells were converted to non-photosynthesising heterocysts. The nitrogenase activity (acetylene reduction[3]) of the symbiotic alga of *P. canina* likewise resembled that of the free-living alga (6–10 nmol C_2H_4 per μg chlorophyll *a* per h) but the nitrogenase activity of the symbiotic alga of *P. aphthosa* (21 nmol C_2H_4 per μg chlorophyll *a* per h) was higher than that of the free-living phycobiont[4,5] and could be accounted for in part at least by the increased frequency of heterocysts. There was also evidence that, in spite of the sustained nitrogenase activity, the symbiotic blue-green alga of each lichen was N-depleted. Thus, compared with free-living algae which accumulate large numbers of cyanophycin granules in post-log-phase growth[6,7], the symbiotic phycobionts showed no large scale deposition of such N reserves.

Physiological differences between free-living and symbiotic algae of *P. canina* were noted when the effect of combined N was investigated. Thus Table 1 shows that, as with other free-living algae[8], NH_3 rapidly inhibited nitrogenase activity by the free-living alga, but had substantially less effect on the nitrogenase activity of the symbiotic alga, although an excess of NH_3 was available. Added NO_3^- did not inhibit nitrogenase activity by the symbiotic alga but partially inhibited that of the free-living alga. That is, in symbiotic algae but not in the free-living algae there is a mechanism which alleviates the inhibitory effect of combined N on nitrogenase.

The activities of important NH_3-assimilating enzymes in free-living and symbiotic algae were then examined. Attention was paid to glutamine synthetase (GS) which may be involved in the regulation of nitrogenase synthesis in heterotrophic bacteria[9,10] and which is the key NH_3-assimilating enzyme in heterocystous blue-green algae[11], to glutamic dehydrogenase (GDH), the primary NH_3-assimilating enzyme in certain eukaryotes, including fungi[12], and to alanine dehydrogenase (ADH) and glutamate-aspartate-aminotransferase (GOT) which occur both in eukaryotic and prokaryotic algae. As Table 2 shows, when the *Nostoc* of *P. canina* was grown free from the lichen, GS activity was particularly high, GDH activity was negligible and GOT and ADH activities were appreciable. In the symbiotic alga, however, GS activity was reduced by 94%, GOT and ADH activities also decreased, and low GDH activities were measurable. In the intact lichen thallus which is mainly fungal hyphae, GDH activity was very high and GS activity was negligible. Possibly the low activities of GDH associated with the symbiotic algae were due to contaminating fungal hyphae in this fraction. In the cephalodia of *P. aphthosa* which consist of *Nostoc* cells and intertwined fungal hyphae, GS activity was much lower than in the remainder of the thallus, indicative of low GS activity in the blue-green algae, but cephalodial GDH activity was much higher than in the remainder of the thallus. Thus, when the blue-green algae develop symbiotically a substantial decrease in activity of their key NH_3-assimilating enzyme GS occurs and in the absence of effective levels of GDH this may result in N-limitation of the algae, in an inability of the algae to grow normally, and in a reduction of the effects of NH_3 and NO_3^- on nitrogenase activity. It is also possible that the low activities of GS, directly or indirectly, are important in the sustenance of a particularly active nitrogenase in such symbiotic algae.

Table 1 Effect of NH_4Cl and KNO_3 on acetylene reduction by disks and by the isolated *Nostoc* of *Peltigera canina*

Concentration of NH_4Cl or KNO_3 (mM)	C_2H_2 reduction after 24 h (% original rate)			
	NH_4Cl		KNO_3	
	Disks	*Nostoc*	Disks	*Nostoc*
0	107	110	107	113
1	58	3	95	42
2	54	3	97	51

The material (disks, 20 × 1.0 cm in diameter, in 50 ml of culture medium[17]) or 50 ml of log phase *Nostoc* were incubated with stirring at 3000 lx and 20 °C for 24 h in the presence of various concentrations of combined N. Acetylene reduction was assayed immediately before addition of the combined N and 24 h later. The level of exogenous combined N (refs 18, 19) did not fall below 0.5 mM and 1.4 mM in the 1-mM and 2-mM cultures, respectively. The initial activities observed were: disks, 7.4 nmol C_2H_4 per µg chlorophyll *a* per h; free-living *Nostoc*, 9.4 nmol C_2H_4 per µg chlorophyll *a* per h. Each value is the mean of triplicate determinations.

To localise NADP-dependent GDH activity cytochemically, sections of *P. canina* thalli and of *P. aphthosa* cephalodia were stained with blue tetrazolium (British Drug Houses, Poole, 0.25 mg ml^{-1}) in the presence of the GDH substrates NADP$^+$ (1 mg ml^{-1}) and glutamate (20 mg ml^{-1}). With *P. canina*, activity was highest in the fungal hyphae closest to the blue-green algae, whereas in *P. aphthosa* cephalodia,

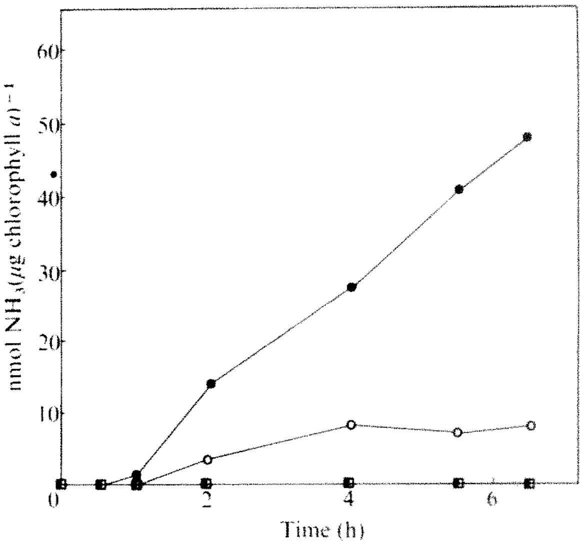

Fig. 1 Time course of production of extracellular NH_3 by 1.0-cm diameter disks of *Peltigera canina* incubated in air + digitonin (●), $A/O_2/CO_2$ (77.96:22.00:0.04, v/v) + digitonin (○), air (■), and $A/O_2/CO_2$ (□). In each experiment 30 disks were incubated with gentle shaking in 50 ml of N-free culture medium[17] at 3,000 lx and 25 °C. NH_3 was determined according to Solorzano[18].

Table 2 Activities of NH_3-assimilating enzymes of *Peltigera aphthosa*, *Peltigera canina* and of the free-living *Nostoc* of *P. canina*

Lichen	Material	Enzyme activities (nmol per mg protein per min) GS	GDH (NADP⁺-dependent)	ADH	GOT
P. canina	Intact thallus	0.8	201.7	3.8	41.0
	Symbiotic *Nostoc*	4.1	2.4	5.5	16.8
	Free-living *Nostoc*	72.4	ND	22.9	40.4
P. aphthosa	Intact thallus	25.7	90.2	—	58.4
	Excised cephalodia	4.5	401.1	—	20.2
	Thallus—cephalodia	17.5	34.8	—	47.0

Peltigera canina and *P. aphthosa* were collected in the field and maintained in the laboratory on N-free medium at 18 °C and 3,000 lx for 24 h before use. The symbiotic *Nostoc* was separated from the remainder of the *P. canina* thallus by the method of Millbank[20]. The free-living phycobiont of *P. canina*, provided by Dr J. W. Millbank, was grown in N-free medium in continuous culture at 25 °C and 3,000 lx. Before enzyme assay the material was washed in 50 mM Tris-HCl buffer, *p*H 7.5, containing 10 mM β-mercaptoethanol and 5 mM ethylene diaminetetraacetic acid. After homogenisation of the lichen material, the homogenates, and the free-living algae, were passed through a French pressure cell at 16,000 pounds per square inch. The extracts were then centrifuged at 35,000*g* for 20 min and the supernatant was passed through Sephadex G-25 to remove low molecular weight compounds then assayed for enzymic activity. The glutamine synthetase (EC 6.3.1.2) biosynthetic assay was that of Kingdon *et al.*[21]. Glutamate dehydrogenase (EC 1.4.1.2.) was estimated by following the oxidation of NADPH at 340 nm in a reaction mixture (3.0 ml final volume): 300 μmol Tris-HCl buffer, *p*H 7.5; 0.3 μmol NADPH; 10 μmol 2-oxoglutarate; 400 μmol NH_4Cl. The glutamate–aspartate–aminotransferase (EC 2.6.1.1.2) and alanine dehydrogenase (EC 1.4.1.1) assays were those of Rowell and Stewart[22]. NAD⁺-dependent GDH was also measured in the above samples using the assay described above with the substitution of NAD⁺ and NADH for NADP⁺ and NADPH. Activity was detected only in the intact thallus (3.8 nmol per mg protein per min) and in the excised cephalodia (4.6 nmol mg per protein per min) of *P. aphthosa*; ND, not detectable; —, not tested.

hyphae surrounding the algae stained heavily but the algae were unstained. The fungal hyphae did not stain in the absence of GDH substrates. Thus, if the N fixed by the symbiotic algae is excreted as NH_3, as would be expected if the primary route of NH_3 assimilation by the algae is blocked, this NH_3 could be assimilated by the fungal GDH.

Finally, we investigated whether the symbiotic *Nostoc* of *P. canina* excreted NH_3. First, disks of *P. canina* were incubated under $A/O_2/CO_2$ (77.96 : 22.00 : 0.04, v/v) or air in the presence and absence of 0.01% (w/v) digitonin, which affects fungal membrane permeability and depresses metabolite assimilation by the symbiotic fungus[13]. Figure 1 shows that during 6.5 h in N_2, but not in its absence, NH_3 was liberated into the medium when digitonin was present. No NH_3 was excreted in the absence of digitonin, and digitonin did not affect nitrogenase activity during the experiment.

Next, *P. canina* disks were exposed to $^{15}N_2$ in the presence of digitonin and the labelling of the extracellular NH_3 and other nitrogenous products was noted. As Table 3 shows, at the end of the experiment the ^{15}N labelling of the extracellular NH_3 was higher than that of the lichen disks and of the organic extracellular N, 50% of the total ^{15}N fixed remained in the disks and, of the remaining ^{15}N incorporated, 50% was released extracellularly as organic N and 50% as extracellular NH_3. Thus as with the symbiotic algae of *Blasia pusilla*[14] and *Azolla*[15], much of the newly fixed N was excreted as NH_3.

Table 3 Incorporation of ^{15}N from $^{15}N_2$ into disks, extracellular NH_3 and extracellular organic N of digitonin-treated *Peltigera canina*

Material	Total N present (mg)	^{15}N-labelling of material (atom % excess ^{15}N)	% of total fixed N in each sample
Disks	70	0.022	50
Extracellular organic N	3.9	0.205	25
Extracellular NH_3	1.1	0.727	25

350 1.0-cm diameter disks of *Peltigera canina* were washed in N-free culture medium[17] for 6 h then incubated in $A/O_2/CO_2$ (77.96:22.00:0.04, v/v) in N-free medium for 12 h. The gas phase was then replaced by $N_2/A/O_2/CO_2$ (10:67.96:22.00:0.04, v/v), the ^{15}N-enrichment of the N_2 being 44 atom % ^{15}N. (All ^{15}N assays were carried out by mass spectrometry using an Associated Electrical Industries MS20 mass spectrometer.) Digitonin (0.01 %, w/v) was also added at 0 time. After 21 h at 1,000 lx and 25 °C the total nitrogen and ^{15}N-labelling of the disks, extracellular NH_3 and extracellular organic nitrogen were determined[23]. The ^{15}N-label of the gas phase did not change over the experimental period. The experiment was run in duplicate.

The above modifications of the symbiotic algae seem to depend on the eukaryotic partner(s) since, as in *Blasia pusilla*[14,16], when the blue-green alga is incubated free from its partners, it reverts to the morphology, physiology and biochemistry of typical free-living forms. Further work is necessary to show whether the eukaryotes produce specific effectors which regulate GS and possibly other NH_3-assimilating enzymes in the cyanophyte, or whether the changes are due solely to internal regulation by the cyanophyte of its metabolism as a result of the presence of the eukaryotes.

We thank the SRC, the NERC and the Royal Society for support, Miss Gail Alexander for technical assistance and Professor D. C. Smith for suggesting the use of digitonin.

Model for the regulation of nitrate assimilation

NITRATE assimilation is one of the two major biological processes by which inorganic nitrogen is converted to ammonia and thence to organic nitrogen. Photosynthetic organisms, with the possible exception of some blue-green algae and plants that have a symbiotic association with nitrogen-fixing bacteria, derive most of their nitrogen from nitrate[1]. The rate-controlling and regulated step in the process of nitrate assimilation seems to be the conversion of nitrate to nitrite, catalysed by the enzyme nitrate reductase[2]. There is a good correlation between the activity of this enzyme and the yield of grain protein in several cereal crops[3-5]. Nitrate arising from chemical fertilisers and industrial wastes is also a major factor contributing to the growth of algae and other microorganisms, leading to the eutrophication of lakes and streams. Thus, the control of nitrate assimilation can be important from the standpoint of both agricultural productivity and water resource management.

In this communication we propose a model (Fig. 1) for the regulation of nitrate assimilation in which CO_2 fixation and nitrate assimilation are coordinately controlled by the intracellular ratio of $[O_2]/[CO_2]$. This model accounts for the observed effects of O_2, CO_2 and light on nitrate assimilation and provides a rationale for the *in vivo* regulation of nitrate reductase by cyanide.

The nitrate reductase from *Chlorella* and several other organisms can exist in either an active or in an inactive form (see ref. 6). *In vitro* experiments with purified nitrate reductase from *Chlorella vulgaris* showed that two components are required for the rapid and reversible inactivation of nitrate reductase[7]. The most potent combination of effectors is the physiological reductant NADH, and cyanide Cyanide reacts stoichiometrically with the NADH-reduced enzyme to produce a stable enzyme–cyanide complex having a dissociation constant of about 10^{-10} M (ref. 8). These results indicated that very low concentrations of cyanide are sufficient to convert the active enzyme to an inactive form. The conversion of the inactive form to the active form by treatment with an oxidant is accompanied by the release of bound cyanide[8]. Nitrate reductase can be inactivated *in vivo* by brief incubation of the cells with ammonia[9] The *in vivo* inactivated nitrate reductase isolated from such cells contains a stoichiometric amount of bound cyanide that is likewise released on conversion of the inactive nitrate reductase to the active form[9] These results suggested that cyanide is a physiological regulator of nitrate reductase activity.

Pistorius *et al.*[10] have shown that the *in vivo* inactivation of *Chlorella* nitrate reductase is stimulated by O_2 and inhibited by CO_2 and nitrate. Both the effect of O_2 and that of CO_2/nitrate are light dependent[10]. O_2 also inhibits photosynthetic CO_2 fixation[11]. Ribulose 1,5-diphosphate (RuDP) carboxylase can function either as an oxygenase or as a carboxylase[12,13]. Lorimer and Andrews[14] proposed that in the reaction of RuDP with the enzyme, an enolate anion of RuDP is generated which would be susceptible to attack by either CO_2 or O_2. CO_2 fixation could therefore be directly regulated by the ratio of $[O_2]/[CO_2]$. As indicated in the

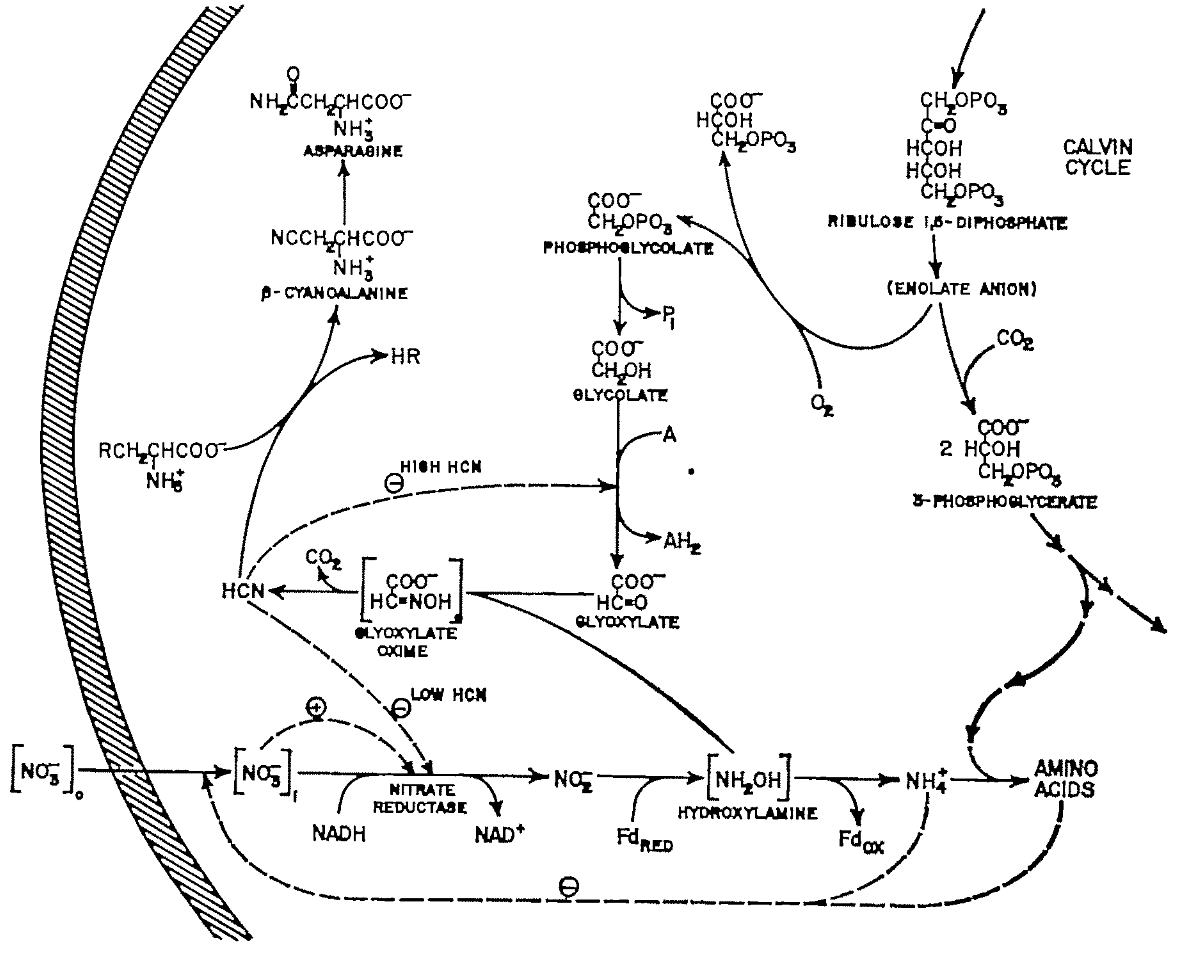

Fig. 1 Model for the regulation of nitrate assimilation. Solid lines represent metabolic conversions. Dashed lines represent inhibition (–) or activation (+) reactions.

model, phosphoglycolate, one of the products of the oxygenase reaction, can be converted to glycolate and thence to glyoxylate[15]. In green algae the oxidation of glycolate to glyoxylate is catalysed by a cyanide-sensitive glycolate dehydrogenase[16]. The physiological hydrogen acceptor for this reaction is not known.

Loussaert and Hageman have recently reported that hydroxylamine is a product of *in vitro* nitrite reduction in the presence of ammonia[17]. A central feature of our proposed model is that hydroxylamine reacts with glyoxylate which is then converted to cyanide and CO_2. This proposal is supported by experiments showing that sonicated extracts[18] of *Chlorella vulgaris* catalyse the formation of cyanide from hydroxylamine and glyoxylate. These reactions were carried out at room temperature in sealed Conway diffusion dishes that contained 0.5 ml of 0.5 N NaOH in the centre well and 2.0 ml of reaction mixture in the outer well. The complete reaction mixture contained 40 mM HEPES NaOH (*p*H 7.5), 5 mM sodium glyoxylate, 5 mM hydroxylamine and 1 mM $MnCl_2$. The reaction was started by the addition of cell extract and was terminated at various time intervals by the addition of 0.2 ml of 50% trichloroacetic acid to the reaction mixture. The dishes were immediately resealed and incubated for an additional 30 min at room temperature to allow complete diffusion of the HCN to the alkali trap. The amount of cyanide in the centre well was then measured by the method of Guilbault and Kramer[19]. The rate of cyanide formation was about 1 nmol min^{-1} mg^{-1}. The activity of nitrate reductase (after activation[7]) in these extracts was about 150 nmol NO_3 reduced min^{-1} mg^{-1}. No significant formation of cyanide was observed in the following controls: (1) absence of hydroxylamine or glyoxylate, (2) with heat-inactivated extracts, or (3) ammonia substituted for hydroxylamine in the complete reaction mixture. The rate of cyanide formation was essentially constant over a 60-min incubation period, was directly proportional to the amount of extract added to the reaction mixture and was stimulated by Mn^{2+}. This stimulation by Mn^{2+} is consistant with the observation that the formation of inactive nitrate reductase, *in vivo*, is impaired in Mn^{2+}-deficient cells[10]. Like nitrate reductase, the enzyme which catalyses the formation of cyanide from hydroxylamine and glyoxylate is found in the supernatant after centrifugation at 100,000*g* for 1 h.

Only very low levels of cyanide ($\sim 10^{-9}$ M) would suffice for the reversible inactivation of nitrate reductase[8]. The concentration of HCN required for the inactivation of nitrate reductase is several orders of magnitude smaller than that which would inhibit respiration[8,20]. The formation of high levels of cyanide could be prevented by the feedback inhibition of glycolate dehydrogenase at higher concentrations of cyanide ($\sim 10^{-6}$ M) (ref. 16). This aspect of the model is also supported by the observation that *Chlorella* cells excrete glycolate at high light intensity, high O_2 tension and low CO_2 tension[21], the same conditions that cause maximum reversible inactivation of nitrate reductase[10]. Added HCN mimics these effects of high O_2 tension[22], suggesting that the cyanide formed internally when cells are illuminated in the presence of high $[O_2]$ causes an accumulation of glycolate.

Excess cyanide could be removed by a reaction sequence in which cyanide is converted to the β-carboxamide of asparagine. Exogenous cyanide is converted to the β-carboxamide group by seedlings of a variety of plants[23]. Fowden and Bell[24] have also shown that seedlings and *Chlorella* convert $H^{14}CN$ to β-cyanoalanine which in turn is converted to asparagine or to the peptide γ-glutamyl-β-cyanoalanine. The feedback regulation of cyanide formation and its removal by the above 'scavenger' pathway would prevent the accumulation of cyanide and the inhibition of other vital metabolic processes such as respiration.

An additional feature of the model is the inhibition of nitrate uptake by ammonia and/or amino acids. A nitrate-uptake system that is independent of nitrate reductase and that is inhibited by ammonia or amino acids has been demonstrated in cultured tobacco cells[25] and in *Neurospora crassa*[26].

A rapid *in vivo* activation of nitrate reductase, independent of *de novo* enzyme synthesis has heretofore not been demonstrated unequivocally. Nitrate, in conditions of high light intensity, high $[CO_2]$ and absence of ammonia causes an apparent *in vivo* conversion of the inactive form of nitrate reductase to the active form[9,10]. Cycloheximide partially inhibits this *in vivo* 'reactivation' of nitrate reductase by nitrate[10], suggesting that the reactivation may be at least partially dependent on *de novo* protein synthesis. Inhibitors of protein synthesis may, however, affect the intracellular concentrations of amino acids thereby inhibiting the nitrate-uptake system[25,26]. This might explain the apparent inhibition of the *in vivo* activation of nitrate reductase by cycloheximide.

It has been demonstrated that when tungsten is substituted for molybdenum in the growth medium, a tungsten

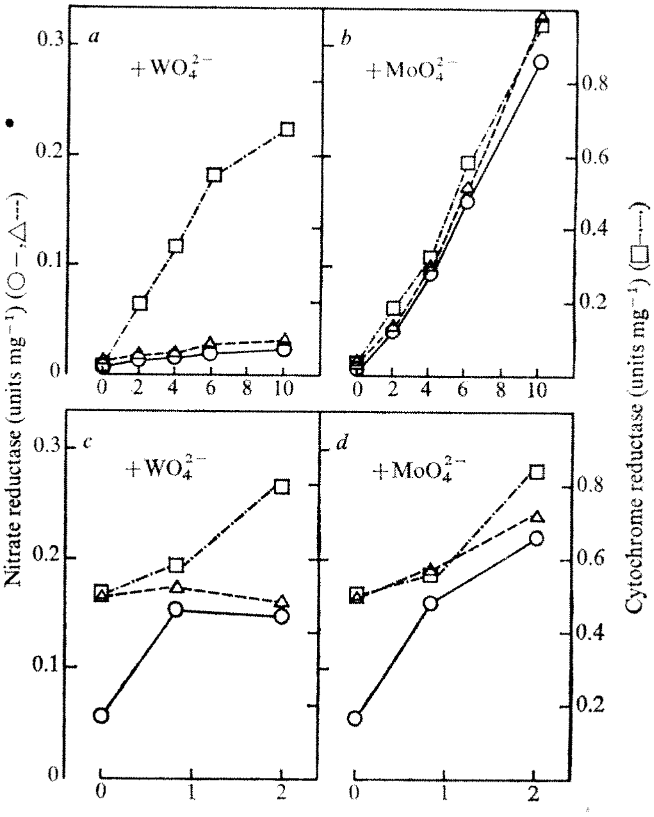

Fig. 2 Nitrate-induced synthesis and *in vivo* activation of nitrate reductase by nitrate. For *a* and *b*, *Chlorella vulgaris* cells were cultured in an ammonium growth medium[29] for 4 d and then were collected and transferred to growth medium containing 10 mM KNO_3 and either 10 μM Na_2WO_4 (*a*) or 10 μM Na_2MoO_4 (*b*). Aliquots of these cell cultures were withdrawn at the indicated intervals, harvested and disrupted by sonication in 10 mM HEPES (*p*H 7.5) and 2 mM KNO_3. The sonicated extract was centrifuged for 10 min at 25,000*g* (4 °C). The supernatant was assayed for NADH–cytochrome *c* reductase activity (□-·-·-·-□) and NADH-nitrate reductase activity before (○———○) and after (△- - - -△) a 2 min incubation with 2 mM potassium ferricyanide to convert the inactive form of nitrate reductase to the active form[7]. Activity is expressed as units (μmol min^{-1}) per mg of protein. The conditions were the same for *c* and *d* except that nitrate-grown cells were preincubated in the ammonium growth medium for 2 h before transfer to growth medium containing 10 mM KNO_3 and either 10 μM Na_2WO_4 (*c*) or 10 μM Na_2MoO_4 (*d*). This short preincubation with ammonium causes an *in vivo* inactivation of nitrate reductase[8,30] in contrast to the disappearance of nitrate reductase and associated cytochrome *c* reductase as occurs on long term cultivation in ammonium-containing medium (*a* and *b*).

analogue of nitrate reductase is formed which has NADH-dehydrogenase (cytochrome *c* reductase) but no nitrate-reducing activity[27,28]. Thus, in the presence of tungstate and absence of molybdate, any new nitrate reductase formed would be expected to have cytochrome reductase activity but no nitrate-reducing activity. By contrast, any increase in nitrate-reducing activity due to the *in vivo* activation of inactive nitrate reductase should be unaffected by tungstate. Therefore, with the use of tungstate, it should be possible to distinguish unequivocally between *de novo* enzyme synthesis and *in vivo* activation of nitrate reductase.

When *Chlorella* cells are exposed to ammonium for long periods (>24 h), the total amount of nitrate reductase, including the associated cytochrome *c* reductase activity, falls to <5% of the original level[29]. When such cells were transferred to a nitrate medium containing tungstate (Fig. 2*a*), there was a normal development of cytochrome *c* reductase activity (see Fig. 2*b*) but no significant development of nitrate reducing activity. Thus, enzyme synthesised in the presence of tungstate has no nitrate-reducing activity. For the experiment shown in Fig. 2*c* and *d*, *Chlorella* cells were exposed to ammonium for 2 h. This short treatment with ammonium causes an *in vivo* inactivation of nitrate reductase[8,30], that is there is no significant change in cytochrome *c* reductase and total nitrate reductase activities but there is a decrease in % active nitrate reductase. When these cells were then transferred to a nitrate medium containing tungstate (Fig 2*c*), there was a normal development of nitrate-reducing activity (measured before activation) over the first 45 min (see Fig. 2*d*). Further development of nitrate-reducing activity, which presumably reflects *de novo* enzyme synthesis, was inhibited by tungstate. These results indicate that the *in vivo* activation of nitrate reductase is independent of *de novo* enzyme synthesis.

Although not indicated in the proposed model, light would have an important role in this regulatory mechanism since ATP and NADPH derived from the light reactions of photosynthesis would be required for the generation of RuDP, the substrate for the reactions catalysed by RuDP carboxylase/oxygenase. As would be predicted from our model, the *in vivo* inactivation and activation of nitrate reductase are both stimulated by light[10]. Also of possible relevance to the proposed model are recent results of Lips and associates[31–33] which suggest that enzymes of CO_2 fixation (RuDP carboxylase), photorespiration (glycolate oxidase) and nitrate assimilation (nitrate reductase) are associated with microbody-like organelles which attach themselves to chloroplasts during illumination.

Since CO_2 fixation by the Calvin cycle is the ultimate source of carbon skeletons for the fixation of ammonia produced by assimilatory nitrate reduction, little or no fixation of ammonia could occur in the absence of CO_2. It is reasonable, therefore, that these two processes be coordinately regulated. When the rate of CO_2 fixation is low, the accumulation of potentially toxic intermediates of nitrate assimilation such as nitrite, hydroxylamine, and ammonia would be prevented. When the rate of CO_2 fixation is high, the formation of sufficient ammonia for the synthesis of organic compounds would be ensured. We propose that this coordinate regulation of CO_2 fixation and nitrate assimilation can be accomplished by the reactions outlined in our model.

Membrane localised gibberellins A_9 and A_4 in wheat chloroplasts

GIBBERELLINS help to regulate plant growth and development, but their mechanism of action is still not clear[1]. Attempts to correlate the levels of solvent-extractable gibberellins in plants with specific developmental events have shed little light on these problems. Turnover rate is one variable of possible physiological importance not accounted for when steady state levels of extractable hormone are measured. Another relevant factor is the way in which the hormones are sequestered or compartmented within the cell; this may reflect both how the hormone acts and is controlled and how it can be extracted. Prompted by recent evidence that gibberellins are released from wheat[2] and barley[3] etioplasts *in vitro* by red light, we investigated whether gibberellins are associated with membranes in wheat chloroplasts. We found that gibberellins (principally GA_9 and GA_4) can be extracted from chloroplast membrane preparations using novel extraction procedures. Quantities found were much greater than the amounts of gibberellins previously extracted from the vegetative tissues of any plant species.

The non-ionic detergent Triton X100 (ref. 4) was used to disperse membranes in chloroplast preparations obtained from the first leaves of 8-d-old seedlings of *Triticum aestivum* variety Kolibri raised under long photoperiods in a heated greenhouse. Leaves in 10-g lots were ground in a mortar and pestle lined with a 50-μm mesh nylon cloth for 2 min at 2 °C in 100 ml of a modified Honda[5] medium at *p*H 7.2 (9% sucrose; 25 mM potassium-Tricine buffer; 8 mM 2-mercaptoethanol; 5 mM magnesium acetate; Dextran-15; (50 mg ml^{-1}); Ficoll (25 mg ml^{-1}); bovine serum albumin (1 mg ml^{-1}). Material not retained by the mesh was centrifuged at 1,000*g* for 10 min and the supernatant was discarded. Figure 1*a* and *b* shows that about 1,000 times more gibberellin activity of low polarity (R_f 0.5–0.7) was present in Triton-extracted than in methanol-extracted chloroplast preparations. A more polar fraction (R_f 0.1–0.2) was prepresent at relatively low and approximately equal levels in the two extracts. Figure 1*c* shows that only slightly more gibberellin activity was found when the pellet was disrupted by sonication before methanol extraction than when the intact preparation was extracted with methanol directly. The gibberellin activity detected in the methanol extracts was comparable with the activity found when an equivalent weight of leaves was extracted directly with 80% methanol and subjected to the same purification procedure.

Most of the gibberellins so far identified in higher plants have been obtained from immature seeds, because the very low levels hitherto found in vegetative tissues have made identification extremely difficult. The levels of the less polar gibberellins extracted from crude chloroplast preparations with Triton are similar to the gibberellin levels found in methanolic extracts of immature seeds. Hence we were able to identify the gibberellins extracted by Triton without recourse to complex purification procedures. After the usual initial purification steps (Fig. 1), the bulk of gibberellin activity could be resolved into two major, relatively non-polar fractions using silicic acid partition column chromatography[8]. The less polar of these fractions was methylated with ethereal diazomethane and subjected to combined gas chromatography–mass spectrometry (GCMS). Mass spectra were recorded at 3 s per mass decade using an AEI MS30 mass spectrometer with a DS50 data system. Ions of mass 330 (M^+) 298 270 and 271, characteristic of methyl GA_9, were detected at the retention time of authentic methyl GA_9 using the DS50 cross scan facility. GA_9 was identified unequivocally when an exceptionally clean mass spectrum was obtained from a Triton extract subjected to an additional purification step in which the methylated extract underwent Gelman instant thin-layer chromatography[9] (ITLC) in benzene : petroleum ether (boiling point 60–80 °C) (3 : 1 v/v). The zone corresponding in R_f with authentic methyl GA_9 was eluted with ethyl acetate before GCMS.

After the same procedures but with petroleum ether : diethyl ether (7 : 3, v/v) as the ITLC solvent, the more polar fraction from the partition columns was trimethylsilylated after ITLC and, on GCMS, yielded a mass spectrum identical with that of authentic methyl trimethylsilyl GA_4. These identifications will be fully documented elsewhere. None of the gibberellins in wheat plants have been identified before.

We were able routinely to use gas chromatography–single ion current monitoring (GC–SICM) to determine the gibberellin content of partially purified extracts as described in the legend to Table 1. Determined thus, the levels of GA_9 and GA_4 in Triton and methanol extracts of crude chloroplast preparations were similar to the levels measured by bioassay.

To check whether the Triton extractable gibberellins were associated primarily with the chloroplasts, 1,000 *g* crude chloroplast pellets obtained in the usual way were resuspended in 20 ml of extraction medium and eluted with more medium through a 38×3 cm column of loosely packed Sephadex G-50[5]. The first green band to elute from the column (1.5 V_0) consisted almost entirely of intact chloroplasts as seen with phase contrast and electron microscopy. Chloroplasts prepared thus contain per unit chlorophyll the same levels of methanol and Triton-extractable GA_9 as the crude 1,000*g* pellet. That the bulk of the gibberellins are released only by detergent treatment, and not by sonication, suggests an intimate association with the chloroplast membranes. Further evidence in support of this hypothesis was obtained as follows. 1,000*g* pellets were either resuspended in the usual medium and then sonicated or resuspended in the usual medium without sucrose to lyse the chloroplasts osmotically. The disrupted chloroplasts were centrifuged at 20,000*g* for 20 min and the pelleted membranes were extracted with Triton or methanol, treated as usual. The gibberellins extracted with Triton were found by GC-SCIM and by bioassay to be in

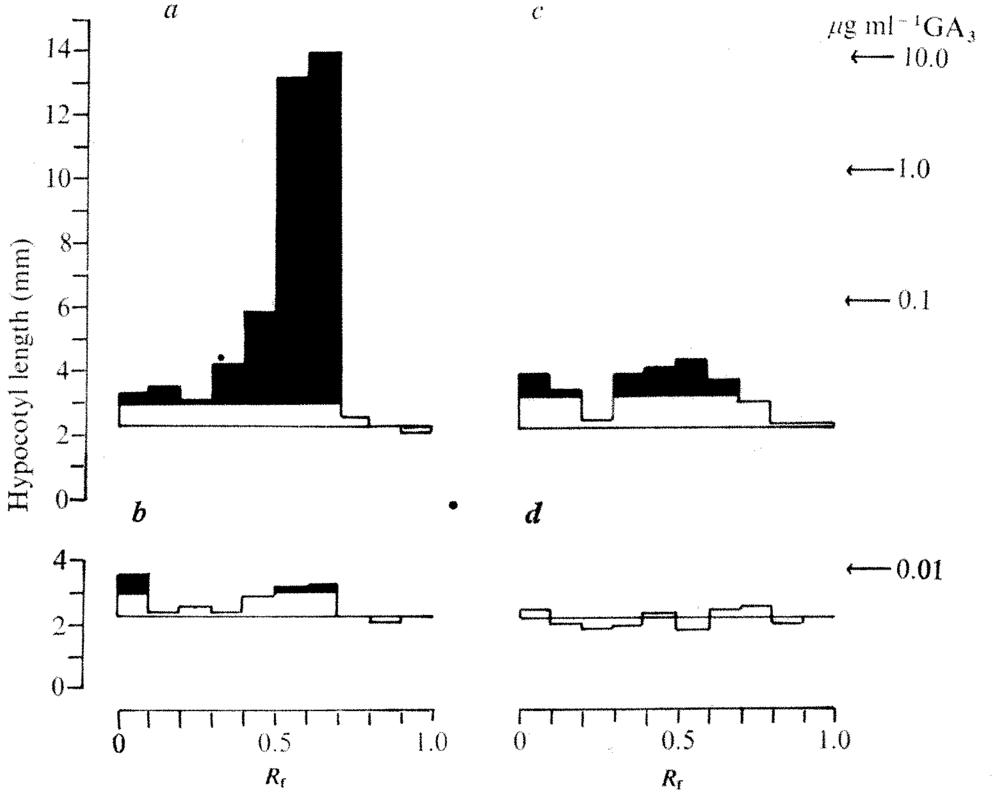

Fig. 1 Gibberellin activity in extracts of the crude 1,000*g* pellet derived from 10 g fresh weight leaf samples. *a*, Pellet resuspended in 50 ml of 2% Triton X100 buffered at *p*H 8.0 in 25 mM potassium Tricine. *b*, Pellet resuspended in 100 ml of methanol : water at *p*H 8.0 (4 : 1, v/v). *c*, Pellet resuspended in 20 ml of grinding medium, disrupted by three 15-s bursts from an MSE 150 W sonicator (nominal frequency 20 kHz), diluted with 80 ml methanol and, after 1 h, centrifuged at 40,000*g* for 1 h and the supernatant taken for further processing. The 40,000*g* pellet from (*c*) resuspended in 50 ml of 2% Triton X100 at *p*H 8.0. All extracts were subjected to a standard initial purification procedure. Methanol was removed under reduced pressure on a rotary evaporator at 35 °C. Extracts were diluted to 200 ml with distilled water, adjusted to *p*H 8.0 and passed through a 2×10 cm column of Dowex IXI-100 formate; the column was washed with a further 200 ml water at *p*H 8.0. Gibberellins were eluted from the resin with 400 ml of ethanol : 1.0 M formic acid (4 : 1 v/v). The eluate was reduced to a small volume of aqueous solution on a rotary evaporator, diluted with 100 ml of 0.1 M Na_2HPO_4, adjusted to *p*H 8.0 and stirred for 1 h with 20 g of insoluble polyvinyl pyrollidone (PVP)[6]. After filtration the extract was adjusted to *p*H 3.0 and partioned three times against half its volume of ethyl acetate. Bulked ethyl acetate extracts were dried with anhydrous magnesium sulphate and the solvent was removed on a rotary evaporator. For bioassay, purified extracts dissolved in methanol were applied to 10-cm wide sheets of Whatman No. 1 chromatography paper. Chromatograms were developed in *iso*-propanol : 0.880 : ammonia : water (10 : 1 : 1, v/v/v), cut into strips corresponding to 0.1 -R_f units and the strips bioassayed directly using the lettuce hypocotyl test[7].

Table 1 Yields of GA$_9$ and GA$_4$ from chloroplast membrane preparations

	Assay method			
Extraction procedure	GC–SICM		Bioassay (μg GA$_9$ equivalents)	
	GA$_9$	GA$_4$	GA$_9$	GA$_4$
Triton X100 extracts (μg mg^{-1} chlorophyll)	2.9	0.9	2.1	0.5
(μg g^{-1} fresh weight leaves (adjusted for membrane recoveries))	7.7	2.4	5.9	1.4
80% Methanol extracts (μg mg^{-1} chlorophyll)	0.005	0.001	0.004	0.001
(μg g^{-1} fresh weight leaves (adjusted for membrane recoveries))	0.013	0.004	0.01	0.003

Crude chloroplast pellets from 10 g fresh weight of leaves were resuspended in 20 ml extraction medium and sonicated as before. Sonicated preparations were centrifuged at 20,000*g* for 20 min and the pelleted material was extracted with Triton or aqueous methanol. The extracts were partially purified (Fig. 1) and for GC–SICM the ethyl acetate extracts were methylated with ethereal diazomethane. The methylated extracts were subjected to ITLC using benzene–petroleum ether (3 : 1, v/v) as solvent for methyl GA$_9$ or petroleum ether–diethyl ether (7 : 3, v/v) as solvent for methyl GA$_4$; zones corresponding in R_f to those of authentic methyl GA$_9$ or methyl GA$_4$ were eluted with ethyl acetate. The ethyl acetate was removed on a rotary evaporator and the extract was redissolved in 2 ml of acetone. Methyl-GA$_9$ or methyl-GA$_4$ content was measured by injecting 1 μl of the acetone extract on to a glass column (182 cm × 0.4 mm inner diameter) packed with 2% OV-1 coated on Gas Chrom Q (100–120 mesh) fitted to a Pye 104 gas chromatograph coupled through a silicone rubber membrane separator to an AEI MS 30 mass spectrometer. Samples were chromatographed isothermally at 228 °C with 40 ml min^{-1} helium carrier gas. The MS 30 was set to monitor current at an *m/e* value of 298 for GA$_9$ or 224 for GA$_4$ with 1,000 resolving power using authentic methyl GA$_9$ or methyl GA$_4$ as reference compounds. High frequency noise was eliminated by a filter circuit adjusted to give the minimum peak distortion and the selected ion current was recorded with a Servoscribe ls pen recorder. The total ion current was recorded on a second Servoscribe. Authentic GA$_9$ added to 50 ml 2% Triton X100 could be recovered after these procedures in yields of > 90%. For bioassay, acidic ethyl acetate extracts were line loaded on to 10 × 20-cm thin-layer chromatography plates spread with 250 μm silica gel. Plates were developed in ethyl acetate–chloroform–acetic acid (15 : 10 : 1 v/v) and dried overnight over a fan. The silica gel was removed in bands corresponding to 0.1 R_f values and bioassayed directly using the lettuce hypocotyl test[7]. Authentic GA$_9$ moved in the solvent system used to R_f 0.85–0.9 and GA$_4$ to 0.65–0.7. Chlorophyll was determined according to Arnon[10].

the membrane pellets (Table 1), which per unit of chlorophyll contained similar amounts of gibberellin as intact chloroplasts. Extracted separately with methanol, the membrane pellet and supernatant yielded approximately equal amounts of gibberellin; combined pellet–supernatant gibberellin content was similar to that of intact chloroplast preparations extracted by methanol.

Circumstantial evidence suggests that the Triton-extractable gibberellins are localised within the chloroplast membranes in a specific manner, rather than simply partitioned into the membrane lipids. The gibberellins are not extracted by chloroform : methanol mixtures which are reported to delipidate membranes completely[11]. And they are not extracted from sonicated chloroplast preparations by 8 M urea or by 1 mM EDTA, which would be expected respectively to release components linked to the periphery of the membrane by hydrogen bonds or by metallic cations[12]. One possibility is that the Triton-extractable gibberellins are intimately associated with non-polar proteins or other molecules located within rather than on the periphery of the membranes. This might explain not only why the Triton-extractable gibberellins are not extracted with methanol but also why methanol renders them not extractable with Triton. The detergent failed, for example, to extract gibberellins from the insoluble residue which remained when the chloroplasts were sonicated and extracted for 1 h with 80% methanol and then centrifuged at 40,000*g* for 1 h (Fig. 1*d*). Furthermore, the amounts of gibberellin extracted by methanol were not increased when Triton was added to unfractionated methanolic extracts or when methanol and Triton were added together. Possibly, methanolic extraction denatures or alters the proteins or other molecules with which the Triton-extractable gibberellins are intimately associated, in such a way that the gibberellins are rendered not extractable even by Triton.

Clearly, there seem to be at least two fractions of extractable gibberellins compartmented within the chloroplast membranes—one released from the membranes by methanol and another released by Triton. Whether these fractions belong to the same physiological pool, part of which is not efficiently extracted by organic solvents, or whether the two fractions are physiologically distinct needs to be determined.

We thank Mr J. K. Heald for assistance with GCMS.

Removal of 5-bromo-2-deoxyuridine incorporated in DNA of regenerating rat liver

THERE are many systems available for the study of *in vitro* DNA repair, including autoradiography[1], inhibition of *de novo* DNA synthesis by hydroxyurea (HU)[2] and use of radioactive[3] or cold 5-bromo-2-deoxyuridine (BUdR) as substrates, followed by density gradient separation[4] or photoirradiation[5] at 313 nm. There are a few methods available for *in vivo* studies of DNA repair[6] based on indirect techniques involving the use of DNA alkaline sucrose gradient centrifugation, or on the use of HU and gel filtration in tissues with low mitotic rhythm (unpublished work). Use of BUdR in DNA labelling does not give satisfactory results *in vivo*, and autoradiography is impractical. We have examined the hypothesis that BUdR, once incorporated in newly-synthesised DNA, can be recognised as a steric encumbrance and so be removed by nuclear DNA repairing enzymes. This removal does occur, and forms the basis of a reliable method for measuring DNA repair in tissues with high DNA-synthetic activity.

Female Wistar rats (in groups of five) weighing 130–150 g underwent partial hepatectomy[7]; 23 h later, that is at the peak of the S phase, a mixture of ^{3}H-thymidine (TdR) and ^{14}C-BUdR (18.5 Ci mmol^{-1} and 60 mCi mmol^{-1}, respectively),

Table 1 Removal of ^{14}C-BUdR incorporated in DNA of regenerating rat liver

*Zero time values were obtained from a group of rats killed 1 h after i.p. injection of 9.1 μCi ^{3}H-TdR together with 1.3 μCi ^{14}C-BUdR (^{3}H/^{14}C ratio = 7) 23 h post-hepatectomy in female Wistar rats (130–150 g) in groups of five. Animals were killed at various times and radioactivity was counted on duplicated 1.5-mg DNA samples. Data are reported as mean ± s.e.m.

†$0.05 > P > 0.01$.

‡$P < 0.01$.

(Radiochemical Centre, Amersham) was injected intraperitoneally in the ratio ^{3}H/^{14}C=7 (9.1 μCi TdR plus 1.3 μCi BUdR). In the first experiment rats were killed 1 h and 1, 3, 8 and 15 d after injection, while in a second experiment rats were killed 1 h and 1, 2, 4, 8 and 15 d after treatment. The livers were removed and processed separately. DNA was extracted, and purified from the isolated nuclei using a phenol method[8] and radioactivity was determined in 0.4-ml samples of supernatant made 0.2 N $HClO_4$ after centrifugation. Two samples (about 1.5 mg) of DNA extracted from each of the livers were dissolved in distilled water, acidified, filtered on Whatman GF/C glass fibre dishes, washed with ethanol and then ether and dried. Finally, 3 ml methylcellosolve and 10 ml scintillation liquid (0.4% PPO and 0.005% POPOP in toluene) were added to each vial and the double labelling (^{3}H and ^{14}C) was counted in a previously calibrated Intertechnique SL 32 spectrometer, provided with external (^{226}Ra) standardisation.

Table 1 shows removal of ^{14}C-BUdR from DNA in regenerating rat livers; results are expressed both as the mean of the ratios ^{3}H/^{14}C and as the mean of DNA specific activity for each isotope ±s.e.m. Figure 1 shows the variation in time of the DNA specific activity for ^{3}H and ^{14}C (multiplied by 7 to be normalised to ^{3}H) from the second experiment. The finding of a ratio ^{3}H/^{14}C in DNA equal to that of injected TdR/BUdR is casual and due to preferential uptake of TdR, diluted in the cell nucleotide pool. In Fig. 2, liver growth is plotted against time, and the quantity of DNA is expressed both as mg and as mg g^{-1} of tissue. CsCl sedimentations of DNA samples confirmed that ^{3}H and ^{14}C labels were associated with the DNA peaks (1.705 density) in the previously reported ratios.

BUdR removal from DNA began 4 d after initial treatment and stopped during the eighth day, that is, within a period in which DNA synthesis is completed and liver mass and DNA quantity per unit of weight have practically returned to normal. We are not aware of any reports of BUdR removal *in vivo* by a purely physicochemical mechanism and so we consider the observed BUdR removal as an indication of DNA repair. An alternative explanation of the data might be that cells were killed following incorporation of labelled BUdR and TdR, and that released ^{3}H-TdR is preferentially incorporated into DNA. This is unlikely, however, because both BUdR (1.7×10^{-7} M) and TdR (3.8×10^{-9} M) were administered in doses well below toxic levels (10,000-fold and 1,000-fold lower, respectively)[9,10]. The ^{3}H-TdR dose used was 100-fold lower than the mutagenic dose in mouse[11], and the dose given per g body weight

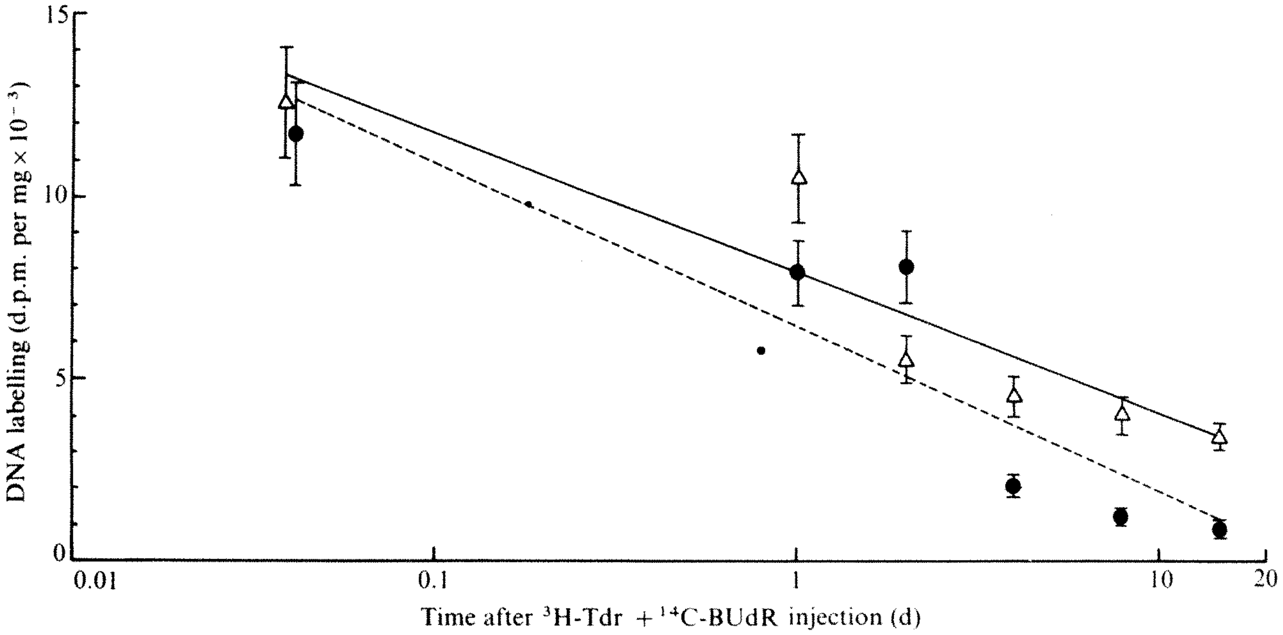

Fig. 1 DNA labelling time course after injection of 9.1 μCi ^{3}H-TdR and 1.3 μCi ^{14}C-BUdR (second experiment) to rats 23 h after hepatectomy (time 0). Data are the mean of duplicate estimations performed on five animals ± s.e.m. ^{3}H regression line: $y = 7851-3885.26x$ ($t = 28.83$). ^{14}C (normalised to ^{3}H) regression line: $y = 6461-4498.79x$ ($t = 38.34$); in both x = time log. Slopes were significantly different at $P < 0.05$, when regression lines were compared.

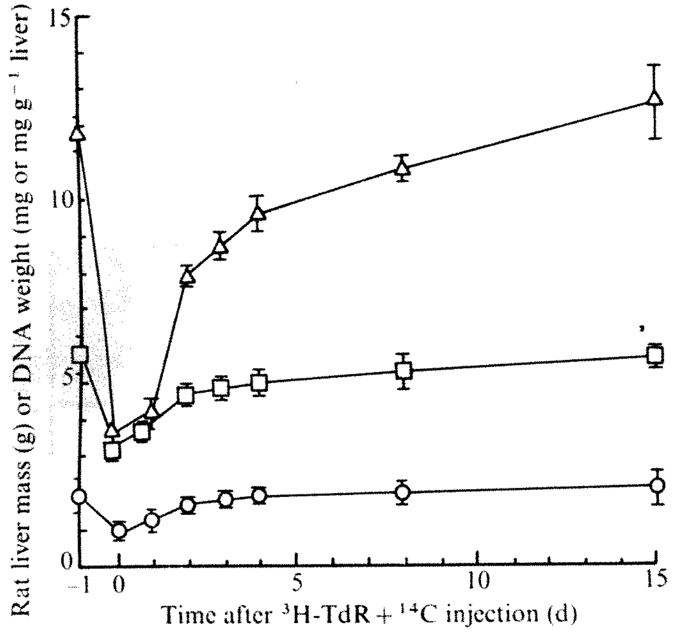

Fig. 2 Time course of rat liver mass as g (□) and DNA weight, both as mg (△) and as mg g^{-1} tissue (○) after partial hepatectomy. Animals were injected with ^{3}H-TdR/^{14}C-BUdR as in Fig. 1, at 23 h after hepatectomy (time 0). Data are the mean five values ± s.e.m.

was sixfold lower than a dose which affects neither rat liver regeneration (as regards liver mass) nor mitotic rhythm and figures[12], in identical conditions. The dose of ^{3}H-TdR we used *in vivo* does not influence cell viability when added to cell culture, an *in vitro* system where physiological removal of radioactive tracer is impossible[10]. On the basis of radioactivity incorporated into DNA, and assuming that there was 10 pg of DNA per cell, there were only 1.6 cell disintegrations within the first 8 d, and even fewer when it is considered that cell division occurs. Variations in ^{3}H/^{14}C ratio occurred when mitotic index was again low. Moreover BUdR is similarly removed in rat spleen cell cultures (our unpublished work) in the presence of excess cold TdR.

It is therefore possible that, when BUdR is inserted into DNA, there is filament breakage similar to that which occurs rapidly *in vitro* after photoirradiation, and that enzymatic repair can follow[13]. BUdR-induced breakage seems to take place more slowly than the radiation-induced process. Removal and the repair processes could follow the molecular mechanism involved in repairing γ-ray-induced damage[5].

The method we describe can be used both to compare repair activity as a function of age in organs with high DNA synthesis and to study the relationship between carcinogenesis and DNA repair in systems, such as regenerating liver, for which data are available on tumour induction by single administrations of *N*-methyl-*N*-nitrosourea[14], dimethylbenz(a)anthracene[15], dimethylnitrosamine[16] and urethane[17].

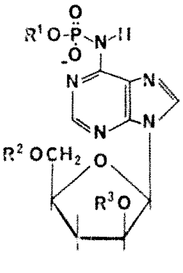
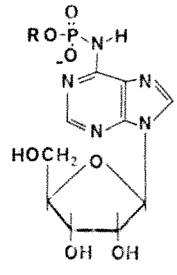
Agrocin 84 is a 6-*N*-phosphoramidate of an adenine nucleotide analogue

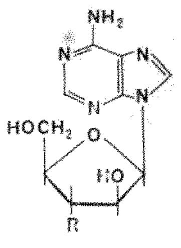
We wish to draw attention to the natural occurrence of an extraordinarily selective antibiotic, agrocin 84, which is a 'fraudulent' member (structure I) of the hitherto unreported 6-*N*-phosphoramidate series of adenine nucleotides (structure II), of which 6-*N*-AMP (II, R = H) is the first member.



I



II



III

Kerr and Htay[1] have shown that the biological control of crown gall, achieved by the inoculation of susceptible plants with the non-pathogenic strain 84 of *Agrobacterium radiobacter*, is due to the production of a bacteriocin by the controlling organism. This bacteriocin, now known as agrocin 84, selectively inhibits the growth of converted pathogenic strains of *A. radiobacter*, while the growth of most non-pathogenic strains is unaffected[2]; this property is utilised in the bioassay, which was originally developed by Stonier[3] for another bacteriocin. Heip *et al.*[4] have outlined a partial purification procedure for agrocin 84 from solid media, but the degree of purification was not established and no structural studies were reported.

We have found that isolation is greatly facilitated by culturing a rough colony variant of strain 84 in a defined liquid medium. After a 10,000-fold purification of the agrocin 84 had been achieved by gradient elution techniques involving charcoal adsorption and anion exchange chromatography on DEAE Sephadex, a correlation between biological activity and the presence of a nucleotide with an absorption spectrum maximum at 264 nm was noted and found to hold for all the chromatographic and electrophoretic systems which have been investigated.

After further purification by electrophoresis on glass-fibre filter paper agrocin 84 has been characterised as an adenine nucleotide with the characteristic spectra shown in Fig. 1*a*. The purified agrocin contained adenine, phosphorus, 3′-deoxy-D-arabinose and D-glucose in the molar ratio of 1:2:1:1. It also seems to contain an as yet unidentified reducing sugar acid, and the presence of other constituents cannot be excluded at the present stage of the purification. An upper limit for the molecular weight of the triethylammonium salt is set at 1,100 ± 100 by an $A_{1\,\mathrm{cm}}^{1\%}$ = 180 and an ε value of 19,860 at 264 nm and neutral *p*H for the purest solid samples obtained to date.

By defining an arbitrary agrocin 84 unit as that amount of agrocin necessary to inhibit totally a zone of radius 1.0 cm within a lawn of pathogenic indicator strain 24, using the

Stonier[3] bioassay, we have found at *p*H 7, that one 264 nm absorbance unit of the purified agrocin 84 contains $8 \pm 1 \times 10^3$ agrocin units. On a molar basis this corresponds to 1.6×10^{11} units mol^{-1}.

The infrared spectrum of agrocin 84 showed the presence of a P–O stretching frequency at 1,225 cm^{-1} and the absence of simple carbonyl groups and the pyrophosphate grouping. The electrophoretic mobility/*p*H profile indicated the absence of any secondary dissociation corresponding to a phosphate monoester.

Glucose and 3′-deoxy-D-arabinose were identified as the main carbohydrate components of an acid hydrolysis of agrocin 84 by chromatographic and electrophoretic comparison with authentic samples; the pentose reference sample was obtained from a crystalline sample of methyl 2,5-di-*O*-acetyl-3-deoxy-β-D-*threo*-pentofuranoside by the procedure of Casini and Goodman[5]. Alkaline hydrolysis (1 M NH_4OH, 100 °C 30 min) of the agrocin 84 produced a crystalline adenine nucleoside containing this unusual pentose, with the typical ultraviolet spectral behaviour ($\varepsilon_{max}^{260.5}$ 14,300, *p*H 12.55; $\varepsilon_{max}^{260.0}$ 14,400, *p*H 6.92; $\varepsilon_{max}^{258.0}$ 14,200, *p*H 1.06) for a 9-substituted adenine nucleoside.

It is now a decade since the corresponding 'fraudulent' nucleoside 9-(3′-deoxy-β-D-*threo*-pentofuranosyl) adenine (structure III, R = H) was first synthesised by Martinez, Lee and Goodman[6] in the course of a cancer chemotherapy programme. Although the original sample is no longer available, the required nucleoside has been synthesised by desulphurising the penultimate intermediate 9-(3-S-ethyl-3-thio-β-D-arabinopentofuranosyl) adenine (structure III, R = CH_3CH_2S–) with Raney Nickel.

The synthetic nucleoside (structure III, R = H) and the nucleoside from the alkaline degradation of agrocin 84 were found to be indistinguishable in all the properties examined, including melting point, mixed melting point, optical rotation, paper and thin-layer chromatographic systems, electrophoretic systems, gas chromatography of the trimethylsilyl derivatives, mass spectra of the nucleoside and its silyl derivative, ultraviolet spectral behaviour, and infrared spectra.

With the establishment of the structure of the nucleoside fragment of agrocin 84 as structure III (R = H), attention was next directed to the nature of the substitution of the nucleoside, which would result in the ultraviolet spectra of the intact agrocin as shown in Fig. 1*a*. Four properties of the agrocin which are particularly relevant, are first, the initial bathochromic shift in the absorption maximum from 264 nm to 270 nm on acidification (Fig. 1*a*); second the relatively rapid hydrolysis of the agrocin in 0.1 M HCl at room temperature to produce a nucleotide with an absorption maximum at 260 nm at neutral *p*H values and whose ultraviolet spectral shape and behaviour are similar to other 'normal' 9-substituted adenine nucleotides; third the extreme thermal lability (110 °C, *p*H 7, 15 min) of agrocin 84 at neutral *p*H to produce a second nucleotide with an absorption maximum at 260 nm; and finally the room temperature hydrolysis of agrocin 84 in alkali (1 M NH_4OH, 25 °C, 3 h) to produce a third nucleotide, which is thermolabile, contains D-glucose, has an absorption maximum at 264 nm, and is similar in ultraviolet spectral behaviour to the intact agrocin. These three nucleotides are readily resolved from agrocin 84 and one another, by electrophoresis in 0.05 M sodium tetraborate buffer at *p*H 9.4.

The reported[7,8] bathochromic shifts for 6-*N*-acylated 9-substituted adenine nucleoside derivative and the known thermolability and acid lability of phosphoramidates led us to postulate the presence of a 6-*N*-phosphoramidate grouping. Model 6-*N*-phosphoramidates of adenosine were therefore synthesised from 2′,3′,5′-tri-*O*-acetyl adenosine[9] and the appropriate phosphate, using dicyclohexylcarbodiimide in pyridine as the condensing agent, under conditions analogous to those described by Tener[10] for the condensation of cyanoethyl phosphate with 2′-deoxyadenosine. Figure 1*b* shows the spectral characteristic of 6-*N*-(cyanoethylphosphoryl) adenosine (structure II, R = $CNCH_2CH_2$–). At *p*H 5.0 the spectral behaviour of the monoprotonated 6-*N*-(hydrogen phosphoryl) adenosine (6-*N*-AMP) (structure II, R = H) with an absorption maximum at 264 nm, ε, 19,500, resembles its cyanoethyl precursor shown in Fig. 1*b*. The non-protonated species of 6-*N*-AMP in 0.1 M sodium hydroxide, shows a shift to 267.5 nm, ε, 19,800.

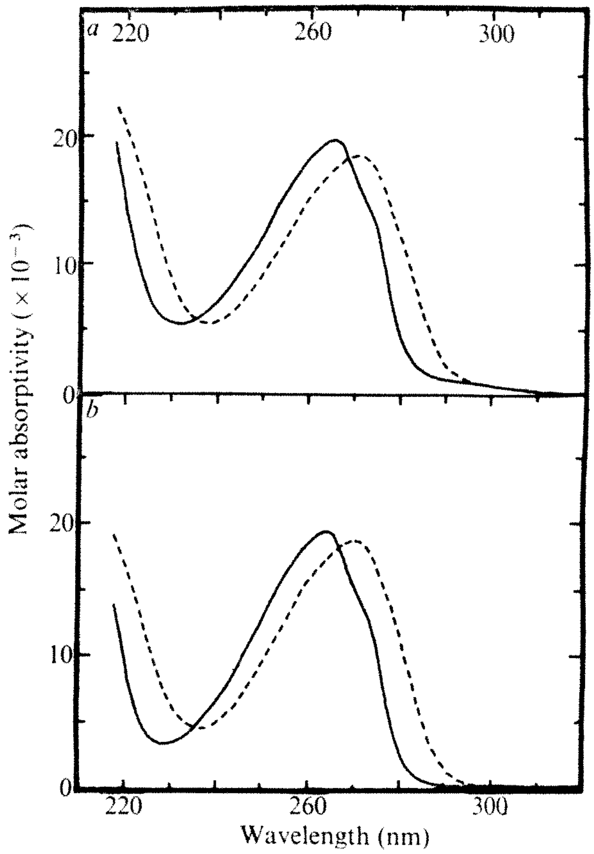


Fig. 1 *a*, Absorption spectrum for agrocin 84 at *p*H 1 (- - -) and 7 (———). *b*, Absorption spectrum for 6-*N*-(cyanoethylphosphoryl) adenosine (structure II, R = $CNCH_2CH_2$–) at *p*H 1(- - -) and 7 (———).

The striking resemblance between the spectra of agrocin 84 in Fig. 1*a* and the 6-*N*-(cyanoethylphosphoryl) adenosine in Fig. 1*b* leaves little doubt that agrocin 84 contains the hitherto unrecognised 6-*N*-phosphoramidate linkage to adenine as shown in structure I, where R^1 is at present considered to contain glucose. R^2 and R^3 represent hydrogen and a second phosphorylated carbohydrate moiety or vice versa.

The current investigation has firmly established the structure of the 'fraudulent' nucleoside fragment and the unique aspect of the phosphoramidate linkage is clearly indicated. If we accept the definition of a bacteriocin as simply 'an antibiotic produced by strains of bacteria and in general active on some other strains of the same species or related species'[11] and do not further restrict it to being 'colicin-like' as mentioned by Reeves[11], then this agrocin 84 should probably be classed as a new type of bacteriocin.

In conclusion, we point out that current attempts to explain all biochemical phenomena involving adenine nucleotides solely in terms of the 2′,3′, and 5′-phosphate esters may be less than adequate and a thorough search for other labile phosphoramidates such as the naturally occurring agrocin 84 and the synthetic 6-*N*-AMP reported here, with their predictably high phosphoryl transfer potentials, should be rewarding.

We thank the Australian Research Grants Committee for support. The award of a Charles John Everard Scholarship to W.P.R. is gratefully acknowledged. The ethylthionucleoside

was kindly supplied by Drs Wood and Lee of the Stanford Research Institute.

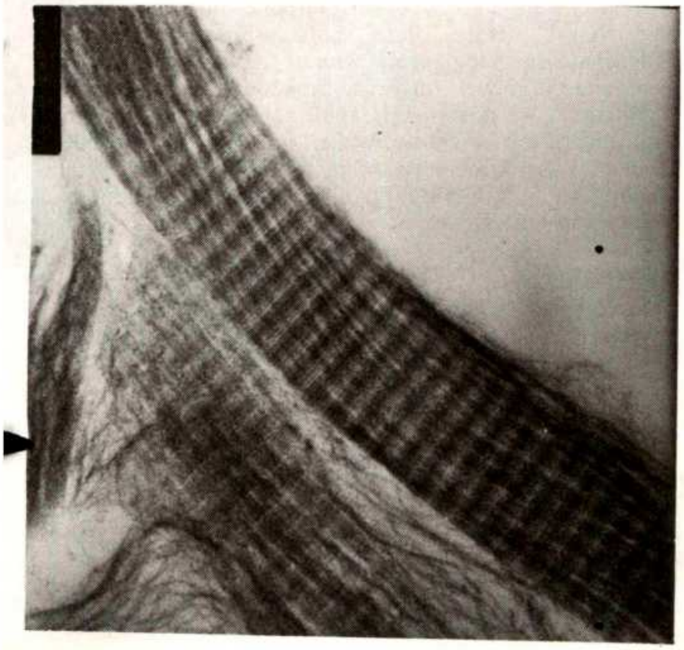
Three-dimensional packing of collagen in bone

Bone collagen, which forms approximately 90% of the organic matrix of bone, differs from rat tail tendon and skin collagen in its solubility properties[1]. Using low-angle X-ray meridional photographs and electron microscopy, however, I have found that the banding pattern of the collagen fibrils of bone is similar to that in other collagenous tissue, but that low-angle X-ray equatorial pattern could not be found.

Many explanations[2,3] have been proposed for the banding pattern of collagen fibrils (Fig. 1) based on the low-angle meridional pattern of X-ray photographs and on electron micrographs. But to describe the packing of tropocollagen molecules within the collagen fibrils in bone, which can be deduced from low-angle equatorial pattern of X-ray photographs, it is necessary to take account of the presence of needle-like mineral particles aligned along the collagen fibrils and the lack of orientation of collagen fibrils with respect to one another.

Fig. 1 Electron micrograph of section of demineralised foetal bone (× 11,000).



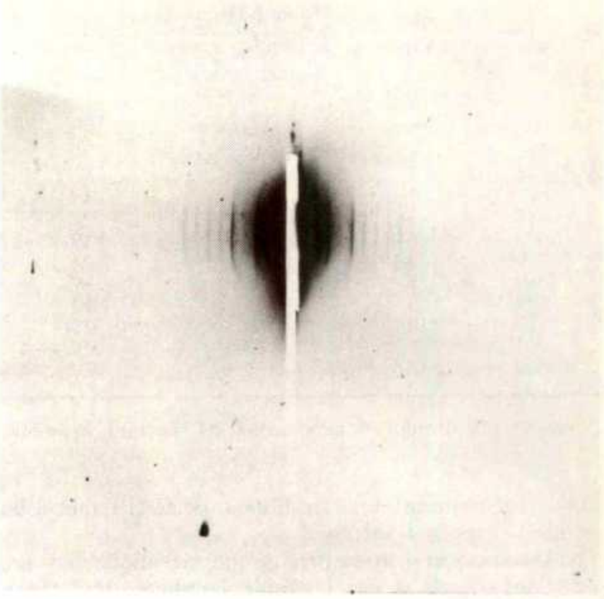


Fig. 2 Low-angle X-ray photograph of demineralised mature bone in water taken at Birkbeck (resolution shows only in one dimension).

Low angle meridional patterns of bone collagen in its mineralised and demineralised form were recorded by using a low-angle X-ray apparatus of the Holmes-Huxley type (mirror and crystal-monochromator)[9] (Fig. 2), but no low-angle equatorial pattern could be found even after 3 d of continual exposure to X irradiation.

The experiment was repeated at DESY (Deutches Elektron-Synchrotron) in Hamburg because synchrotron radiation is a more powerful source of X irradiation, and because in that situation[8] meridional and equatorial patterns can be recorded simultaneously. Low-angle X-ray photographs of calcified turkey tendon (as a reference) and

Fig. 3 Low-angle X-ray photograph of turkey leg tendon (dry) taken at DESY.

demineralised and mineralised human cortical femoral bone were used (Figs 3, 4 and 5).

The distances and intensities of the meridional low-angle X-ray lines (rings) shown in Table 1 indicate that there is little difference between the distances and intensities of the various orders of the low-angle meridional lines (rings) in tendon and bone. The main difference between the X-ray photographs is that in bone the meridional lines are extended to form full circles. Thus there is no low-angle X-ray equatorial pattern and it is not possible to deduce the three-dimensional packing of the collagen molecules within the fibrils or even to state that there is a three-dimensional order, as seen in tendon. The photographs also show that there is a preferred orientation of the collagen fibrils at about 22–23° from the c axis and that the continuous scatter due to the short axis of the mineral particles (Fig. 5) is perpendicular to the zone of preferred orientation of the collagen fibrils. This suggests that the long axis of the mineral particles lies along the long axis of the collagen.

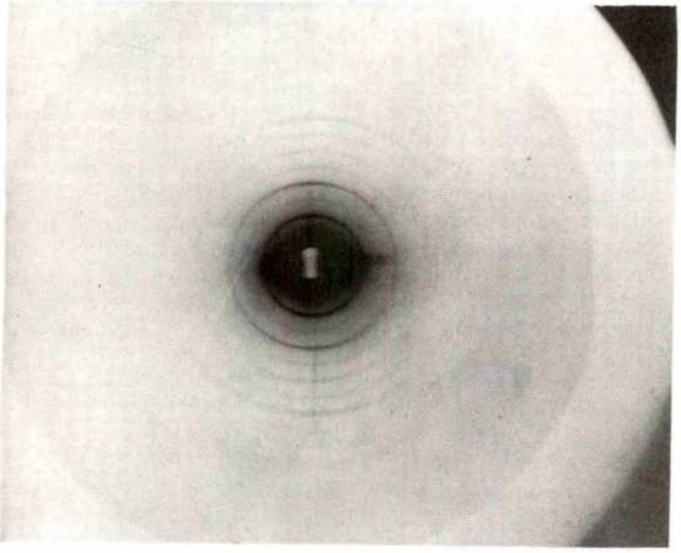

Fig. 4 Low-angle X-ray photograph of demineralised mature bone in water taken at DESY.

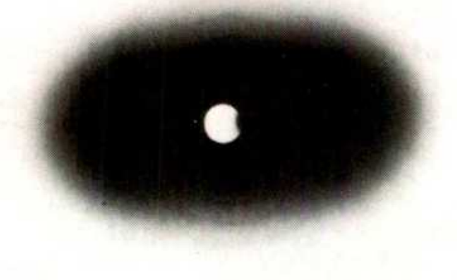

Fig. 5 Low-angle X-ray photograph of mineralised mature bone in water taken at DESY.

These results show that the ultrastructure of the collagen fibrils of bones and other collageneous tissues is similar when examined by electron microscopy and low-angle X-ray diffraction (meridional pattern).

There are two possible reasons for the failure to observe a low-angle equatorial pattern : either the lack of orientation (full rings) conceals the equatorial pattern or there is no equatorial pattern and hence no three-dimensional ordering within a collagen fibril in bone. In either case low-angle X-ray pictures alone cannot show whether three-dimensional packing exists within the collagen fibrils in bone, and the models for rat tail tendon, based on the same technique[4–7] are not directly applicable to bone collagen.

This work was completed while I was at Birkbeck College, London. I thank members of the Department of Crystallography and also EMBO for a fellowship and the use of facilities at DESY.

Energy analysis of wave-power and wind-power systems

Musgrove[1] paints a depressing picture of the energy analysis of wave power but seems to have largely overlooked the literature on its progress[2,3] The model tested by Swift-Hook *et al.*[4] was of amateur construction as I can personally vouch. Since then the generous support of the Department of Industry has allowed developments which point to an optimum duck diameter of about 15 m instead of the 50 m suggested by Denton *et al*[5]. This reduces the displacement to 200 tonnes per metre instead of the 2,000 quoted by Musgrove.

There is a further respect in which Musgrove's analysis is incorrect. He assumes that we intend to use steel, but the high energy content of steel is a strong incentive to use as little of it as possible Concrete requires only one seventh of the energy of steel[6] and it is suitable for much of the structure.

I am keenly aware of the many difficulties facing wave power and so I am hesitant to accept his prediction that (with correct input data) the energy repayment period will be 16 years divided by 70 which is eighty or ninety days.

Musgrove replies—In my recent letter[1] I estimated that the energy recovery period of a rocking float wave power system would be about 16 years Salter believes that this may be greatly reduced. In particular he suggests that reducing the diameter from about 50 m to about 15 m will reduce the energy recovery period by a factor of ten; the use of concrete instead of steel will then, he suggests, reduce the energy recovery period by a further factor of 7

My original letter did consider the effect of reducing the diameter of rocking float systems but, as I pointed out, reduced diameter gives reduced efficiency and an increased ratio of structure weight to displacement; the gain is therefore appreciably less than Salter suggests. Moreover, the simple calculation, which in my letter gave an energy recovery period of 16 years, was based on a wave power system sited at Station India, 700 km out in the Atlantic, where the annual average power flux is 77 kW m^{-1}. A more typical location is Seven Stones, off Land's End, where the annual average power flux is 26 kW m^{-1}. At this location a 50 m diameter rocking float system would have an energy recovery period of approximately 47 years, and lack of alignment between the wave power system and the incident waves will tend to increase this figure. Reduced diameter does however give some reduction in the energy recovery period and hence I concluded that overall one could expect to achieve an energy recovery period of about 16 years

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

This estimate does assume steel construction, consistent with the assumption, made by Denton *et al.*[2], that the cost per unit displacement of rocking float wave power systems will be comparable with that of existing supertankers. The specific energy content of concrete is, I agree, much lower than that of steel, but no one has yet built a concrete supertanker. I sincerely hope that the use of concrete will allow a seven-fold reduction in the energy recovery period of rocking float wave power systems. However, even if this can be achieved, it should be recognised that wind power systems have the potential to provide as much energy as wave power systems, and present much less formidable development problems.

Use of mechanical barriers instead of guard rows in field experiments

A technique in which vertical strips of Vinyl copolymer foil were used to separate experimental plots in a large field experiment on fruit trees was reported in *Nature* in 1962[1]. The experiment, involving different water and nitrogen regimes, reached a successful conclusion in 1975, and during 1976 an examination was made of the foil and of the behaviour of the roots when they encountered it. The foil was intended to serve as a barrier to root extension across plot boundaries in place of guard rows of trees. This was achieved surprisingly well; roots were contained without any penetration of the foil and remained at the depth at which they had met the barrier and turned.

Since the barriers were laid to a depth of 0.86 m, root exploration downwards might have led to serious poaching from adjacent plots. However, this does not appear to have occurred even after 15 years.

In this experiment the need for 4.4 ha of land with guard trees was reduced to 1.9 ha; this saving of experimental land together with greatly reduced risks of inter-plot variability and the satisfactory containment of treatments and roots at a cost considerably below that of concrete barriers[1] probably afford the technique a wide application.

Plutonium and americium in fish

PENTREATH and Lovett[1] have presented data on $^{239+240}$Pu/^{238}Pu ratios in plaice which cause us some concern in the light of what we have recently reported on the probability of biological discrimination between different plutonium isotopes[2]. Although not discussed in their report the ratios in different fish tissues from any one composite sample seem to show approximately two- to threefold differences in the uptake behaviour of ^{238}Pu and $^{239+240}$Pu, depending on the time of year. As no consistent trends among the ratios in the various tissues seem evident, we question the significance of these differences. Counting errors associated with the $^{239+240}$Pu measurements run typically about 20% (range 4–47%). The errors for the ^{238}Pu measurements are not reported but undoubtedly are higher due to the lower levels of ^{238}Pu in the samples. Furthermore, where counting error for $^{239+240}$Pu is the least (for example, gut contents), the ratios are more consistent and tend to approach a mean value of 4.4, which is in good agreement with the ratio (4.3) measured in surface sediment[2] collected from the same general area in July 1975. In fact, if the same relative counting errors reported for the $^{239+240}$Pu measurements are assigned to the corresponding computed ^{238}Pu values, comparison of the mean values of the ratios for all tissues from each collection do not indicate differential behaviour between the isotopes. We propose that if the counting errors associated with both the ^{238}Pu and $^{239+240}$Pu measurements were propagated, the resultant errors about the ratios would indicate that the apparent differences in plutonium isotope behaviour in certain tissues suggested by their data are not, in fact, significant.

Furthermore, we question the advisability of computing concentration factors for plutonium and americium in plaice in which only filtered seawater concentrations of the actinides are used. In this case the impression given is that ^{241}Am accumulates in plaice muscle fivefold over that of $^{239+240}$Pu. In another study[3], concentration factors in worms based on total plutonium and ^{241}Am in Windscale sediments indicate that the accumulation of plutonium is favoured over that of ^{241}Am by a factor of two. The discrepancy could be due to a 'species effect'; however, it also may be simply an artefact of the different way in which the concentration factors were computed.

Summation of the monthly discharge data reported by Pentreath and Lovett gives an estimated integrated annual discharge ^{241}Am/plutonium ratio of about 1.4, which is not too unlike either that measured in the sediments[3] (1.7) sampled in July 1975 or those that can be computed from their data for the various fish tissues (especially November 1975) and gut contents. These similarities suggest to us the possibility of a real ^{241}Am/plutonium ratio in water somewhat higher than 0.2 reported for ^{241}Am and $^{239+240}$Pu in their filtered sample. One recent report[5] states that 30% of the $^{239+240}$Pu in their filtered samples. One recent report[4] states that 30% of the $^{239+240}$Pu in Windscale waters is associated with filterable particulates (>0.22 μm). While apparently no comparable published data for ^{241}Am exist, there are indications[5,6] that ^{241}Am may be strongly particulate in seawater. We recognise the limitations involved in determining concentration factors; however, until more information is at hand concerning the bioavailability of both soluble and particulate forms of these elements, we believe that concentration factors based only on one fraction of the total element in water may be artificially high.

[6] Murray, C. N., and Fukai, R., in *Impacts of Nuclear Releases into the Aquatic Environment: IAEA-SM 198*, 179–191 (International Atomic Energy Agency, Vienna, 1975).

PENTREATH AND LOVETT REPLY—The errors associated with the ratios of $^{239+240}$Pu/^{238}Pu were omitted in order to avoid a discussion on them. Fowler and Beasley are correct in assuming that most of them are not significantly different, as deduced from errors associated with counting. But there were one or two samples which did seem to be different and these are being investigated further. By and large, however, we are generally impressed as to their lack of variance in view of the widely differing ratios which obtain in the Windscale area. Fowler and Beasley argue from the axiom of a constant ratio, assumed to be $\simeq 4.3:1$. In fact the ratio in the Windscale discharge is not accurately known but seems to have declined from $\simeq 20:1$ to $\simeq 4:1$ in the last 10 years as deduced from measurements made on surface sediments[1]. The ratio thus also varies with depth in the sediment, and this variance with depth differs from one area to another. The fish may therefore have been exposed to slightly different seawater ratios and to largely different ratios in ingested material. Because each organ may have a different biological half-time for plutonium, different ratios could be expected in the organs of some fish. This is rather speculative, however, and it would be very difficult to demonstrate in individual fish and could only explain large ratios.

With regard to the comments concerning the calculation of concentration factors, these calculations were made using the only data available at the time—filtrate sea water samples taken from the same area and at the same time as the August fish samples. These data were kindly proffered by a colleague and we thought the calculations made with them would be of interest; we still do. In doing so, however, we wished neither to commend nor condemn the use of filtrate seawater values for the general calculation of concentration factors. There are as many arguments against using total seawater values—such as the variability in particulate matter in shoreline areas—as there are for their use. The views on this subject of one of us (R.J.P.) are discussed at length elsewhere[2]. For the Windscale area the greatest sources of error for plaice are likely to be, as stated in our paper, the variable discharge rate and the movements of the fish into and out of the area close to the discharge pipe.

Finally, with regard to the amounts of ^{241}Am relative to those of plutonium, we remarked that the concentrations of the former may well have been influenced by a large release at the end of 1974. It is of interest that in samples taken in February 1976 the ratio was $>2:1$ in the majority of organs whereas that of the discharge during the previous six months has been $<0.5:1$.

In short, therefore, the principal objective of the paper was to give some indication of the concentrations of plutonium and americium in plaice in comparison with the amounts of these radionuclides discharged. The points raised by Fowler and Beasley were not discussed as we considered it more advisable to obtain further data rather than attempt to over-interpret those few data which we had already obtained.

reviews

Ethology of ethology

John R. Krebs

Growing Points in Ethology. By P. P. G. Bateson and R. A. Hinde. Pp. viii+548. (Cambridge University: Cambridge, 1976.) £16.

MY reaction on perusing this volume was one of optimism for the future of ethology. An appreciable proportion of the eighteen contributions to this symposium, held in June 1975 to celebrate the 25th anniversary of the Madingley Field Station (Cambridge, UK), discuss interesting new ideas and approaches or bring new evidence to bear on areas of current excitement. In comparison with a parallel volume produced by Madingley ethologists and their associates 15 years ago the theoretical arguments are less concerned with semantics and classification, and more with real attempts to seek underlying generalisations. It is also comforting to note that most of the major areas of interest have changed considerably in 15 years. The editors, who have done an excellent job in writing brief discussions to summarise, coordinate, and occasionally criticise the individual essays, have arranged the volume along the lines of Tinbergen's classical 'four questions'—causation, function, evolution and development. There is also a considerable section on 'human ethology'.

In spite of the risk of being accused of chauvinism, I must state that I found two of the most original articles to be those by Dawkins and McFarland, both of whom have tried to develop new approaches to constructing general theories of behaviour Dawkins argues that explanatory principles of the mechanisms of complex behaviour should come at the purely behavioural, rather than physiological level. After the burial of some early ethological models of motivation this sort of approach has not been much developed. But since the complete physiological description of complex behaviour is a distant and perhaps not even fruitful goal, "software" explanations, as Dawkins calls them, are obviously of crucial importance. Dawkins goes on to reason on functional, "neuroeconomic" grounds that evolution will tend to develop hierarchical control mechanisms of behaviour, and that this should be a general principle of behavioural organisation. He also describes various analytical tools for detecting hierarchical properties of overt behaviour.

McFarland also argues for software explanations of behaviour, but from a different standpoint. He suggests that even if one knew all the physiological mechanisms underlying, say, feeding and sexual behaviour in the dog, one would still not be able to look at a dog and predict whether it will eat or copulate next, because this will depend on how the dog balances the two tendencies against one another in making a decision. The decision rules can only be analysed at the behavioural level, and the problem is essentially an ecological one, because the animal will have been designed by evolution to make ecologically sensible (adaptive) decisions. McFarland then outlines a theoretical method for tackling the difficult problem of how a cost–benefit analysis of decision making can be achieved. The aim of the theory is to predict the optimal decision rules, which can then be tested against the actual data. Although this type of approach has been used in the ecological literature on foraging behaviour, this is the first attempt to apply the rationale to many different behaviour patterns at the same time.

The recent surge of interest in kin selection theory, and especially in its role in the evolution of altruistic behaviour, is reflected in the articles by Clutton-Brock and Harvey on primate social groups, and by Bertram on lion prides. The former paper is a useful discussion of aspects of primate social organisation, such as pair bonding, altruism, aggression and sexual dimorphism, in the light of current evolutionary thinking. Bertram takes the analysis of kin selection further (to my knowledge further than any other vertebrate study, with the possible exception of the work on group territorial birds) by calculating the degree of relatedness (r_0) between the various members of a lion pride. Bertram then discusses whether or not kin selection can account for various altruistic acts in the pride. For example, mothers suckle one another's cubs, even though the degree of relatedness between a mother and these cubs is very low, about 0.075. So kin selection is not likely to have played a major role in the evolution of this trait. On the other hand, the observation that males more than females are tolerant of cubs feeding at kills, fits in well with the calculated differences in r_0: 0.31 for males and cubs, and 0.18 between females and an average cub. Clutton-Brock and Harvey discuss an analogous example of dominant Japanese macaques tolerating subordinates according to how closely related they are.

The section on human ethology contains two particularly useful articles (by Hinde and Hinde, and Blurton Jones) in which the interface between ethology and social psychology (in the former) and anthropology (in the latter) are explored. Hinde and Hinde make a convincing case that it is now possible to study on a truly scientific basis the qualitative nature of inter-individual relationships, a problem from which most ethologists would have recoiled in horror ten years ago. Blurton Jones urges that the deductive approach, based on natural selection theory, used for explaining and predicting social organisation in animals, should also be applied to human cultures. Peculiar cultural customs should not be regarded as quirks of chance drift, fascinating and inexplicable, but viewed as ecological adaptations. In this way, he argues, it should be possible to develop a coherent theory of cultural differences.

Returning to my opening comment, this volume shows convincingly that ethology is not, as E. O. Wilson has prophesied, about to meet its death at the hands of neurophysiology and sociobiology. There is still a remarkably exciting atmosphere resulting from the blending together of causal, developmental and functional questions about behaviour, that still characterises ethology. ☐

John Krebs is a Lecturer in Zoology at the Edward Grey Institute of Field Ornithology, Department of Zoology, University of Oxford, UK.

Hydrodynamics and water waves

An Introduction to Hydrodynamics and Water Waves. By Bernard Le Méhauté. Pp. viii+323. (Springer: Berlin and New York, 1976.) DM 60.60; $24.80.

AN obvious question to ask about this book is: what are the special contributions which it offers to an already well endowed literature on hydrodynamics and water waves? The declared aim of the book is to provide a text based on a set of lecture notes for engineering students, that introduces the mathematical aspects of fluid mechanics with explanations of physical meaning to help practising engineers to read mathematical texts and keep pace with new developments reported in scientific journals. It is intended, moreover, to have a wide range of application and in particular to appeal to "students of coastal, hydraulic and civil engineering, naval architecture, physical oceanography, marine geology and sedimentology".

Although it inevitably covers much well trodden ground, it fulfils its aims and has much to offer in clarity of explanation and in its orderly presentation of a broad selection of theoretical material. It may be disappointing, however, to those seeking a close contact with current engineering developments.

The text is divided into three main parts concerned, respectively, with the derivation of the basic equations of fluid motion, mathematical treatment of the equations, and water wave theories. There are two appendices, one dealing with wave spectra and associated statistical properties, and the other with problems of scale modelling.

Examples of clarity include well illustrated accounts of the distinctions between streamlines, stream tubes, streak lines and particle paths and of the significance of dilatation, shear and rotation in interpretating the kinematic equations. I specially commend the many well organised tabular summaries of key details and formulae which students will surely find very helpful and which offer convenient working references for practising engineers. Students should also appreciate the selection of illustrative problems at the end of each chapter for which answers are given in the back of the book. Although prominence is given to development of basic theory relevant to a broad treatment of water waves, material is included on flow in porous media and pipes, and on open channel hydraulics. Its claim to appeal to students in a wide range of professional fields therefore seems justified.

Although the book offers a clear and broadly based conceptual framework for the study of theoretical fluid dynamics the degree of contact with current engineering technology may be disappointing to those with a more practical turn of mind. A particular feature, for example, that I find rather frustrating is the almost total absence of cited references. There are lists called "References" at the end of each part but these might more appropriately be headed "Recommended background reading", since there are hardly any explicit references to these works in the text. The reader is therefore repeatedly tantalised by the introduction of complex ideas such as tensors, conformal mapping, ship waves and diffraction theory which are only very briefly discussed without mention of any references for further study.

N. Hogben

N. Hogben is a Senior Principal Scientific Officer at the National Maritime Institute, Middlesex, UK.

Acetylcholine, the model transmitter

Biology of Cholinergic Function. Edited by A. M. Goldberg and I. Hanin. Pp. xiv+716. (Raven: New York, September 1976.) $42.

BOOKS for biomedical scientists often promise more than they actually provide because the titles of convenience they bear have been conjured up by ingenious editors who wish to confer (on a disparate collection of symposium papers, for instance) a suggestion of cohesiveness and completeness where none exists. It is a pleasure to be able to declare at the very outset that *Biology of Cholinergic Function* escapes this criticism: it really does provide everything—perhaps more than—its title offers. I find it difficult to believe that anyone who buys the book will be disappointed with his purchase, even though his intellectual enrichment will be bought at the cost of economic impoverishment to the tune of £26 at this morning's rate of dollar exchange.

Neurotransmission processes attract a good deal of attention nowadays, and deservedly so, but in the midst of our animated discussions concerning such lively topics as monoamines and mental illness, the reawakening of interest in the possible transmitter roles of ATP, substance P and histamine and the enthusiasm in many quarters in an increasing range of transmitter amino acids, it is easy to ignore acetylcholine, the earliest, the best authenticated and the most pervasive mediator of them all. Cerebral control systems rarely lack cholinergic synapses even though recent attention may seem to have been largely focused on their more immediately glamorous non-cholinergic components. Work on acetylcholine has, however, continued apace during the years when other substances have occupied the centre of the stage; and no worker in, or student of, the field of chemical transmission can afford to ignore it. It is conveniently assembled for him within the substantial covers of this book.

This massive compilation (more than 700 pages) is encyclopaedic in scope with exhaustive and up-to-date surveys of the literature (papers published as recently as 1975 are referenced) and of recent experimental findings. The main body of the text—18 chapters in all—discusses acetylcholine metabolism and actions in vertebrates and invertebrates, at subcellular and at whole organ levels, at peripheral and central sites, in muscle and in nerve. Those who champion the claims of non-cholinergic transmitters would do well to pay particular attention to the chapter that discusses the interaction of cholinergic and non-cholinergic transmitter processes and to the group of four chapters that together form a section on cholinergically linked diseases. The book is enriched for the laboratory worker by the inclusion of two appendicular tables. One of them, nineteen pages long, provides information concerning the acetylcholine content and cholinesterase activity of the tissues. It lists the results of all the studies that have worked their way through into the literature. The other table, only two pages shorter, does the same for the actions of drugs on the acetylcholine system. These tables are described in the preface as compendia of 'cholinergic parameters' but, this semantic monstrosity apart, the literary style of the book as a whole is tolerable if not exactly memorable.

Multiauthor texts are prone to exhibit irregularities in style and in depth of treatment and to suffer from omissions and repetitions that irritate the busy reader. This volume cannot be faulted on these grounds because the twenty-nine contributors worked together as a team under the guidance of editors who clearly took their duties seriously. All twenty-nine authors live in the United States but this does not unfairly bias the book towards American workers and attitudes. I hope that this judgment is not unduly influenced by the fact that my own modest contributions to the subject of the book are not ignored.

James Crossland

James Crossland is Professor of Pharmacology at the University of Nottingham, UK.

PROCEEDINGS QUICKLY

Hormonal Receptors in Digestive Tract Physiology

Proceedings of the First International Symposium on Hormonal Receptors in Digestive Tract Physiology, held in Abbaye de Royaumont, France, 22-24 September 1976

INSERM SYMPOSIUM, No. 3

edited by S. Bonfils, P. Fromageot *and* G. Rosselin

1977 xx + 520 pages US $ 47.95 / Dfl. 120.00
ISBN 0-7204-0618-8

The major features of this book are: the biochemical, immunological and biological characterization of peptide hormones or synthetic analogs with emphasis on gut hormones; study of hormone receptor interaction binding; and the analysis of the cyclic nucleotide system in the intestinal tract, salivary gland, external pancreas and liver.

Hormones and Cell Regulation*

Proceedings of the First INSERM European Symposium on Hormones and Cell Regulation, held at Le Bischenberg, Bischoffsheim, France, 27-30 September, 1976

edited by J. Dumont *and* J. Nunez

1977 240 pages US $ 24.95 / Dfl. 62.00
ISBN 0-7204-0622-6

Leading scientists discuss the most recent developments in the field of hormones and cell regulation, ranging from various types of hormone and neurotransmitter receptors to the regulation of cellular secretions, glucose metabolism and protein synthesis. Further meetings are planned and this book is the first in a series.

HLA Systems - New Aspects

Proceeding of the International Symposium on HLA Systems - New Aspects, Bergamo, Italy, 25-26 September, 1976

edited by G. B. Ferrara

1977 180 pages US $ 22.95 / Dfl. 57.00
ISBN 0-7204-0617-X

Research on HLA has become intensive and this book concentrates on those areas where the most significant developments are taking place, including: the biological and biochemical properties of histo-compatibility antigens; serology and transplantation; and MLC typing in man.

Rheumatoid Arthritis

Cellular Pathology and Pharmacology

Proceedings of the Cambridge Rheumatism Group Symposium on Rheumatoid Arthritis: Cellular Pathology and Pharmacology, held in Cambridge, U.K., 21-23 September, 1976

edited by J. L. Gordon *and* B. L. Hazleman

1977 x + 286 pages US $ 33.75 / Dfl. 84.00
ISBN 0-7204-0621-8

This book provides the most up-to-date review of advances in genetics, immunology, tissue physiology and therapeutics related to rheumatoid arthritis. It will prove invaluable to clinicians who wish to know the current views of this growing area of research.

Regulation of Cell Membrane Activities in Plants

Proceedings of an International Workshop held in Pallanza, Italy, 26-28 August, 1976

edited by E. Marrè *and* O. Ciferri

1977 xii + 334 pages US $ 31.95 / Dfl. 80.00
ISBN 0-7204-0615-3

The papers presented in this volume constitute the first attempt to integrate two of the most important and, until now, relatively separate fields of plant physiology - physiology of transport and hormonology.

Modern Trends in Bacterial Transformation and Transfection

Proceedings of the Third European Meeting on Bacterial Transformation and Transfection, Granada, Spain, August 31 - September 3, 1976

edited by A. Portolès, R. López *and* M. Espinosa

1977 xii + 332 pages US $ 31.95 / Dfl. 80.00
ISBN 0-7204-0608-0

This up-to-date review of molecular genetics covers the following topics: physico-chemical aspects of competence; processing of irreversibly bound DNA in gram-negative and gram-positive bacteria; recombinational events and heterologous transformation; restriction enzymes mapping and cloning; and transformation and clinical aspects.

CHARLES C THOMAS • PUBLISHER

PHYSICIANS' HANDBOOK OF NUTRITIONAL SCIENCE (2nd Ptg.) *by* **Roger J. Williams,** *The Univ. of Texas, Austin, Texas. Foreword by* **I. Newton Kugelmass.** A straightforward, sound, conservative and readable account of the crucial facts of nutrition are provided in this book. In the few instances where the author speculates or voices his own opinion, the difference between fact and opinion is made evident. The twelve basic principles of nutritional science are clearly outlined by the author and are reviewed by several prominent nutritional experts. Some of the topics considered are basic principles underlying nutritional science, internal nutrition, prenatal nutrition, biochemical individuality, and problems with environment and its effect on nutrition. *'76, 128 pp., $9.75*

ESSENTIALS OF BACTERIAL AND VIRAL GENETICS *by* **David M. Carlberg,** *California State Univ., Long Beach, California.* Beginning with the fundamentals of modern genetics, this book progresses through the chemical and biological nature of molecules responsible for the storage and transfer of hereditary information, the genetic code and mutations. Molecular biology of spontaneous and induced mutations are emphasized as well as characteristics and isolation of bacterial mutants. A general discussion of recombination is followed by coverage of transformation and conjugation in bacteria. The final two chapters cover genetics of the viruses, encompassing the viruses of the bacteria, the eucaryotic microorganisms, and the higher plants and animals. *'76, 336 pp., 166 il., 35 tables, $24.75*

REGULATION OF DEPRESSED METABOLISM AND THERMOGENESIS *edited by* **L. Jansky,** *Charles Univ., Prague, Czechoslovakia, and* **X. J. Musacchia,** *Univ. of Missouri, Columbia, Missouri. Foreword by* **Charles G. Wilber.** *(30 Contributors)* Biochemistry, physiology and adaptive functions of thermoregulation are covered, combining reviews of intracellular events, electrophysiological events, and features which establish heat economy in the defense against cold. Interrelationships between the natural phenomenon of hibernation and the laboratory experimental phenomenon of hypothermia are given considerable attention. The regulatory mechanisms which take part in and occur at various levels of body temperature are also considered along with current studies of cold acclimation and new approaches to the regulation of hypothermic depressed metabolism. *'76, 304 pp., 111 il., 7 tables, $23.75*

NUTRITION, TIME AND MOTION IN METABOLISM AND GENETICS *by* **Sydney J. Webb,** *Univ. of South Florida, Tampa, Florida.* An integrated view is provided of modern biological data concerning the effects of nutrition on genetic continuity and its role in the control of metabolic events. A new dynamic mechanism by which nutrition may control metabolism and genetic continuity is described, based on effects of nutrition on the molecular make-up of cells, the ability of cells and metabolic events to withstand stress at given times during the lifetime of a cell, the time at which given events occur, and the direction in which sequences of events take place. *'76, 426 pp., 104 il., 46 tables, $29.75*

Biophysical Chemistry

An international journal devoted to the physical chemistry of biological phenomena

Since its inception in 1972, BIOPHYSICAL CHEMISTRY has rapidly become one of the major scientific outlets for the publication of research in this interdisciplinary field. This is in accordance with the official scope of the journal which reads *"The journal is devoted to the interpretation of biological phenomena in terms of the principles and methods of physical chemistry".*

BIOPHYSICAL CHEMISTRY is receptive to articles which deal with biological molecules and systems and to papers which treat systems serving as models for same. Treatments, phenomenological as well as molecular, of the biological functions of individual biological macromolecules and of supramolecular structures which these macromolecules can form with each other and with smaller molecules are within the journal's domain.

2 volumes are scheduled for publication in 1977
Subscription price in 1977: Dfl. 268.00/US $107.00 (postpaid)
Specimen copies are available upon request.

Fifty Years of the Ultracentrifuge

Proceedings of the Conference, Bethesda, Maryland, February 24-26, 1975

edited by MARC S. LEWIS *and* GEORGE H. WEISS, *National Institutes of Health, Bethesda, Maryland.*

Reprinted from the journal Biophysical Chemistry, Vol. 5, No. 1/2

1976 viii + 286 pages. Price: US $45.95/Dfl. 115.00
ISBN 0-7204-0511-4

An article entitled "The Ultracentrifuge, A New Instrument for the Determination of Size and Distribution of Size of Particles in Amicroscopic Colloids" was published by The Svedberg and Herman Rinde in the December 13, 1924 issue of the Journal of the American Chemical Society. Thus was described the basic instrument and techniques which J. D. Watson in "The Molecular Biology of the Gene" characterized as "Perhaps the most striking contribution of physical chemistry to the study of biological macromolecules . . .". The readers of this book should not need amplification of that statement.
In spite of the fact that these Conference Proceedings celebrate a fiftieth anniversary, ultracentrifugation is far from being a static field of scientific endeavour. For this reason, with the exception of Professor Kai Pedersen's inaugural paper reviewing the development of the ultracentrifuge in Svedberg's laboratory, the conference focussed on some representative current topics in ultracentrifugation where the major portion of the work has not been published.

Great men and the mainstream

History of Mankind: Cultural and Scientific Development. Volume 5. Parts I–IV: The Nineteenth Century. Edited by C. Moraze. Pp. 1,394. (George Allen and Unwin: London, 1976.) Parts I–II: £15; III: £15; IV: £15.

THIS curious 'volume' appears in three substantial tomes. The various chapters in it are written by various authors, or teams of authors; many of these are based in French institutions (other European countries being little represented) while others are from the USA, the USSR, and other nations. Sometimes the author is acknowledged at the top of his contribution, whereas for others one must search among the small type at the beginning of the first tome; no credit seems to be given to the translators, who have produced smooth versions of what were presumably papers for the most part not written in English.

The work is curious for various reasons; first because it was clearly written many years ago, as indeed is admitted in the preface where a date of "before 1960" is given. We are therefore getting a warmed-up hash, many parts of which have become obsolete long since; and it is even a half-baked hash, since the bibliographies have been omitted. By this tardy and incomplete publication, justice is hardly done to the various contributors, whose reputations will not be advanced by association with this project.

Even odder is the fact that the chapters were evidently sent to referees in various countries for comments; but were then published in their original form, with the referees' comments appended. Occasionally the author has commented on these comments, and his remarks also appear. The chapters are therefore accompanied by hostile annotations, often all too justified: but because of the omission of the bibliographies, we find dogmatic statements by the author and commentator; and cannot choose between them since we do not know on what evidence they are based. To publish an historical work without a proper account of the sources used is like publishing a scientific paper without any experimental details. Even for the illustrations, we are not always told where and when they were first published, although we are told which institutions made them available.

History was the province of a muse, and one might hope that a work of history would be a work of art; but if so, one would be disappointed with this volume, in which few of the chapters are written with any verve. Some contributors have an axe to grind—this can be a great help in an historical essay—but this usually leads only to the dullness of Marxist terminlogy; whereas others are preoccupied with the hopeless attempt to leave nothing out.

It is the first tome, dealing with the history of science and technology, to which readers of *Nature* are probably most likely to turn; and we can therefore examine it in more detail. In the introduction by the editor, abstractions chase one another in what is a completely schematic and impressionistic essay, being neither narrative nor detailed case study. When we come to mathematics and astronomy, we find the account is completely 'internal' and is moreover full of sentences of the kind: "Tom, Dick, and Harry also made important contributions to this field". The Russian referee made the point that any social dimension is completely lacking; and the same can be said of the other writings on the physical sciences, those on medicine and the life sciences being better though clearly out of date.

The narratives concentrate on great men and on the mainstream, and tend to lapse into the passive voice; there is little feeling that science is carried on by people called scientists, and that an important part of its history is the study of their collective behaviour. It was in the nineteenth century that science became a profession; that science became specialised, with the general journals of the academies being supplemented by those of societies catering for one science, or part of one; that formal courses in the universities leading to first and higher degree began; and that governments and industries began to employ scientists in large numbers as new legislation and new processes were introduced. This is not apparent from these internal accounts; which is not surprising, because the emphasis in the history of science has shifted in the past twenty years or so, away from accounts of how we got to where we are now, often written by superannuated scientists, towards attempts to recover how past science actually worked and what people were trying to explain or control. These essays are monuments, of varying quality, to an elderly and amateurish tradition; the most interesting is the critical note on the history of technology by Melvin Kranzberg.

In general, therefore, it is hard to see who would ever use this monument to international cooperation, and harder to see who one would recommend to use it. **David Knight**

David Knight is a Lecturer in the History of Science at the University of Durham, UK.

Light-emitting diodes

Light-Emitting Diodes. (Monographs in Electrical and Electronic Engineering.) By A. A. Bergh and P. J. Dean. Pp. viii+591. (Clarendon: Oxford; Oxford University: London, 1976.) £22.

THE general public first became aware of light-emitting diodes (LEDs) when pocket calculators made their dramatic entry on to the market. The miniature calculator was in fact made possible by LEDs, although the more recent development of reliable passive displays, such as liquid crystal devices, would eventually have filled the gap. For many years preceding this sudden appearance, LEDs were the subject of intense research in solid-state laboratories in many parts of the world.

The history of this period is an exciting one, with its full share of disappointments and surprises, and the authors of this book have played an important part in promoting the theory and the technology of the subject. It is disappointing that, contrary to early expectations, conversion efficiencies from electrical energy to visible light remain low in spite of the massive effort put into improving them, so the rapid technical advance of the 1960s and early 70s has now slowed down. The fact that LEDs have now found wide commercial applications, makes this a period of stability and therefore a most appropriate time for the appearance of this comprehensive work on the subject.

Nearly half of the book is devoted to a deep and detailed account of the theoretical aspects of carrier injection and the factors affecting the efficiency of light generation, most particularly in the III–V compounds. There follows a good account of the interesting field of up-converters (infrared to visible)—phosphors which seem to defy the basic rules of phosphor physics. Even though this technique has not found commercial application, it may prove of great importance if solid-state lasers are developed with output wavelengths more closely matched to the excitation band of the few available phosphors.

The remainder of the book is devoted to the technology, design and application of LEDs and associated devices, and here again the treatment is detailed and comprehensive. A minor disappointment (perhaps inevitable if the book is to be constrained to a reasonable length) is the treatment of photometry. Although a whole chapter is devoted to this subject, and many aspects are enlarged on in the chapter on LED design, the results are put in the form of generalised equations. Photometry is such a jungle of definitions, concepts and units that it is a permanent headache to the engineers trying to compare the merits of different light-emitters. An appendix containing some worked examples would have been very helpful.

The work is naturally devoted to the most theoretically tractable light-emitting devices, especially the III–V semiconductors, although there are brief discussions on SiC and ZnS. It is impressive in its deep treatment of the subject, and the enormous range of study is indicated by the collection of more than a thousand references. This makes it a valuable source-book and a necessary addition to the library of any physicist or engineer working in this field. **D. H. Mash**

D. H. Mash is a member of the staff of the Materials and Components Laboratory, Standard Telecommunication Laboratories Limited, Harlow, Essex, UK.

Reptilian physiology

Biology of the Reptilia. Vol. 5: Physiology. Edited by C. C. Gans and T. S. Dawson. Pp. xv+556. (Academic: London and New York, October 1976.) £16.80.

THE preceding volumes of this encyclopaedic survey, which appeared between 1969 and 1973, were devoted to morphology; and herpetologists interested in physiology have had to await patiently the turn of their own speciality. The first of the physiological series, however, should not disappoint them. The literature on the subject is remarkably scattered because reptiles have been studied, not only in their own right but also as subjects for physiological and pharmacological assay. In the book under review, an attempt has been made to provide an overall summary orientated towards reptiles as a taxon rather than towards single topics such as metabolism, thermoregulation, or water balance. In this endeavour, the editors have enlisted authors who, in each case, have contributed signally towards elucidating the particular topics they summarise. The cast is all-American, but at least the book was printed and bound in Great Britain.

In their opening chapter, entitled 'Reptilian physiology: an overview', the editors emphasise the ecological aspects of environmental physiology. This is followed by a detailed discussion of 'Methods for the physiological study of reptiles' by Harry S. McDonald. Subsequent chapters are as follows: 'Metabolism' by Albert F. Bennett and William R. Dawson; 'Respiration: mechanics, control and gas exchange' by Stephen C. Wood and Claude J. M. Lenfant; 'Circulation' by Fred N. White; 'Regulation of acid-base balance in reptiles' by Barbara J. Howell and Hermann Rahn; 'Osmo-regulation' by P. J. Bentley; 'Salt glands in reptiles' by William A. Dunson; and 'Renal function (with special emphasis on nitrogen excretion)' by William H. Dantzler. The volume concludes with a comprehensive index, but this does not seem to have been checked with quite the thoroughness usually characteristic of Academic Press.

Throughout, the reader will be struck by the heterogeneity of the Reptilia, which is reflected in their physiology. For instance, in many reptiles the salt gland is the major route for excretion of electrolytes; yet these glands have evolved independently, over and over again, in the process of adjustment to dry or saline environments. Great variation exists in the regulation of nitrogenous excretion, and this too may be related to habitat as well as to the end products of metabolism, the ability of the cloaca or bladder to regulate the volume and composition of the urine, and the ability to excrete ions by extra-renal routes. Similarly, metabolic rates are extremely variable, but little attention has yet been directed towards their functional correlates. The vast diversity of respiratory mechanics, lung morphology and gas transport mechanisms, is matched by comparable diversity in habitats, habits and levels of activity. The heterogeneity referred to above is thus clearly related not only to phylogenetic divergence but also to adaptive radiation within the various orders and suborders.

The search among living reptiles for intermediate evolutionary linkages with mammals and birds has diverted attention from the adaptive features and control mechanisms of the reptilian cardiovascular system. Yet, such features and mechanisms form an important part of the integrative physiology of the class. Reptiles have, potentially, a large contribution to make both to cellular biology and to ecology, and the future of reptilian comparative physiology should be linked closely with these areas.

Relatively few of the physiological processes discussed in this important volume have yet been investigated intensively, and any such studies comprise only a few species. Much work remains to be carried out before reptilian physiology can be understood really adequately. This book plays an important rôle in emphasising both what is, and what is not, now known.

Molluscan delights

Pseudothecosemata, Gymnosomata and Heteropoda (Gastropoda). By S. Van Der Spoel. Pp. 484. (Bohn, Scheltema and Holkema: Utrecht, 1976.)

As once aptly observed by Dr Joel Hedgpeth, taxonomy is man's oldest profession, his "first task in the Garden was not to work for his living—that came after the Fall—but to name every beast of the field and every fowl of the air". Too soon interrupted in this, it has been left to succeeding generations to complete a task which increased in size with every new exploration, including the waters of the sea, and with every development in the capacity for magnification.

The significance of taxonomy was enhanced with the demonstration of the fact of evolution. What had been accepted as the works of a highly ingenious, if in certain aspects a by no means beneficent, Creator now appeared as the contemporary endpoints of innumerable, often interlocking, lines of evolutionary change. Taxonomy records the outcome of the most significant sequences of events that have occurred during the history of this planet.

To a marine malacologist it is difficult to imagine two more fascinating groups than prosobranch Heteropoda and opisthobranch Pteropoda (Euthecosomata, Pseudothecosomata and Gymnosomata) evolving independently as holoplanktonic gastropods. It is a delight to see with what elegance they are treated in this volume by Dr S. Van Der Spoel of the Institute of Taxonomic Zoology, Amsterdam. It succeeds an earlier one, in 1967, dealing solely with the Euthecosomata and is to be followed by a third concerned with the biology of all planktonic molluscs.

This surely is an ideal example of the manner in which the products of evolution should be treated with adequate description and synonomy of every species, accompanied by 166 beautifully drawn line figures—and how fully these exquisite animals merit such attention—followed by 81 maps showing world distribution. Appendices contain diagrams revealing the diversity of taxa in the different faunal centres with others assisting in the use of keys for identifying species difficult to separate, notably in the heteropod Atlantidae. Recent information about the Euthecosomata brings the earlier volume up-to-date, and a reference list of over 80 pages covers the entire literature.

Differing widely in origin, the heteropods and pteropods differ also in distribution, a possible consequence of their different periods of origin. There are more heteropods in the Indo-Pacific but pteropods are commoner in the Atlantic. From this it is postulated that the former evolved in the greater oceanic area. But, being more thermophilous, they found difficulty in passing through colder southern waters into the Atlantic. They are not, however, absent in that ocean and nowhere do more spectacular species of both groups live together than in the Mediterranean, where this reviewer has found much pleasure in studying living representatives.

Dr Van Der Spoel's book is a work of combined scholarship and research and forms a permanent addition of the highest value to zoological knowledge. It should be contained in every museum, every marine laboratory and every University library. It is an indispensible work of reference to marine biologists, both applied and academic. It will be a delight to every malacologist.

Sir Maurice Yonge, formerly Professor of Zoology at Bristol, then at Glasgow, is Honorary Fellow in the University of Edinburgh, UK.

Biology of Kinetoplastid flagellates

Biology of the Kinetoplastida. Vol. 1. Edited by W. H. R. Lumsden and D. A. Evans. Pp. xxvi+563. (Academic: London, New York and San Francisco, 1976.) £18.00.

The parasitic members of the flagellate order Kinetoplastida of the phylum Protozoa have always attracted more attention than the free-living forms, and the species of two genera, *Trypanosoma* and *Leishmania*, which infect man, have attracted the most. It is easy to forget that these genera are only two out of sixteen or more, that many trypanosomes cause no harm to their hosts and that it might be possible to learn as much about trypanosomiasis and leishmaniasis from comparative studies on related forms as from the trypanosomes and leishmanias of man.

To many protozoologists, the literature is top-heavy with information on the Kinetoplastid flagellates of medical and veterinary importance and it is the intention of this multi-author volume (and its companion when it is published) to redress this imbalance and to present the Kinetoplastida as a whole. Difficult as this is to achieve, it looks as if the two volumes between them will do just that.

This volume, for a number of reasons explained by the editors, is mainly concerned with trypanosomes, apart from the first two chapters (by K. Vickerman, and K. Vickerman and T. M. Preston) which deal with the diversity and cell biology of the kinetoplastid flagellates as a whole. Both these chapters contain a considerable amount of original thought and research material. There are also four comprehensive reviews of trypanosomes, of birds (J. R. Baker), of bats (C. J. Marinkelle), of primates other than man (C. J. Marinkelle) and of the subgenus *Herpetosoma* (D. H. Molyneux). These, with their well presented tables and check lists, will be invaluable sources of information for years to come.

Two of the remaining chapters cover the rapidly advancing fields of the biochemical aspects of taxonomy (B. A. Newton) and oxidative metabolism (I. B. R. Bowman and I. W. Flynn). Informative and useful as these are at present they will be even more useful when read in conjunction with the chapters on the taxonomy of the leishmanias and biochemical aspects of *Trypanosoma cruzi* which are promised in volume 2.

Two further chapters deal with the subgenus *Megatrypanum* (E. A. Wells) and *Trypanosoma rangeli* (A. D'Alessandro). Although their inclusion can be justified on the grounds that the information contained in them is not adequately summarised elsewhere, they are really too specialised to justify such extensive coverage in a book of this kind. The remaining two chapters on innate resistance to trypanosome infection (R. J. Terry) and antigenic variation (A. R. Gray and A. G. Luckins) are again rather specialised, and would have been better associated with other papers on immunity also due to be published in volume 2. In any case, antigenic variation could do with a rest from reviews for a year or so.

This is a most valuable work of reference but could have been so much better if the reproduction of the plates and electron micrographs had been of better quality, and if all the chapters had been updated from their original 1973 form as some of them have been. The publication of volume 2 is eagerly awaited. Perhaps it would not be too much to hope that each chapter in volume 1 will be briefly updated and that better quality paper will be used for the plates.

F. E. G. Cox

F. E. G. Cox is Professor of Zoology in the School of Biological Sciences at King's College, University of London, UK.

Protein crystallography

Protein Crystallography. By T. L. Blundell and L. N. Johnson. Pp. xiv+565. (Academic: London, New York and San Francisco, 1976.) £17.00.

FOURTEEN years after the award of Nobel prizes to Crick, Kendrew and Perutz, this is the first textbook to be published on protein crystallography by an established practitioner in the field. Perhaps this indicates the compulsive preoccupation of the protein crystallographer with the mechanics of his work, but in any case the event is to be welcomed.

One of the attractions of protein crystallography is that narrow specialisations are not allowed. Without sound grounding in mathematics, physics, crystallography, inorganic chemistry, organic chemistry, biochemistry and biology, one will constantly run into problems one cannot evaluate. The experimenter needs in addition a smattering of knowledge of instrument design, high vacuum technology, electronics, chemical engineering and computer science. Such versatility is demonstrated admirably by the authors.

The character of the book as a work of scholarship first emerges in a discussion of the selection of heavy metal compounds for introduction into proteins to provide isomorphous crystalline derivatives. The chemistry of different classes of transition metals and the properties of various categories of complex ion are related to the types of isomorphous substitution which have been obtained. Much of what is offered has not appeared in any review—it is an original arrangement and interpretation of the evidence leading to conclusions which are perfectly orthodox as inorganic chemistry, but which will profoundly change the strategy which protein crystallographers adopt.

Another penetrating analysis deals with an unresolved conflict in the literature between two methods for the exploitation of anomalous scattering effects, due to A. C. T. North and B. W. Matthews. The germ of the idea is traced back to an Oxford thesis by M. Harding; we are led forward to an analysis with no approximations by Singh and Ramaseshan; a tacit assumption in Matthews' choice of the positive value of a square root is pointed out, and his method is clearly related to the "FHLE" method.

In a survey which ranges from film developing technique and microdensitometry to the exploitation of electron diffraction and Mössbauer scattering there are many other stimulating and original insights. The expert will derive refreshment and pleasure from them. Unfortunately the beginner will be less satisfied. The authors have provided introductory chapters which seem to be aimed at students who know no biochemistry and no crystallography. These chapters make no concessions to the problems of teaching these subjects, and provide an inappropriate *hors d'oeuvre* to the main meal. Some of the obscurities are simply slipshod (that hydrolysis of proteins with boiling mineral acids yields mixtures of up to twenty amino acids), but others will cause serious confusion (the only definition of a Fourier transform is to use it as a synonym for diffraction pattern, for example).

In practice the price of the volume will keep it out of the hands of students, at least in Europe, and it seems a pity that the authors should have misdirected so much effort to cater for them. A good student text is still desperately needed. The book is splendidly up-to-date, including many 1976 references. For some reason the first few pages look rather as though they have been set on a pre-War typewriter, and occasionally one can see evidence of proof corrections, but otherwise the book is well produced. It was a surprise to see several familiar illustrations without acknowledgment.

David Blow

David Blow works at the MRC Laboratory of Molecular Biology, Cambridge, and will shortly become Professor of Biophysics at Imperial College, University of London, UK.

Plutonium and other actinides

Transuranium Nuclides in the Environment. (Proceedings of a Symposium organised by the US ERDA and the IAEA, San Francisco, 1975.) Pp. 724. (IAEA: Vienna; HMSO: London, 1976.) £22.88.

THESE 41 technical papers form an indispensable basis for assessing the "growing concern about man's ignorance of the biogeochemistry of [plutonium and other actinides] . . . in relation to . . . long-term buildup, availability, and transport in the environment" (Noshkin). Nowhere is this concern more apt than the UK, which reportedly discharges to the Irish Sea some 0.3% of its Pu throughput—of the order of 10^4 Ci since 1960.

The message of these papers is clear: our ignorance of pathways is extensive for Pu and is virtually complete for the higher actinides (such as Am) that are more active biochemically and that may be the dominant hazard. Among the wide range of concentration factors for Pu and higher actinides—from none to several orders of magnitude per trophic level, and from strong discrimination to modest concentration in food chains—exceptions are more common than rules. Unexpected interactions with soil microbes, natural chelates, marine worms, mammalian digestive fluids, and fungi (some of which incorporate actinides into aerial spores) likewise falsify familiar axioms. Particle size is important to these effects, to astonishingly high mobility in soil, to resuspension and adsorption on plant leaves, and to human inhalation (generally a greater hazard than ingestion). Even the chemical behaviour of, say, ^{238}Pu and ^{239}Pu differ markedly. And Pu contamination is indeed ubiquitous: quoted ranges exceed 40 km for routine emissions of a US reprocessing plant, 80 vertical m for bomb residues in coral, and 500 km for dust from Nevada dispersion tests. Both on land and in water, Pu concentrations can be far lower *at* a point source than at distant sites of favoured deposition.

The most impressive and disquieting example cited is G. L. Meyer's celebrated account of Maxey Flats, Kentucky, a site containing some two-thirds of all US commercial low level nuclear wastes buried during 1963–74. Over 1.6 MCi, including over 80 kg ^{239}Pu and unknown amounts of 300-odd other nuclides, were buried in steel drums and in wood and cardboard boxes. The trenches, in a humid forest underlain by jointed and leaky strata, promptly flooded. Runoff, groundwater, and wind carried contamination off-site (hundreds of metres in a decade) by every 'normal' route plus a few new ones, raising "serious questions about knowledge and concepts of plutonium mobility in the environment"—to say nothing of management. But a British participant, rightly questioning the suitability of the site, was told it seemed preferable to marine discharge, and the marine pathway analyses in other papers hardly contradict this.

The book's attempt to deal not only with actinide pathways but also with the biomedical effects of exposure suffers from too little space and diversity. Although current standards, linearity, neglect of isotopic chemical differences and of gonadal dose, and conventional dosimetry are all properly queried, the brief and truncated reviews hardly do justice to the richness of the controversy. In summary, an important reference work with strong relevance to public policy.

That Was the Weak Force, That Was

For all that science is the great emergent culture of the twentieth century and that its ground rules are known to more educated men and women than those of any other cultural activity, it is still a strangely back-room affair as far as most members of the general public are concerned. There is more than residual belief that scientists should stick to science and that non-scientists can't be expected to understand a word of it. For this reason we have a lot to be grateful for in the offerings of BBC Television's *Horizon* as a long-running and generally successful attempt to portray a vast and comprehensible world of science in the terms of its human practitioners. We also have reason to appreciate the occasional televised *Controversy* debate as a sign that the scientist can have as important things to tell the public as do politicians, economists and administrators. But should we feel the same way about the occasional 2-hour-or-more programmes that BBC screens under Mr Nigel Calder's guidance? The double showing in Britain this week of *The Key to the Universe* has raised again nagging doubts that have surrounded Mr Calder's previous presentations: *The Violent Universe, The Mind of Man, The Restless Earth, The Life Game, The Weather Machine* and *The Human Conspiracy*.

It is Mr Calder's belief, put forward in *Nature* **245,** 293 (1973), that close to the frontiers, communication of science to the layman is easier than in well-established areas because of the excitement, the starkness of the questions, the lack of jargon. Unfortunately, it is not equally evident that two hours is the right length of time to be spent on the subject, or that everything exciting within the subject should be covered. In the above-mentioned article Mr Calder himself described the problems of an overabundance of material, but he has often created the impression of not having pruned hard enough; the result has been a bewildering patchwork the underlying unity of which is not at all clear. In this most recent programme he managed to mention (in this order) neutrinos; the four forces; quantum mechanics; Feynmann diagrams; gravitons; gauge theory; Weinberg-Salam theory; renormalisation; 'heavy electrons' (muons); neutral currents; strangeness; the Ω-particle; quarks; colour; gluons; strings of gluons; anti-matter; exploding galaxies; radio background; big bang; lost symmetries; gravity 'frozen out'; latent symmetry . . . before the interval. We saw at least seventeen high-energy or astronomical facilities. We were introduced colloquially to 'cosmic alchemy', 'pattern makers', the 'starbreaker', the 'fire-maker' force, our 'phantom friends', 'old man gravity', 'crazy ideas', 'spooky' black holes. We were treated to verbal infelicities like 'they are no luxuries, the electrical and mechanical aids at the Inter-Universities Institute for High Energies', and visual infelicities like the bizarre rope bridge from which Mr Calder declaimed, at times Messiah-like.

The initiated found a certain amount to admire in all this—new insights, nice turns of phrase, some clever visual work. The uninitiated, which must have been 99.9% of the audience, can only have been thoroughly confused by the profusion of jewels in the crown which were picked up in no apparent order, admired and put back, and with few concessions to those who blinked at the wrong moment.

Mr Calder and his team make one fundamental mistake: they underestimate the serious-mindedness of the audience. Viewers are not there by mistake or because they have been watching the previous programme; they are prepared to settle down for the required couple of hours to learn and many are even prepared to watch the programme twice. Such viewers don't need a breathless approach, they are prepared to devote time to fixing new ideas in their mind, if necessary by repetition, by schoolroom techniques and by relation to everyday experiences. They would also appreciate an historical account of why we are where we are; twenty minutes or half-an-hour of bringing the average viewer up to speed would indeed erode the number of exciting new concepts that could be crammed in, but it might ensure that the understanding of those concepts retained was more profound.

There is a serious danger in the presentation of science to the public that it should seem too esoteric and confusing. This widens the rift between scientists and non-scientists and does little to help persuade the young to turn to science. Mr Calder has consistently tried to avoid this by getting right amongst the discoveries as they come out, and in principle he is correct. But in practice the erudition he acquires in researching his programmes ends up overloading his audience, who may come to just the wrong conclusion that science indeed is somewhat too esoteric and rather too confusing for them. □

What role for fission?

Leslie Shepherd assesses the contribution nuclear fission can make to the energy requirements of the next 50 years

DURING the 1960s annual world energy demand was expanding at a rate of 4.5% a year. If that trend had continued, then 50 years from now the energy demand would be almost ten times as great as at present. With the emphasis that is now being set on the need for more careful and efficient use of energy, however, a lower rate of growth of perhaps 3.5% a year seems more probable for the future.

On this basis, 50 years from now we should be consuming primary energy at a rate of 1.5×10^{18} kilojoules a year and the cumulative consumption in those 50 years would be 3×10^{19} kilojoules. It is extremely unlikely that more than two-thirds of this could be met by fossil fuels because of the limitation on the total economic resources of petroleum oil and natural gas ($\sim10^{19}$ kilojoules) and the feasible rate of extraction in the case of solid fuels. In fact, if the mining of coal and lignite were steadily increased by a factor of 5 over the next 50 years, the cumulative energy yield from these would be no more than 10^{19} kilojoules.

Nuclear fission, as the only practical alternative energy source to coal and oil on the scale which we are concerned with, therefore, may have to contribute at least one-third of the cumulative consumption by the year 2025 and thereafter provide the bulk of the future demand.

Uranium utilisation

Since uranium is the only natural source of fissile material, U-235, it is the basic raw material of nuclear power. One tonne of natural uranium contains sufficient U-235 to yield 5×10^{11} kilojoules of energy. The OECD's survey listing the reasonably assured and estimated additional resources of uranium from rich ores, published in December 1975, gives a current total of 3.5 million tonnes, the U-235 content of which, on its own, would yield only 1.75×10^{18} kilojoules. This is not a very impressive amount of energy—no more, in fact, than the present measured reserves of natural gas would yield.

Fortunately, the real reserves of fission energy, if they are properly exploited, are certain to be orders of magnitude greater than this figure suggests. This is partly because exploration of uranium resources is still in its early stages and the actual amounts economically extractable are certain to be far greater than indicated in contemporary estimates. In addition, nuclear reactors not only consume the fissile U-235 charged into them, but also generate fresh fissile material by neutron absorption in the so-called fertile isotopes U-238 (which constitutes more than 99% of natural uranium) and Th-232 (the whole of natural thorium); this process of converting fertile to fissile material enables us to increase the fissionable content of nuclear fuel many fold.

The principal fissile isotopes resulting from these fertile captures are Pu-239 (from U-238) and U-233 (from Th-232). The amount of energy which we are able to derive from the originally mined natural uranium (and thorium) will be determined by the extent to which these secondary fissile isotopes can be generated and utilised starting from the primary U-235. This is a question of the 'neutron economies' of the various possible reactor systems and the fuel cycles adopted in them—the Uranium Cycle involving U-238/Pu-239, and the Thorium Cycle involving Th-232/U-233.

Not all of the neutrons absorbed in U-233, U-235 and Pu-239 cause fission; a proportion of the neutrons captured produce the higher isotopes U-234, U-236 and Pu-240, which in turn can absorb further neutrons yielding still higher isotopes. In fuels which have been in a reactor for some time the fissile components build up into a chain of isotopes (U-233, U-234, U-235, U-236 in the thorium fuel cycle, and Pu-239, Pu-240, Pu-241, Pu-242 in the uranium cycle). All of these isotopes have to be taken into account in evaluating neutron economy.

Neutron economy

Neutron economy refers to the balance of the processes which produce and absorb neutrons in a nuclear reactor. Each fission is the result of the absorption of a neutron in a fissile nucleus, and in the process fresh neutrons are emitted. One of these is required to produce a further fission, the balance going either into productive or non-productive processes. The productive process is neutron-absorption in the fertile isotopes, U-238 or Th-232, which yields new fissile material. Non-productive processes include:

- neutron-capture in the fixed materials making up the reactor core;
- absorption in fission products as they build up and in the control rods which are introduced to maintain the neutron balance as the fuel burns up;
- the non-fission neutron capture in the fissile species, which was mentioned above (the ratio of non-fission captures to fission captures is referred to as the α-value of the fissile species in question);
- neutron leakage from the reactor core.

It is, of course, the neutron absorption in fertile material, leading to the generation of fresh fissile isotopes, which is important, since it determines the ultimate amount of energy which may be derived from uranium and thorium resources. The ratio of fresh fissile atoms produced to those consumed in the chain of events described is known as the conversion ratio. If this is less than unity the amount of fissile material in the reactor steadily diminishes during operation and loss has to be made up periodically. However, if the ratio is greater than unity (it is then called the breeding ratio), there is a surplus of fissile materials available for other reactors and the system is said to breed.

Neutron economy varies according to the type of reactor and the manner in which it is operated; it also depends on the fuel cycle (uranium or thorium) adopted. The optimum situation is achievable in fast reactors, where breeding is possible largely because of the relatively low α-values in all the fissile materials when the neutron energy is high.

The uranium cycle is better than the thorium cycle in fast systems. This is because of the greater yield of neutrons in the fission of Pu-239 as compared with U-233, and because the most energetic neutrons can cause direct fission of the fertile U-238 (an effect which is far less pronounced in Th-232) and, by this means, boost significantly the number of available neutrons. In thermal reactors, the α-value is very high for Pu-239 (~0.6) and low in the case of U-233 (~0.1) with the result that much higher conversion ratios are possible with a thorium fuel cycle than with a uranium fuel cycle.

Thus from the standpoint of achieving the maximum energy output from natural uranium resources there is an incentive to develop fast reactors with the uranium cycle and to use the thorium fuel cycle in thermal reactors.

Thermal reactor characteristics

In a global context three categories of thermal reactor are of interest: light water reactors (LWR), heavy water reactors (HWR) and the helium-cooled

---

Dr Shepherd is the former head of the now defunct Dragon High Temperature Reactor Project at Winfrith, Dorset.

high temperature reactor (HTR).

As far as neutron loss in the moderator is concerned, light water is worst, carbon is intermediate, while heavy water is essentially non-absorbing. The same remarks apply to light and heavy water as coolants; no neutrons would be absorbed in a helium coolant. LWR and HWR cores both incorporate a large amount of neutron absorbing metal in fuel element cladding and pressure tubes, so that these systems are appreciably worse in this respect than the HTR which includes no metal structure. Taking these factors into account both the HTR and the HWR have an advantage over the LWR.

The proportion of neutrons lost by absorption in fission products (more or less independent of reactor type) depends upon the extent to which these are allowed to build up relative to the core inventory of fissile material, that is to say the degree of fuel burn-up before it is discharged from the reactor for reprocessing. Reprocessing separates out the fission products from the unburned fissile material which can then be recycled in the reactor. Reprocessing is an expensive matter and for that reason among others it is desirable to keep a high inventory of fissile material in the reactor core (if a good neutron economy is desired) to avoid too frequent recycling.

The yardstick in the evaluation of future thermal reactors is the current uranium fuel cycle LWRs. These operate at present with no recycle. The conversion ratio in the single fuel cycle is about 0.60, and more than half of the Pu-239 produced is actually consumed in this cycle. An LWR of 1000 MW gross capacity, operated in this way for 30 years at 80% load factor, would require 6,000 tonnes of natural uranium. At this rate about 25 million tonnes of uranium would be required to yield the 10^{19} kilojoules indicated above as a cumulative energy target over the next 50 years. This amount could be reduced by about 40% if fuel were recycled to use up all residual U-235 and plutonium.

Both the HWR and the HTR would achieve a better performance than the LWR with the uranium fuel cycle for the reasons already given. In the case of the HTR, the superior thermodynamic efficiency of the power conversion cycle*, arising from the higher temperatures achieved, would also mean that the useful energy ultimately derived would be substantially higher than with the water cooled reactors.

The biggest gain, however, would come from the use of the thorium fuel cycle in thermal reactors because of the greater yield of neutrons from U-233 compared with Pu-239. This would carry a potential advantage of about 0.4 in conversion ratio compared with the uranium cycle LWR and even introduce the possibility of operating thermal reactors as breeders. However, this would require very large inventories of fissile material in these reactors so that the initial large requirement of mined uranium would offset the advantage of the breeding for a very long period, certainly longer than the 50 years considered here.

Furthermore, U-235 being the only naturally occurring fissile material, all nuclear fuel cycles must begin with this isotope. This means that there is an initial phase in which the neutron economy is determined partially by the characteristics of U-235, with a consequently lower conversion ratio during that phase.

High conversion thorium fuel cycle thermal reactors would require some 5–7 million tonnes of uranium to be mined over the next 50 years in order to achieve an energy output of 10^{19} kilojoules. This is in excess of the presently estimated resources of uranium from high grade ores. Without doubt, the present figures greatly underestimate the actual available resources, particularly if one takes into account the acceptability of using much more costly uranium in high conversion or breeding systems.

At the end of that time, however, at the 3.5%-a-year rate of energy growth the annual nuclear energy demand would be $\sim 10^{18}$ kilojoules and would be increasing. It is difficult to envisage meeting this requirement without having built up an adequate breeder reactor capacity. This provides the incentive to develop a technically and economically viable fast reactor and to have such a system established on a substantial scale 50 years from now.

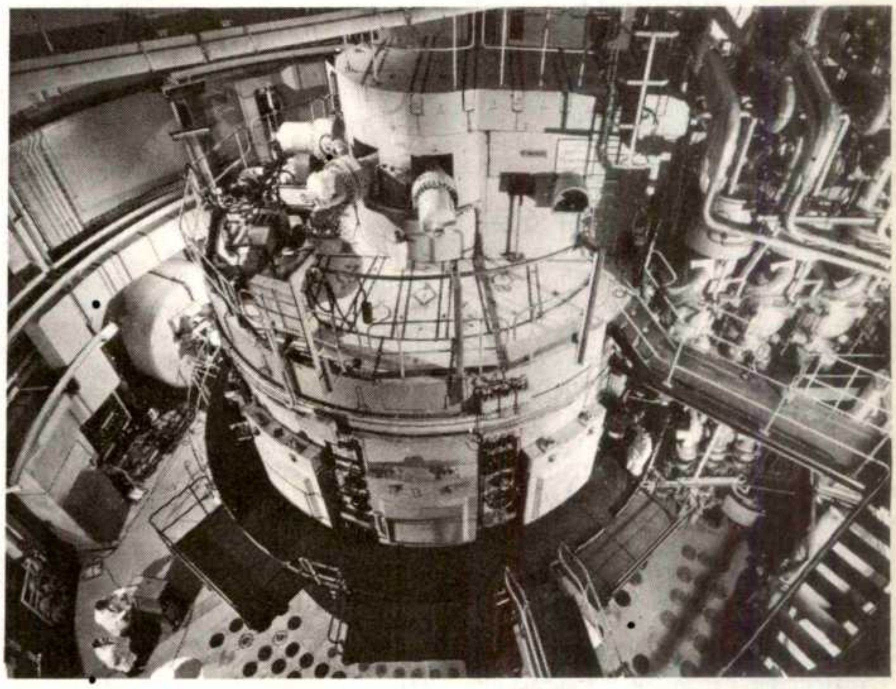
Fast reactor exploitation

A fast reactor using plutonium will have an initial induction phase in going from U-235 to Pu-239, as would be the case in building up a U-233 inventory in a thermal reactor. Currently, the accepted strategy is to use thermal reactors (predominantly LWRs) to produce the necessary plutonium inventories for fast breeders. Unfortunately, this is a particularly inefficient process, a non-recycle LWR yielding only about a quarter of a kilogramme of fissile plutonium per MW-year.

Taking four tonnes as being a minimum plutonium inventory for a sodium-cooled fast breeder of 1000 MW capacity (2.5 tonnes in the core and 1.5 tonnes in recycle), its production would require an LWR of corresponding power output to operate for 20 years at 80% load factor, consuming more than 3,000 tonnes of uranium in the process.

Subsequently, the fast reactor would yield excess plutonium which would be available to build up further inventories. There is a possibility, however, that the doubling time—that is to say the time for the fast reactor to generate sufficient excess plutonium to provide a further reactor inventory—may be very long, which would make for an excessively slow build-up in the ratio of fast reactors to LWRs.

In such circumstances there would be, certainly over the next 50 years, an unacceptably high preponderance of



UKAEA

A view of the Dragon

---

*An electricity generating HWR would have a thermal efficiency of 30% compared with 40% for a steam cycle HTR and 45–50% for a binary cycle HTR.

LWRs over FBRs, so that one would be far removed from an overall breeding situation and the total uranium demand could be significantly higher than for a programme based only upon high-conversion thorium fuel cycle reactors.

This approach is unnecessary, however, it being much more logical to start fast reactors with U-235 and produce the eventual Pu-239 inventory *in situ*. In this way all of the plutonium would be produced and consumed in its most favourable environment. The time to produce a full plutonium inventory and, therefore, a true breeding situation would be much shorter and the uranium input very much reduced, possibly by a factor of four, compared with the LWR approach.

A further advantage of this course is that it would make the fast reactor independent of any thermal system, and it would relieve the latter of the requirement to work on the uranium fuel cycle in order to provide plutonium for fast systems.

While thermal reactors are not appropriate sources of plutonium for fast reactors, it is worth stressing that the converse is not true, insofar as U-233 could be generated efficiently in thorium introduced into the blanket of a fast breeder reactor. In this way a fast reactor with a good breeding ratio could support high conversion thermal reactors with a combined energy output several times greater than its own.

This is an important possibility leading to a symbiosis of a small number of fast breeders with a larger number of high conversion helium-cooled high temperature reactors, which would be preferred to the fast reactor on all counts other than neutron economy.

Conclusion

In the foregoing a world viewpoint has been taken deliberately, because no individual nation can hope to proceed in an isolated manner in resolving problems of such significance as those presented by the energy situation.

Unless some viable major alternative energy source (such as nuclear fusion) comes along, there will be a minimum cumulative requirement of 10^{19} kilojoules of thermal energy from nuclear fission over the next 50 years, and at the end of that time the annual energy contribution will need to be 10^{18} kilojoules a year. The requirement is far beyond the capabilities of light water reactors working on their present uranium fuel cycles, but it would not be beyond the capacity of thorium fuel cycle thermal reactors, notably the high temperature reactor, provided that they were being followed up with a well established programme of fast reactors.

However, the strategy of using thermal reactors (predominantly LWRs) to produce the plutonium inventories needed for breeding does not appear to be viable. The rapid exploitation of the breeding capabilities of fast reactors requires that they should generate their own plutonium from the initially available U-235. On this basis the evolution of fast reactor exploitation would proceed independently of the programme of thermal reactors. Eventually, the two would come together in a symbiosis, in which an overall breeding situation would be maintained with a minimum of fast reactors. ☐

FRANCE

Debating nuclear power

Alexander Dorozynski reports from France on the nuclear power debate there

THIS year may be decisive for the ambitious French programme of rapid development of nuclear energy. Well before the debate triggered by the "all nuclear" decision of the Pierre Messmer government in March 1974 physicists and ecologists started voicing worries about the programme's safety and reliability, and the doubters appear still to be growing in numbers and in political weight.

The controversy has spread beyond the potential dangers of a technology that has not been entirely mastered. Those arguments find a focus in the huge nuclear waste treatment plant in La Hague, at the tip of the Cotentin directly south of Bournemouth, and in the Superphénix fast breeder reactor, to be located just 44 km from Lyon. The debate now extends to many of the economic and political arguments advanced by the powerful Electricité de France (EDF), the state monopoly employing some 100,000 persons and one of France's largest and most powerful enterprises.

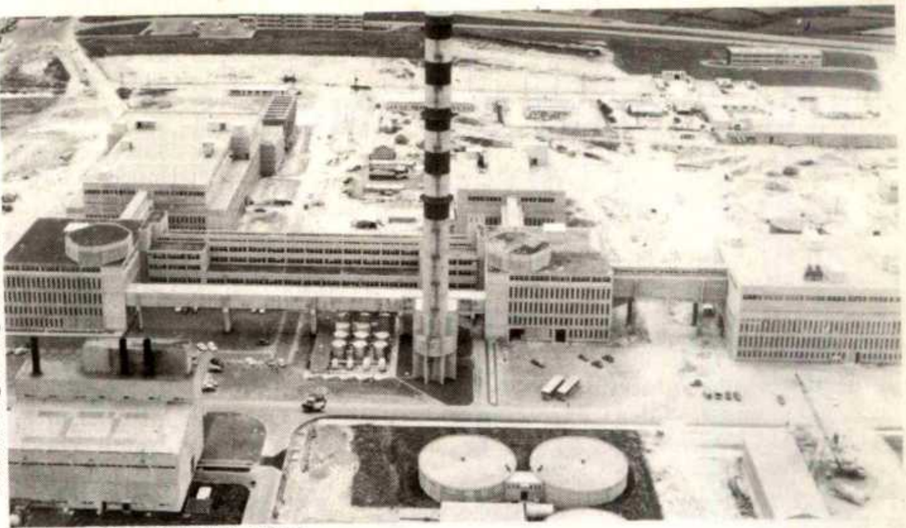
The Ministry of Industry and Research has been only marginally effective in dealing with the 'dissidents', and in the face of mounting public awareness, a public relation campaign is being mounted by EDF. Embarrassingly, some of the approaches to be taken have been revealed by an ecological weekly, *La Gueule Ouverte*, which has published a confidential EDF document giving recommendations about how to deal with different categories of opponents, such as the public at large, members of the parliament, physicians, teachers, journalists, and so on.

Now another publication, *Science et Vie*, France's largest science magazine, is publishing the results of a debate it has organised about the economic soundness of the programme. The debate put face to face economists from the EDF and members of the Institut Economique et Juridique de l'Energie (IEJE), a small group formed at the University of Social Sciences of Grenoble. A guest participant was Professor Irvin C. Bupp, Jr, a Harvard University economist who has taken part in a MIT study of the evolution of the price of water reactors in the US—PWRs are being installed in France under a patent agreement with Westinghouse.

The initial nuclear programme has already been toned down under Valery Giscard d'Estaing's presidency: annual plant construction will be decreased from a 6,000 MW capacity in 1976 and 1977 to 5,000 MW in 1978, and the goal of producing by 1985 nuclear energy equivalent to 60 million tons of oil has been adjusted downward to 55 million. But until now, few had challenged the figures authoritatively produced by EDF concerning the price of the nuclear kilowatt, and the cost of nuclear plants.

"The only economists who have ventured to challenge official figures are those of the IEJE," points out one participant, Jean Marie Chevalier, professor of economics at the University of Paris-Dauphine. "In fact, the nuclear programme has been imposed upon the country by EDF and the Commissariat a l'Energie Atomique (CEA). Never has there been the slightest counter-expertise. The government let it go without compromising itself. Thus, if need be, it will be able to reject upon EDF the responsibility of the aberrant situation we might end up with." The figures are now likely to be subjected to close scrutiny.

For instance, EDF economists have tagged the nuclear KWh with a cost of 7.5 centimes, while that of the 'classical', oil-fired KWh varies between 11.5 and 12.5 centimes. IEJE economists ask if this price is realistic. Just across the border, in West Germany, the nuclear KWh is priced at 6 pfennig (12 centimes), and Patrice Romain of the IEJE maintains



Reprocessing plant at La Hague

Nuclear Engineering International

that if engineering costs, insurance, cost of processing waste and of dismantling reactors are included, the EDF price goes up steeply. Then there is the cost of uranium, which has gone up from \$5 a pound in 1973 to \$40 a pound. Nuclear fuel cost, once estimated at 20% of total costs, has now reached 30% and is still growing. If waste treatment is included, notes Jean-Marie Chevalier, it may reach 60%.

Similarly, the cost of constructing nuclear power plants is challenged. Is it closer to the FF2,150 per installed KWh, as quoted by EDF, or to FF6,700, the price France would like to charge for similar installations in Iran? Does this difference mean that a cost in constant francs must be upped by 50–100% for a foreign country, that more safety factors are included for export, or that EDF discounts some hidden costs that appear elsewhere in its budget? In the United States, Bupp notes, this cost was \$130 per installed KWh in 1965, \$300 in 1972, and is estimated today at some \$700 (about FF3,500).

Another major argument frequently advanced for the intensive development of nuclear power is also being challenged: that of energy independence. According to a report to the National Assembly, French requirements in uranium from now to 1985 are estimated at 85,000 tonnes, and by 1990 at between 115,000 and 125,000 tonnes. "If France had to count on its own resources, these would be exhausted between these two dates," states the report. France may have interests in mining operations in Niger, Gabon and Canada, but it is wondered if there is a guarantee that these interests will be preserved.

There are questions, too, about France's real independence with regards to enrichment. France's uranium enrichment plant at Pierrelatte, designed for military purposes, has insufficient production capacities. The Tricastin plant nearby should only be operative in 1980—if all goes well.

None of the 'dissidents', whether physicists or economists, argue against nuclear power as such. Their major objection is that the EDF plans for producing energy from the atom and using electricity as a vector have closed the door to alternatives. In 1977, only FF30 million will be devoted to research in new energy sources, as against FF2,474 million budgeted for CEA projects.

"We are making a mistake by not playing the card of natural gas," adds Chevalier. "Gas is found everywhere—in North Africa, the Middle East, the Soviet Union, Holland, under the North Sea. It is energy which, unlike oil, is not dominated by multinational firms. . . Contracts between state and state could be made to preserve equitably the interests of both parties. And gas is a decentralising energy, unlike nuclear power, which leads to the development of maxi-sites and of national distribution networks. With gas turbines, we can produce locally and on a small scale electricity and heat, thereby reducing social costs."

Chevalier believes that no other form of energy can be made available as rapidly as gas, and that within four years, a flow could be created that would represent a saving of FF25–35,000 million. Meanwhile France, which imports three-quarters of the energy she consumes, could explore alternatives before the nuclear 'solution' becomes irreversible. ☐

● **Azim Kidwai writes from Karachi:** Although nuclear cooperation between Canada and Pakistan has ended (see *Nature*, January 6, page 9, and also January 13, page 95), the deal with France for the supply of a nuclear reprocessing plant still stands. The plant was one of the main bones of contention in the dispute with Canada. Considerable pressure on Pakistan to cancel the French deal also came from the USA. Pakistan defended the right of two sovereign states to enter into such agreements, but to allay the fears of those who thought that the plant would be used for other than peaceful purposes, it showed its willingness to negotiate further safeguards even though the agreement had been cleared by the International Atomic Energy Agency.

The ending of Canadian assistance will have its effects. The only nuclear power plant running in Pakistan, the 137 MW Karachi nuclear power plant (KANUPP), was supplied by Canada. Its fuel, essential spare parts and the technical assistance for its maintenance were from Canada. A policy of self-reliance may now be the order of the day, and the Chinese experience when Russian technical assistance was withdrawn in the early 1960s is being cited.

The supply of fuel to KANUPP may pose no problems, as fuel fabrication is likely to be arranged from sources other than Canada. Eventually fuel is to be fabricated in Pakistan itself, and had Canada not, two years ago, stopped the shipment of equipment for fuel fabrication from Canada to Pakistan, the fuel for KANUPP would now be locally available. Considerable uranium bearing sandstones have been discovered in the northern areas of Pakistan in the Dera Ghazi Khan district and a survey of uranium bearing ores has been completed with the assistance of the International Atomic Energy Agency. Plans are in hand for their exploitation.

KANUPP feeds into the Karachi grid only 85 MW on average, and although its closure for long periods could be a source of irritation a 125 MW steam-powered generating unit is under installation, to be commissioned by July next. Another five gas-turbines each of 25 MW have also been urgently ordered for Karachi as a further reserve to be commissioned by July 1978.

The Pakistan government called the Canadian action arbitrary, adding that it violated three bilateral agreements on cooperation with Pakistan in peaceful uses of atomic energy. She found unreasonable the new conditions for which Canada was asking. One was that Canadian safeguards "will cover Pakistan's entire nuclear programme, not merely the nuclear facilities provided by Canada". Pakistan also found unacceptable the demand that even if "Canada should terminate all nuclear cooperation with Pakistan under the bilateral agreements, Pakistan shall nonetheless remain bound by its commitments under those agreements for the rest of the operating life of KANUPP". ☐

USA

Carter's energy problem

As America freezes energy matters grow more important. Colin Norman reports from Washington on the continuing search for an energy policy

It didn't take long for President Jimmy Carter to be brought face to face with the energy crisis. Within a week of taking office, he was forced to ask Congress for emergency powers to deal with a critical shortage of natural gas in parts of the eastern United States—a shortage brought about by an extraordinarily cold winter and several years' lack of a coherent energy policy. Though at this stage Carter can do little more than spread the shortage around, urge people to be less profligate in their use of energy and pray for warmer weather, the new Administration is promising to set things right in the long term with a comprehensive energy policy, a strong conservation plan and an overhaul of the federal energy bureaucracy.

Clearly, energy matters are going to keep the Administration busy, but at least it will have no shortage of outside advice. In that regard, a mammoth study now being put together by the National Academy of Sciences is likely to prove particularly influential. Due to be completed by June 30, the study is one of the most ambitious projects the Academy has yet undertaken. It involves some 250 people, sitting on a variety of panels and committees, who are now channelling their advice to a steering committee co-chaired by the ubiquitous Harvey Brooks, professor

Changing of the guard

- As the new Carter Administration settled into its first full week in office, selection of the second-level Presidential appointees began in earnest, but by the end of the week, none of the key science posts had been filled. The most important job, head of the Office of Science and Technology Policy (OSTP) and Science Adviser to the President, was still open following the departure of H. Guyford Stever on January 20. About the only sign of movement is that Carter has asked the Defense Secretary, Harold Brown, to draft a list of potential candidates for the OSTP post, a curious assignment since OSTP has little influence over defence matters, and most other Presidential appointments are being handled by a team in the White House.

As for the major science agencies, Donald Fredrickson, the popular director of the National Institutes of Health (NIH), had not heard by the end of last week whether he will be kept in his job. At a press conference, however, Joseph Califano, the new Secretary of Health Education and Welfare, promised to end the politicalisation of NIH, but he said he hadn't made up his mind about Fredrickson's future. Similarly, Robert Seamans Jr, has departed as head of the Energy Research and Development Administration, but no successor has been named. It is widely reported, however that Douglas Costle, a former staff member of the Congressional Budget Office has been chosen as head of the Environmental Protection Agency, to replace the already-departed Russell Train.

About the only major scientific appointment so far is that of Patsy Mink, a former Congresswoman from Hawaii, to be Assistant Secretary of State in charge of science and technology affairs. The post was once held by Dixy Lee Ray, the former head of the Atomic Energy Commission who is now Governor of Washington State, but she quit with a blast at Henry Kissinger because of his indifference toward her office. The selection of Mink, a lawyer, for a post which many people consider should be held by a scientist, or at least by somebody well versed in scientific matters, will not do much to enhance the status of the office.

- Meanwhile, at the other end of Pennsylvania Avenue, Congress is finally getting itself in gear for the new session. The plan to reorganise the committees of the Senate, which was drafted last year by a special select committee, has now been picked over and amended by the Senate Rules Committee and it is expected to be debated by the full Senate this week. Although several more changes are anticipated, the chief committee alignments for science and technology affairs are likely to remain virtually as proposed by the select committee.

The Joint Committee on Atomic Energy, which has already been cut up by the House, will be completely done away with, and all jurisdiction for energy policy and energy research and development will be placed in an expanded Interior committee, under the chairmanship of Senator Henry Jackson. Responsibility for biomedical research will be consolidated in a new Committee on Human Resources, based on the old Labor and Public Welfare Committee, which means that Senator Edward Kennedy's subcommittee will retain its jurisdiction. The rest of the responsibility for science and technology, including overall science policy affairs, will be placed in an expanded Commerce Committee. Senator Adlai Stevenson, who chaired the select committee, is expected to end up with chairmanship of the key Commerce subcommittee dealing with science and technology.

The only major change from the select committee's proposals is that jurisdiction over the National Science Foundation (NSF) will go to the Human Resources Committee. On the face of it, a decision to put NSF affairs into a committee which deals with health and welfare rather than into the Commerce Committee, which deals with science, may seem a bit illogical. The reason is that Kennedy, whose NSF subcommittee now handles NSF matters, is a member of the Human Resources Committee but not of the Commerce Committee, and he wants to hang on to his NSF jurisdiction. That's the way Congress works.

On the House side, the Science and Technology Committee, which has picked up responsibility for nuclear research and development from the Joint Committee on Atomic Energy, has been reorganised. Chairmanship of the subcommittee on Science, Research and Development, which deals with NSF, has been assigned to Representative Ray Thornton, a Democrat for Arkansas. Energy matters will be handled by two sub-committees, one of which will deal with fossil energy and nuclear fission and fusion, while the other will deal with solar and geothermal energy, energy conservation and basic energy research. Rep. Walter Flowers, a long-serving member from Alabama, claimed the chairmanship of the fossil and nuclear subcommittee, while Representative Mike McCormack, who was widely expected to get authority over nuclear matters, was left with the solar and geothermal subcommittee. Flowers' views on energy policy are little known, but his new post will give him plenty of visibility, a useful asset if, as expected, he decides to run for the Senate in 1978.

Colin Norman

of technology and public policy at Harvard, and Edward Ginzton, chairman of Varian Associates.

A tantalising preview of some of the conclusions likely to emerge from the study surfaced last week when the steering committee issued an interim report, essentially suggesting that energy use in the United States will grow at a slower pace than most other studies have anticipated. The committee suggests, moreover, that the country can adjust to a slower rate of energy growth without sacrificing economic or social goals.

If the Academy does indeed come up with such a conclusion, it would add considerable weight to the view put forward a couple of years ago by the Ford Foundation's Energy Policy Project, namely that energy growth can be gradually reduced over a decade or so to a very low rate, without either causing economic stagnation or radically altering people's lifestyles. The practical consequence of such a development—if true—would be that there may be much more flexibility in long term energy supplies than is generally realised; Mr Carter could, for example, carry out his campaign pledge to slow down the present breakneck pace of the breeder reactor programme, without running a large risk of causing massive economic disruptions toward the end of the century.

Further evidence of the growing acceptance of the view that energy growth is likely to slow markedly is also to be found in a meticulous study of the possible consequences of a nuclear moratorium, produced recently by the Institute for Energy Analysis (IEA), headed by Alvin Weinberg. The study predicts that total energy use in the year 2010 will lie between a low of about 118 quads and a high of about 159 quads, compared with 71 quads in 1975. It notes that "even our 'high' estimate . . . is much lower than most previously published estimates. If our estimates are valid, they could imply considerable rethinking of those elements of energy policy and energy R&D policy that are premised on higher overall projections."

Because of those lowered energy growth rates, the study estimates that the economic and environmental impacts of a nuclear moratorium (which would prohibit the construction of new reactors after 1980 but allow continued operation of reactors on line by 1985), though severe, would be smaller than is generally believed. It is assumed that most of the energy shortfall would be taken up by a switch to coal in the short term, with growing input from alternative sources such as solar energy, which would tend to increase the cost of energy by a total of between $31,400 and $42,000 million by the year 2010, the study estimates. That would amount to less than 1% of the gross national product each year. As for employment, the study predicts that a moratorium would result in the loss of about 50,000 jobs in the nuclear and related industries, but "the displacement caused by the moratorium would be temporary".

The environmental implications of a switch from nuclear to coal could be relatively severe. If the moratorium is coupled with limitations on oil imports, which would be likely, between 100 and 300 million more tons of coal would have to be mined each year in the period between 2000 and 2010 than would be the case without a moratorium. That would probably despoil larger areas of land for strip mines, increase atmospheric levels of carbon dioxide, and possibly increase pollution from sulphur dioxide, oxides of nitrogen, hydrocarbons, particulates and carbon monoxide. Increased use of pollution control technologies would, however, take care of some of the increases.

Though such impacts are relatively large, they certainly do not add up to the level of economic and social disruption predicted by the nuclear industry last year during the referenda in seven states on nuclear power.

The expectation that energy growth in the United States will slow down over the long term without precipitating economic stagnation, which drew sharp criticism when the Ford Foundation published its study, is therefore growing in acceptance. It means that President Carter may have more flexibility when he chooses his long range energy plans, but it won't help much over the next few years. Only some warmer weather would do that. ☐

AUSTRALIA

SCORE scores

Peter Pockley reports from Sydney on Australia's data collecting project for research expenditure

INACTIVITY on questions of priority and level of financial support for science in Australia has regularly been justified on grounds of a lack of reliable data on expenditure and manpower. In the early 1970s, the then Department of Education and Science started the first national data collecting operation and graced it with the acronym of Project SCORE (Survey and Comparison of Research Expenditures).

The project, however, was for some years plagued by problems of definition, management and staffing. But it did manage to grind out in 1973 a detailed set of figures for the financial year 1968–69 (the Australian financial year runs from July 1 to June 30, with the exception of the universities whose accounts run from January 1 to December 31—just one of the problems faced by the number crunchers). These figures came out just as inflation began to canter up towards the gallop of 1975 and 1976, and this, coupled with the long delay between year of study and year of publication, greatly diminished their value.

The Department of Science has now begun publishing the second set of Project SCORE data. These refer to the financial year 1973–74; being more recent, the project scores more useful points for the student and politician of science alike. However, the criteria used in collecting and processing the data are not entirely consistent with the 1968–69 figures because the project changed to following OECD prescriptions very closely. This makes international comparisons valid, but has negated any reliable and precise statements on national *trends* in expenditure and manpower which are so urgently needed for drumming complacency out of politicians. This will have to await the next publication planned for the financial year of 1975–76 (the Department now hopes to collect data at two-yearly intervals).

Project SCORE reveals that in 1973–74 the Gross Expenditure on Research and Development (GERD) amounted to 651 million Australian dollars (£1=$1.58). This represents 1.3% of the Gross Domestic Product (GDP) of $50,557 million for the year under study. The manpower involved in GERD was equivalent to 53,300 man-years, representing 0.9% of the Australian work-force of 5,867,700; 48% of the manpower effort was attributed to professional persons. There are, however, no figures for the supply and demand of professionals, nor are these available from other sources to confirm or deny the now popular belief in Australia of an oversupply of scientists and technologists at a time when overall unemployment is nudging 5% of the workforce.

Using OECD's definitions, 91% of GERD was spent in the natural sciences, and 9% in the social sciences and humanities, assuming all business enterprise expenditure to be in the former. Basic research took 28% ($184 million) of GERD, applied research

37% ($238 million) and experimental development 35% ($229 million).

Socio-economic objectives groups accounted for intramural expenditure as follows, assuming all expenditure in the business enterprise sector to be in the economic development group: economic development 59%, advancement of knowledge 26%, national security 9%, and community welfare 6%. These and other broad figures quoted are broken down into fine detail in Project SCORE's publications.

As a percentage of GDP, Australia's GERD (natural sciences only) was in the middle rank of OECD's 18 member countries for the calendar year 1973. Australia's figure, adjusted to that year, was 1.2%, compared with the USA 2.3%, UK 2.1%, Germany 2.0%, Netherlands 1.8%, Japan and France 1.7%, Sweden 1.6%, Belgium 1.3%, Canada and Norway 1.1%, Austria 1.0%, and New Zeland 0.9%.

Changes in Australian R&D expenditure in the five years from 1968–69 to 1973–74 are difficult to quantify because of the changed criteria. Project SCORE's published figures for 1968–69 put total GERD at $334 million, approximately half the 1973–74 figure of $651 million without taking inflation into account. If compared at constant prices, GERD has increased about 35%, but when measured as a percentage of GDP, the GERD figures are closely comparable.

The relative financial support of Australian R&D has remained fairly static over the five-year period between comprehensive data collections and analyses. The figures thus support the general contention from more superficial indicators that neither the Liberal nor Labor governments of recent times gave significantly more or less attention to science than to other areas of government finance. Using the superficial indicators for the period since 1973–74, it is at least certain that the relative standstill position has been maintained, and quite likely that there has been a significant slippage. For example, it is believed that the number of staff engaged on industrial R&D has dropped by as much as 40% over the two years from 1973–74. □

IN BRIEF

Gloomy energy report

In a sombre analysis released last week of projected global energy supply and demand to 1985, an OECD publication, *World Energy Outlook*, warns of a likely shortfall in oil supply that will mean either higher prices or shortages or both. The report, calling for a "transformation" and "revitalisation" of energy policies in industrial countries, urges them to increase indigenous energy production and improve conservation through a combination of financial measures, including investment incentives and use of the price mechanism, and regulations, embracing direct and indirect conservation measures and relaxed environmental requirements.

Brazilian deal developments

Reports in Brazilian papers suggest that Brazil is determined to resist pressure from the United States to change the terms of its controversial nuclear deal with West Germany. There are also signs that Argentina, which has its own nuclear ambitions, is proferring support for the stand. The reports follow others in the Brazilian press indicating a possibility that the US might consider supplying Brazil with nuclear fuel if it gave up that part of the German deal which includes both enrichment and reprocessing facilities.

The US Vice-President, Walter Mondale, apparently urged West Germany to restrain sales of nuclear technology when he visited Bonn last week as part of his diplomatic tour of key western capitals, and the possibility has emerged of including tighter curbs on trade in sensitive technology. Nothing specific was disclosed regarding the Brazilian deal, however.

Brazil has not signed the nuclear Non-Proliferation Treaty, and although the deal is permissible under the treaty, it is hardly in keeping with President Carter's intentions in the field of international trade in nuclear technology.

Safety bodies established

The UK Health and Safety Commission has announced the establishment of two more bodies which are to be part of the advisory committee structure that will help it discharge its obligations under the Health and Safety at Work Act. One is the Advisory Committee on Toxic Substances, and will be chaired by the Director of the Health and Safety Executive's Hazardous Substances Division; committee members include four with relevant expertise and the CBI and TUC have each nominated four. Attention will focus on new chemicals, but not nuclear materials, which a new committee to replace the Nuclear Safety Advisory Committee will examine.

The other committee is the Advisory Committee on Dangerous Substances, to be chaired by the Executive's Deputy Director. This will concern itself with flammable and explosive substances, and includes three expert members as well as three each from the CBI and TUC.

A third committee, the Medical Advisory Committee, is already functioning, and one of the approximately 18 industry-based bodies, for agriculture, is also in operation.

Finland nuclear report

Finland should put a sharp brake on its nuclear energy plans, says the report of an energy committee under the leadership of the Finnish Minister for Trade and Industry, Arne Berner. Finland's shaky economic situation demands that investments should be confined to projects which will increase employment and the development of exports, rather than to nuclear power: instead of the string of reactors which the government had thought of building around Finland's coast, the committee suggests that no new reactors should be built before 1985. If more energy is needed before then, it should come from non-nuclear sources and problems connected with nuclear energy should meanwhile be studied more closely.

Finland has four reactors under construction, at Lovisa and Olkiluoto, and the first is due to be loaded in a few months' time. By 1985 it is expected that they will be producing about 14% of the country's total energy consumption. Water power will supply about 23% (30% last year), with most energy continuing to come from oil, coal and peat.

There has been no general public debate about nuclear energy in Finland as there has been in Sweden, although groups living near the reactors have protested. The committee's report offers them no comfort. If Finland does build more nuclear power stations, it says, they will probably be sited near the existing ones.

Budgets announced

The 30-member Executive Board of the World Health Organisation last week recommended a budget for WHO activities in 1978 of $165 million. The World Health Assembly will consider the proposal at its 30th session in Geneva in May.

The Council of the European Space Agency, meeting in Paris, approved programme budgets for 1977 last week of 481.1 million units of account, some 3 million down on those proposed. The programmes include Aerosat, Ariane, Marots, Meteostat, OTS and Spacelab. The Ministerial Council holds its first meeting later this month and will discuss the level of resources for 1978–80.

Self-control by bacteriophage lambda

from a Correspondent

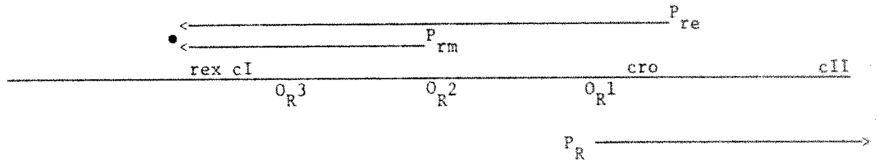
IT has been known for some time that the control of repressor synthesis in bacteriophage lambda is not a simple phenomenon. Such are the intricacies of the regulatory circuits involved in fact, that the subject was largely confined to European laboratories. Now, much of the lambda DNA sequence containing the *cis*-regulatory elements of repressor synthesis has been deciphered (Waltz *et al.*, *Nature* **262**, 665; 1976; Ptashne *et al.*, *Science* **194**, 156; 1976), and we can all take a crack at explaining the mechanism.

Shortly after infection of a sensitive *E. coli* by lambda, large quantities of repressor protein are synthesised. This repressor is translated from message initiating at a promoter, P_{re}, located several hundred nucleotide pairs to the right of the repressor structural gene, *cI*. Transcription from P_{re} depends on two phage products, *cII* and *cIII* which are not synthesised in an established lysogen. The maintenance level of repressor, about 200 repressor monomers per cell, is much lower than the infection level and depends on the activity of a different promoter, P_{rm}, located close to *cI*.

Transcription from P_{rm}, like transcription from P_{re}, is not constitutive. Repressor can be inactivated and its rate of reappearance measured over a long period. What is found is that, once a cell has lost repressor, it is very slow to resynthesise it. Since a prophage makes but two phage products, repressor and Rex, it would appear that one of these is responsible for maintaining the activity of P_{rm}. The experiments of Waltz *et al.* and Ptashne *et al.* demonstrate that repressor is its own inducer.

By the use of restriction endonuclease DNA fragments containing the *cI* control elements, the control of repressor expression can be shown *in vitro* at the level of mRNA synthesis. If the fragment is incubated with RNA polymerase, no transcription of *cI* is observed. Instead, all the transcripts initiate at the P_R promoter—the rightward promoter which is active in lytic phage development but repressed in a lysogen. Addition of a small amount of repressor to the incubation mixture turns off P_R transcription and activates *cI* transcription from P_{rm}. If large quantities of repressor are added, all transcription from the fragment is eliminated, including *cI*.

A simplified map of the control region is given below.



To the right of *cI* are three operators, or repressor binding sites, O_R1, O_R2 and O_R3. These sites are 17 base pairs long and are separated by spacers 3 to 7 base pairs long. They differ slightly in sequence and function from each other; O_R1 binds repressor more strongly than O_R2 or O_R3. Sequences recognised by RNA polymerase for rightward transcription, P_R, are located within O_R1 and O_R2. Repressor, by binding to these operators, prevents RNA polymerase from binding to P_R. O_R3 is not required to repress P_R; its role is to regulate the synthesis of repressor in lysogens. The control region displays a symmetry centred around the middle of O_R2, such that O_R3 contains a sequence similar to P_R, but with the opposite orientation. This is P_{rm}.

The sequence of the control regions from mutant phage have been obtained and support these assignments. Mutations in O_R1 or O_R2 destroy their capacity to bind repressor. A mutation located between O_R1 and O_R2 inactivates P_R, and a base change in the spacer between O_R3 and O_R2 destroys P_{rm}.

Speculating on the control of repressor synthesis on the basis of the DNA sequence we can see that the sequences of P_{rm} and P_R are not quite identical. This could explain why an additional factor, repressor for example, is required for P_{rm} activation. Moreover, the P_{rm}-promoted mRNA begins with AUG, and the codon corresponding to the amino terminus of repressor is found immediately adjacent to this triplet. Thus the P_{rm} message contains no leader sequence, hitherto thought to be essential for ribosome binding. This is not the case for the mRNA initiated at P_{re}, which carries the sequence GGTGAT. Since, under optimal conditions, P_{rm} and P_{re} are both very efficient promoters, the low level of repressor in a lysogen is due to inefficient translation of the P_{rm} mRNA, presumably because it is leaderless.

Unfortunately, it is still not obvious how repressor stimulates *cI* transcription. Perhaps P_{rm} competes with P_R for RNA polymerase, and the role of repressor is to block the binding of RNA polymerase at P_R. If this were the case, we would expect that mutations which reduce the efficiency of P_R as a promoter would relieve the repressor requirement of P_{rm}. Mutations isolated so far in P_R do not have this character. Alternatively, repressor bound at O_R1 may interact with RNA polymerase to stimulate directly its binding at P_{rm}. Ptashne notes that the distance between O_R1 and the initiation of *cI* transcription is the same as the distance between the start point of *lacZ* transcription and the site in the *lac* operon where the postive-control cyclic AMP binding protein interacts.

With either model, repressor synthesis in a lysogen will be negatively regulated at O_R3, where repressor protein competes with RNA polymerase for binding to DNA. The interplay of these positive and negative control circuits assures that the maintenance level of repressor will be confined to narrow limits.

The ability to isolate and sequence mutations in regulatory regions is certain to be tested again at other interesting lambda loci; notably at P_{re} and at the sites of action and recognition of the lambda control functions *N*, *Q*, *cII*, and *cIII*. □

Triassic extinction or Jurassic vacuum?

from Andrew Milner

In Charles Kingsley's *The Water Babies*, the author makes the observation that one cannot claim that water babies do not exist until one has seen them not existing. This little paradox is particularly pertinent to the fossils of terrestrial animals and what we deduce about them, particularly when they are absent from rocks of a given age.

If a taxon is absent from the fossil record for a given period of time, we logically assume that either it was genuinely absent or that it was present but that circumstances did not permit preservation. If the taxon or its descendants subsequently reappear as later fossils or living forms, we can be certain that the absence was due to non-preservation. If it never reappears the problem remains open and becomes: when did this taxon become extinct? Attributing a point in time to an extinction is only valid when the fossil record is comparably complete before and after the supposed event. Only if an animal is absent from an otherwise rich assemblage or if its ecological replacement is present, can one claim to have seen that animal "not existing".

The discovery of a temnospondyl amphibian in the Lower Jurassic of Australia announced by Warren in this week's issue of *Nature* (page 435) is a reminder of this. The Order Temnospondyli radiated during the Carboniferous to reach its greatest diversity in the Upper Carboniferous and Lower Permian. Many lineages became extinct during the Permian but others extended into and through the Triassic, and by the late Triassic several families remained, including the capitosaurs, brachyopids, metoposaurs and plagiosaurs. That the extinction of these families had taken place at the end of the Upper Triasic was virtually dogma. So much so that, as Warren notes, an earlier discovery of a fragment of Jurassic temnospondyl had been assumed to be a reworked bone from the Triassic simply because there was no precedent for it to have been any younger.

However, in order to have such fossils of Lower or Middle Jurassic amphibians or terrestrial vertebrates, one must first have vertebrate-bearing continental sediments of the same age and these are singularly scarce. The Upper Triassic of Europe, North America, Africa, India and China has produced an extensive range of terrestrial vertebrates including temnospondyl amphibians, procolophonids, chelonians, thecodonts, rhynchosaurs, dicynodonts, and early dinosaurs, crocodiles and mammals. By the Upper Jurassic, a very different assemblage of continental vertebrates is known from Europe, North America and East Africa. The chelonians, crocodiles, dinosaurs, pterosaurs and mammals predominate. The temnospondyls, procolophonids, rhynchosaurs, thecodonts and dicynodonts are all absent, presumed extinct, and in most cases their ecological replacements can be seen to be present. But when were they replaced? Did they become extinct synchronously on the Triassic–Jurassic boundary as a literal interpretation of the record would suggest? Or were they gradually replaced during the Lower and Middle Jurassic? Warren's amphibian suggests the latter possibility as do the tritylodonts which extend from Upper Triassic to Middle Jurassic.

•

Several recent discoveries offer the hope that this problem will eventually be solved. A sauropod dinosaur has recently been described from the Lower Jurassic Kota formation of India (Jain *et al.*, *Proc. R. Soc.* **B188,** 211; **1975)** and new microvertebrate localities of Middle Jurassic age have been found on the Isle of Skye (Waldman and Savage, *J. geol. Soc.* **128,** 119; 1972) and in Oxfordshire (Freeman, *Science* **194,** 1053; 1976). We still do not have a rich assemblage of early Jurassic terrestrial vertebrates but further excavation of these localities and Warren's Queensland locality may provide us with enough material to characterise the Lower and Middle Jurassic faunas and hence determine the chronology of the turnover of terrestrial vertebrate taxa between the Upper Triassic and Upper Jurassic. ☐

Astrophysics in Boston

from James Pringle

> The Eighth Texas Symposium on Relativistic Astrophysics took place on December 13–17, 1976 in the Copley Plaza Hotel in Boston, Massachusetts. The proceedings of the Symposium will be published as a special issue of the Annals of the New York Academy of Sciences. Nearly a thousand astronomers and physicists were present for this biennial jamboree and there might have been many more but for the competing attraction of the mid-January American Astronomical Society which was taking place in Hawaii.

X-ray astronomy featured prominently in four of the ten sessions. In the session on X-ray astronomy itself R. Novick (Columbia University) reported on the first unambiguous detection of polarised radiation in X-ray astronomy. With the X-ray polarimeter on board OSO 8, he and his group have found that at X-ray energies the Crab Nebula is 22% polarised with a significance of some 15 standard deviations. This compares with 19% polarisation in the optical. The position angle of the polarisation is essentially the same in both energy bands. He presented marginal evidence for the polarisation of the X rays from the Crab pulsar itself, and indications that the swing in position angle of the X-ray polarisation direction through each pulse is comparable to that seen in the optical. In addition Cygnus X-1 may be polarised at the 3% level (a 2½ standard deviation result) and, at a higher level of confidence, Cygnus X-2 may be polarised at the 5% level. E. Boldt (Goddard Space Flight Center) reported on some further high time resolution observations of the black hole candidate X-ray source Cygnus X-1, which continues to display X-ray activity on timescales as short as a few milliseconds. He gave tentative evidence that there may be a repetitive occurrence in these millisecond bursts with a timescale of about 10 ms and speculated that this might be identified with material falling within the last stable circular orbit for a black hole of some 17 solar masses.

Ken Pounds (University of Leicester) gave a preliminary report on the catalogue of X-ray sources being prepared from data from the Ariel V satellite and on a programme of optical identification of previously unidentified high galactic latitude sources (UHGLs for short). He argued that most of the 50 or so UHGLs in the UHURU catalogue of X-ray sources are now accounted for and so the UHGL mystery is solved, although the attentive in the audience noted that he had at the onset reported some 45 new UHGLs found by Ariel V.

The discovery of bursting behaviour

at X-ray energies is becoming increasingly common, although the implied link in the title of the session "X-ray bursters and Globular Clusters" was rather controversial. Walter Lewin (Massachusetts Institute of Technology) argued strongly that, although two of the bursting sources were almost certainly within globular clusters, the connection between the others and globular clusters was by no means proven and that the distribution of bursters within the galaxy is unlike that of the globular clusters. Jerry Ostriker (Princeton University) disagreed and argued, perhaps less convincingly but no less strongly, that the two distributions are remarkably similar. Lewin went on to discuss individual bursting sources of extraordinary complexity from MXB 1743-29 which bursts only once a day or so to MXB 1728-34 which is known as the 'rapid burster' producing bursts of X rays some 5,000 times a day. As more and more details of the bursting behaviour accumulate, it becomes more difficult for theorists to find a convincing explanation of the phenomena. Don Lamb (University of Illinois) was given the problem of finding something intelligent to say on the theoretical aspects of the bewildering observational results. He discussed a variety of possibilities including bursts of nuclear burning on the surfaces of neutron stars, and accretion events involving material held up by the magnetosphere of a neutron star sporadically going unstable and crashing to the surface.

Part of the limelight at the session on Neutron Stars was stolen by J. Trümper (Max-Planck-Institut, Munich) who had flown in especially to announce data obtained in a balloon flight looking at Hercules X-1 in the energy range 20–120 keV. It had been thought previously that the X-ray spectrum of Hercules X-1 did not extend significantly above about 30 keV. Trümper reported that the source had been seen well above 30 keV and the X-ray pulses (with a period of 1.24 s) were seen up to energies as high as 70 keV. Moreover, he presented evidence for an emission feature in the spectrum above 40 keV which he interpreted as an emission line due to cyclotron radiation at an energy of 53 keV—there is no other likely reason for the production of an emission line at this energy. If this is true, it implies that Hercules X-1 is indeed a magnetised neutron star and that the magnetic field is in the region of 2–5×10^{12} gauss (depending primarily on which harmonic of the gyrofrequency the emission is supposedly produced). Following this talk, Leventhal (Bell Laboratories) reported on γ-ray balloon observations of the Crab Nebula made to detect γ-ray lines. He gave evidence for a strong γ-ray line at an energy of 400 keV and speculated that this might be the 510 keV electron–positron annihilation line redshifted from the surface of the Crab pulsar: the redshift would imply that the pulsar is a neutron star of mass 1.4 solar masses, a value highly favoured on stellar evolutionary grounds.

Low mass X-ray binaries were discussed by Anne Cowley (University of Michigan) in the session on Close Binary Stars. The most intriguing source recently discovered to emit X rays is the star AM Herculis. This was already known to be a "nova-like variable", implying that a large amount of flickering is present in the optical light. It has since been found to display a 3-h period, probably due to orbital motion, in optical light and in radial velocity and to emit soft X rays which vary with the same period. Most remarkably, the optical light is highly circularly polarised (5–10%) with the degree of polarisation changing on the same 3-h period. It seems that this polarised light can only be due to cyclotron emission, implying the presence in the system of a magnetic field with a strength of over 10^8 gauss.

The second morning was devoted to quantum theory in strong gravitational fields. Stephen Hawking (Cambridge University) spoke on black holes and unpredictability. Inside a black hole, there is always a singularity which is a place where space and time come to an end and all the laws of physics break down. Provided the black hole can prevent any information about the singularity from leaking out, however, any observer not in a black hole would not be affected by the breakdown of predictability which occurs at the singularity. This "cosmic censorship" is endangered by Hawking's discovery that quantum effects allow particles and radiation to tunnel out of black holes. This radiation has an added degree of randomness over and above that associated with quantum mechanics. Equivalently, he concluded, one could say that "new random information is entering our universe from regions (either singularities or 'worm holes' leading to other universes) about which we have no knowledge".

In the session on Gravitational Theories Larry Smarr (Harvard University) gave a talk with the ominous sounding title "Computer Generated Space-Times". He reported on a continuing effort to solve Einstein's field equations in their full time-dependent form by means of numerical methods. One of the aims of this research would be, for example, to study the collision of two black holes with a view to discovering how much energy is radiated away in the form of gravitational radiation.

Irwin Shapiro (Massachusetts Institute of Technology) opened the session on quasars with a talk entitled

Membrane-bound proteins

from I. B. Holland and R. H. Pritchard

MEMBRANE-associated proteins are hard to study. They will probably be insoluble in aqueous solvents, there is often no simple assay for them and consequently they will probably defy purification. Studying their function may not be a simple matter either. The way a protein which facilitates transport of a small molecule across a membrane works will need to be investigated with the protein *in situ* or attached to an artificial membrane. Silhavy *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **73,** 3423; 1976) have found a new way of studying these proteins using the sophisticated box of tricks available to the *Escherichia coli* geneticist. They selected rare variants of this bacterium in which a gene coding for a protein involved in transport of maltose, and thought to be membrane bound, was fused to a gene coding for an easily assayable enzyme (β-galactosidase). The fused genes made a fusion protein which had the NH_2-terminal end of the transport protein and the COOH-terminal end of β-galactosidase. This hybrid protein had β-galactosidase activity which could be used to show that it was located in the cytoplasmic membrane. Thus an enzyme normally found in the cytoplasm had been carried to the membrane suggesting that the maltose transport protein is indeed membrane bound and that its COOH-terminus is not needed for this binding to occur.

Silhavy *et al.* hope to use their technique to investigate the structural features of proteins which lead them to associate with membranes. Their experimental strategy may be equally useful in identifying otherwise non-assayable proteins and for histochemical studies.

Unfortunately, in organisms with underdeveloped or emerging genetic technologies it will not be possible to engineer the variants required to make fusion proteins. This may only be a temporary difficulty in the exploitation of a promising idea.

"Apparent Superrelativistic Expansion of Quasars: Evolution or Revolution?". He reported on further radio VLBI (very long baseline interferometry—with baselines extending across the Atlantic) observations of quasars which show source structure down to an angular site of 0.001 arc s or less. Almost all the sources observed show time variations and some 10–15% of them show components which are separating from each other with apparent velocities greater than that of light. In the quasar 3C279 two compact radio sources are seen about 8 parsecs apart which appear to be flying apart at a speed some 25 times that of the velocity of light. There is as yet no convincing explanation of this phenomenon.

Dealing with theories of quasars, Martin Rees (Cambridge University) argued strongly that the observational evidence, including the VLBI observations presented by Shapiro, all tended to indicate that quasars are powered by a single massive object in the nucleus of a young and distant galaxy, and further that the most likely candidate for such an object would be a massive black hole. He described how such a black hole could provide the huge luminosity required (about 10^{46} erg s^{-1}) by slowly devouring the dense cluster of stars that is likely to be around it.

The final afternoon session was devoted to a discussion of galaxies. Harry van der Laan (Leiden Observatory) presented the latest observations of double radio galaxies by the Westerbork telescope. Polarisation observations provide a means of delineating the global structure of the magnetic field in the giant radio lobes: in general the field lies along any elongated features extending over very large distances and lies perpendicular to the intense radio hot spots at the outer edges of the radio lobes, as if the spots act like snow ploughs gathering field as they expand from the centre. He also discussed statistical evidence on the way the power houses which produce the double radio sources are distributed among elliptical galaxies. Somewhat surprisingly the evidence suggests that although the more massive (and brighter) elliptical galaxies are more likely to be endowed with an active power house, the size of the power house provided is independent of the size of the galaxy in which it is placed.

E. Salpeter (Cornell University) presented some 21-cm observations of galactic rotation curves using the newly re-surfaced Arecibo disk to extend the measurements out to radii of some 100 kpc from the centre. The graph of rotation velocity against radius should remain roughly constant if there is a massive unseen halo of faint stars (or even Jupiters) surrounding the optical galaxy, but should otherwise decrease with increasing radius. He found that the only galaxies observed which did not show evidence for a massive halo were those which had a close enough binary companion which would by now have stripped away the outer parts of any such halo, had it ever existed.

Alar Toomre (Massachusetts Institute of Technology) ended the conference with a light-hearted and amusing talk showing how tidal interactions between galaxies can produce spiral structure tantalisingly similar to that observed. He finished by showing how if a perturbing galaxy scores a "bulls-eye" by passing through another galaxy sufficiently close to the centre, the perturbed galaxy shows a bright, expanding ring structure. □

Animal behaviour and earthquake prediction

from John M. Logan

A conference on Animal Behaviour and Earthquake Prediction, sponsored by the United States Geological Survey, was held in Menlo Park, California on October 23–24, 1976.

CAN variations in animal behaviour help to predict earthquakes? As early as 100 AD Pliny advocated its use, but until recently the topic has received little serious scientific attention. Efforts now being made by the Chinese have, however, stimulated renewed interest in the topic. It has become especially relevant as other postulated precursors such as v_p/v_s ratios, electrical resistivity, radon content, electromagnetic variations and changes in the electrostatic field are either being questioned or are in the developmental stages.

The first question to be asked is whether there is any scientific basis for the popular reports of abnormal behaviour of animals, birds, fish and reptiles before earthquakes? If so, can animal behaviour then be considered as a reliable predictive indicator; what are the physical or chemical factors causing the anomalous behaviour; what appropriate research programme can be suggested to investigate behaviour patterns and their associated stimuli; and finally, can the biological indicators eventually be replaced by physical receivers? It became apparent at the outset that the various skills of geologists, geophysicists, and biologists would be needed. Thus, possibly the most diverse group of scientists ever to discuss the problem of earthquake prediction was brought together at the conference.

Anecdotal reports by non-scientists from many parts of the world contain many similar observations of animal behaviour before earthquakes. These observations come from people who could not possibly have had contact with each other or have read reports from other areas. This lends credibility to the observations, and provides a large body of evidence supporting the contention that animals do sense something before earthquakes. Apparently the response of animals is not restricted to a single species or genus, but spans a very wide spectrum of biological forms which suggests that there is either more than one stimulus or a universal one that can be detected by a wide variety of organisms. Furthermore, with the possible exception of reports of snakes coming out of the ground in mid-winter, few of the responses reported are truly 'abnormal' or extreme. Most involve normal forms of activity which take place either at elevated levels or at unique times. Thus, the term "abnormal behaviour" is somewhat misleading.

D. Mead (San Jose Mercury) witnessed the unusual behaviour of a cow immediately preceding one of the aftershocks at Oroville, California, and was told that similar actions had been observed before previous earthquakes. Soon he felt the aftershock. Most convincing of all was the report by H. Kraemer, B. Smith, and S. Levine (Stanford University) on the behaviour of chimpanzees preceding a magnitude 3.7 event. This is one of the few scientifically based studies available, and the correlation between the chimpanzees' behaviour patterns and the earthquakes is very convincing.

Precursive physical phenomena associated with earthquakes that might serve as stimuli for recognisable variations in animal behaviour were discussed at some length. The important point was made that earthquakes have a number of causal mechanisms rather than any single one. Fracture of rock along a new fault, breaking of asperities along existing fault zones, fracture of gouge zones, material and other instabilities along fault surfaces all may release seismic energy. It is possible that not all earthquakes are preceded by the same precursive events, and it follows that potential stimuli for perturbations in animal behaviour may not be present in all earthquakes.

It was pointed out that observed changes in air pressure, gravity, elevation and tilt all fall within the normal range experienced by animals throughout the day and are doubtful stimuli of behavioural variation. D. Hill (US Geological Survey) demonstrated that acoustic emissions could only be considered a potential stimulus if they were centred within a few hundred feet of the surface and almost beneath the animal. Observed variations of a few gammas in electromagnetic signals associated with earthquakes also seem unlikely to produce significant variations in biological responses, as these are an order of magnitude less than the normal diurnal variations experienced by the animal if it stands still; if it moves about, it will experience changes of hundreds of thousands of gammas in a single day. Changes in near surface water level may provide a possible explanation for some behaviour such as snakes leaving their holes in midwinter, but such changes certainly cannot be cited as a stimulus for the majority of the reported behavioural perturbations. The two remaining areas —changes in the electrostatic field and gas emissions before earthquakes — have not been investigated in great detail and both may be potential stimuli. The conclusion reached was that either electrostatic (or other electrical) effects are the primary causes of unusual animal behaviour, or some other effect not yet investigated (smell?) is operating.

A number of examples of the extreme sensitivity of biological systems to small changes in their environment was reported. Most of the anecdotal reports of animal behaviour can probably be classified as startle responses and are probably not learned. Stimuli producing the startle response may simply exceed some noise level or may be due to variations of the pattern of stimuli within the normal range experienced by the animal. If the latter is true, then detecting variations in patterns of stimuli will prove much more difficult than detecting a critical level of the signal.

In conclusion, it was pointed out that an earthquake prediction programme making use of animal behaviour may take two forms. The first is the recognition of variations in animal behaviour preceding earthquakes and its use as a predictive tool without understanding the mechanics of the process. This empirical approach, if successfully developed would satisfy the immediate need of earthquake prediction. Research could, and probably should, be oriented to this end. The second approach involves an investigation of the stimuli involved, which could lead to direct monitoring of the physical signal without the intermediate step of observing animal behaviour.

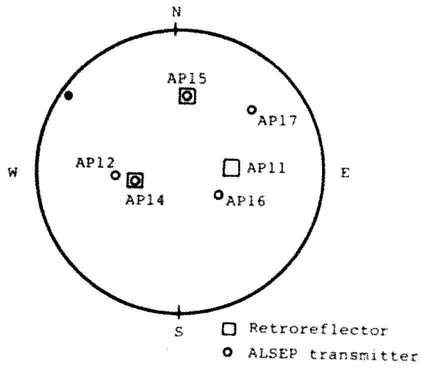
The interdisciplinary nature of the problem is extremely stimulating. Future research will clearly involve geologists, geophysicists, and biologists. I feel that the conference has successfully identified the problem, asked the pertinent questions and posed a number of hypotheses. Future work, it is hoped, will bring this to a level of scientific benefit to mankind. □

Moon measurements

from A. H. Cook

Placing optical retro-reflectors and radio transmitters on the surface of the Moon has proved to be one of the most significant and lasting achievements of the Apollo programme. The retroreflectors of which three were placed in the US programme and one (of French construction) in the USSR programme, have been used to reflect pulses of light emitted by laser transmitters on the Earth so that the round trip travel time of the pulse and hence the distance between a point on the Earth and one on the Moon can be measured very accurately, to within about 30 cm at present. So far almost all the measurements have been made from the Macdonald Observatory in Texas (Bender *et al., Science* **182,** 229; 1973). The radio transmitters have been observed by interferometers with very long baselines (VLBI) which are sensitive to the rotation of the group of transmitters about the line joining the centres of the Earth and the Moon (King *et al., J. geophys. Res.* **81,** 6251; 1976). Accuracies corresponding to between 1 and 10 m on the surface of the Moon are achieved.

The distance between a point on the Earth and one on the Moon depends on three factors: the motion of the Moon in her orbit about the Earth, the rotation of the Earth upon its axis and the oscillations of the Moon about her centre of mass. The three factors can be separated (the separation would be sharper if more laser observatories were in operation on the Earth and especially one in the southern hemisphere) and in consequence a great deal of physics can be studied. Thus the orbit of the Moon contracts because of the friction which damps the tides upon the rotating Earth; it may also be possible to check certain rather general relativistic theories. It is hoped that precise measurements of the relative positions of terrestrial observatories will lead to direct observation of movements of tectonic plates and to improved understanding of the very imperfectly known variations in the vector of the Earth's spin. In astronomy improved measurements of the Moon may lead to a better fundamental catalogue of star positions.



Retro-reflectors and radio transmitters used for analyses of lunar librations (King *et al., op. cit.*). AP denotes the Apollo mission which carried the equipment.

One of the most exciting consequences of the observations is the improved knowledge of the lunar librations. The Moon moves about the Earth in such a way that, seen from the Moon, the Earth remains almost but not quite in a fixed position relative to the axes of inertia of the Moon. Now the Moon has three unequal moments of inertia and also there are important terms of high harmonic order in the gravity field, and in consequence when the Earth moves with respect to the Moon it exerts torques which cause the Moon to rock about the lunar centre of mass. That rocking motion is the physical libration of the Moon. The amplitudes are small and difficult to observe visually from the Earth but by using laser ranging to the Moon the motion has already been observed in detail with high accuracy. The interest of observations of the libration lies in the fact that the libration depends on the moments of inertia of the Moon and when the observations of libration are combined with those of the second harmonic coefficients of gravity as obtained from artificial satellites about the Moon (Gapcynski *et al., Geophys. Res. Lett.* **2,** 353; 1975), then the three moments of inertia may all be obtained separately (Williams *et al., The Moon* **8,** 469; 1973). The moment of inertia of a celestial body is a key property in the study of its constitution because it depends on the way the density varies from the centre outwards. If the density were constant the moment of inertia in non-dimensional form would be 0.4 exactly, and when the density decreases towards the surface, the non-dimensional moment of inertia is less. The value for the Moon now seems to be close to 0.392, less, but not much less than 0.4. This is a stringent constraint on models of the lunar interior and because the value is so close to 0.4, it is most desirable to have it measured with as great an accuracy as possible.

It is here that the radio transmitters come in. Because of the fact that the technique of VLBI measures the rotation of the group of transmitters about the line of centres of the Earth and the Moon, it is insensitive to the Earth's rotation and to the Moon's orbital motion, and so leads to a very clear separation of the librations from other motions. The publication (King *et al.*, *op. cit.*) of the results obtained by combining lunar laser ranging with VLBI observations of the lunar radio transmitters is thus a landmark in lunar studies. The remarkably low uncertainty of 0.003 is attributed to the estimate of 0.392 for the value of the non-dimensional polar moment of inertia. It is also important that certain of the higher gravitational harmonics can be derived from the librations because there are considerable uncertainties in their derivation from the orbits of artificial satellites alone.

Clearly a great advance has been made in our knowledge of lunar dynamics in the past few years, and that in itself emphasises how much there is still to learn about the dynamics of the Earth. As already mentioned, one of the most important steps forward would be to obtain data from a lunar laser ranging observatory in the Southern Hemisphere, and there are indeed now good prospects of obtaining such data as a result of cooperation between US and Australian groups, in which British workers are also participating. As ever when new possibilities of precise measurements are realised, a new world of knowledge seems to be opening. □

Cheap uranium from bacteria?

from a Correspondent

An International Atomic Energy Agency research coordination meeting on the bacterial leaching of uranium ores was held at the University of Warwick on December 13–15, 1976 under the chairmanship of Professor Donovan Kelly, of the Department of Environmental Sciences, University of Warwick. The meeting was formally hosted by the UK Department of Energy.

During the 1960s it was found that uranium could be recovered from the acidic waters running through dumps of uranium mining wastes or from water hosed on to the walls of worked-out uranium mines. This solubilisation of uranium was subsequently found to be due to the activity of a specialised group of unusual bacteria called *Thiobacillus ferrooxidans*, which obtain energy for their growth from oxidising iron from the ferrous to ferric form in very acidic environments. These bacteria are always found in acid mine waters when pyrite (iron sulphide) is present in the ore being mined. They attack the pyrite and produce sulphuric acid and ferric iron, which in turn chemically converts the insoluble uranium ore into soluble uranyl sulphate. The possible economic importance of this process as a potentially cheap means of uranium recovery was early recognised by the IAEA, whose headquarters are in Vienna, and which has supported research and development into the bacterial leaching of uranium for a number of years.

The meeting at Warwick University was the third coordination meeting (earlier ones were in Ankara in 1972 and Vienna in 1974), held to review recent developments and to review the present status of the whole subject after some ten years of active work in many countries. Scientists from Austria, Canada, Finland, Hungary, India, Romania, South Korea, Yugoslavia and the UK and USA took part. Much of the work discussed had been financed by the IAEA and ranged from the basic microbiology of the process over economic aspects to the safety and control of uranium recovery.

With the likely demand for uranium for nuclear power generation in the Western World alone between 1976–2000 standing at 4 million tonnes of U_3O_8, mining companies have increasingly been looking at ways of recovering uranium from ores containing progressively less uranium, and to ways of recovering the small amounts of uranium left in the wastes from the processing of richer ores. Bacterial leaching provides just such a process, since the bacterial activity is as effective in removing essentially all the uranium from a 0.03% U_3O_8 ore as from a 0.3% ore, without necessarily being more costly, whereas the difference between these ores for conventional extraction processes is sufficient for the lower grade one to be uneconomic to work at acceptable prices. Bacterial leaching thus enables countries with only low-grade 'uneconomic' ores to exploit their natural resources cheaply and of course can also be used for low cost recovery of uranium from high-grade ores.

Since the IAEA programme began, the state of the art of bacterial leaching has progressed from minimal understanding and exploitation to the current state of having a rather full understanding of the fundamental microbiology and biochemistry of the process, to have proved large scale pilot plants and built at least one commercial scale plant. The latter, reported at the meeting, will become operational in Canada in 1977 and will produce a million pounds of U_3O_8 a year, using 3,000 tonnes of crushed ore per day.

The meeting discussed the basic studies of growth and physiology of the iron bacteria, largely carried out by Professor Kelly's group, the immunological characterisation studies performed in Korea, and work on the control of leaching activity and pilot plant operation in Romania, Yugoslavia and India. Much time was devoted to the evaluation of large scale plants, their engineering design, efficiency, responses to environmental factors such as seasonal temperature variation, supply of oxygen and of other nutrients, and possible hazards in the operation of the extraction systems. Britain has been active in the design and evaluation of practical leaching systems and the use of the bacteria to generate ferric iron from various sources to be used in leaching. A report on the work of the Warren Spring Laboratory in this field was received with considerable interest. The very large scale alkaline leaching of uranium in Hungary was reported in full and provided further information of basic use in plant design.

The conclusions of the meeting, reported to the IAEA, included the recommendation that bacterial leaching of uranium should be developed and encouraged as a cost-competitive method of recovering uranium, involving smaller capital and running costs than conventional methods, with the incalculably valuable bonus of enabling treatment of ores otherwise prohibitively costly to treat. It was foreseen that work in this field would proceed to progressively more controlled processes and that the areas requiring further work could be detected by constructing the realistic process flow sheets and mathematical models that work to date had made feasible.

A long-standing problem in many mining operations is the release of polluting acids and metals into the environment. One conclusion of this meeting was that controlled exploitation of leaching of waste rock from conventional mining operations was to be encouraged and exploited not only to recover uranium and other metals, but to minimise the likelihood of environmental pollution by uncontrolled natural leaching. It is clear that the economic, biological, sociological and engineering aspects of the bacterial recovery of uranium will occupy many workers for years to come. □

review article

Targeting of drugs

Gregory Gregoriadis*

Recent work suggests that specific association of drugs with their targets could be achieved by means of a versatile carrier capable of transporting drug molecules from the site of application directly to the site of action.

An important prerequisite for success in the application of pharmacologically active agents is specificity. Unfortunately, most agents interact with non-target sites as well. This is well illustrated in cancer chemotherapy of which the slow progress can be attributed to the failure of cytotoxic molecules to act on malignant cells only. Poor selectivity can often be worsened by the failure of agents to enter the target area. Thus, in certain cases of drug resistance development, cells (for example malignant cells) become impermeable to drugs, and in antimicrobial therapy antibiotics have little or no access to intracellular sites harbouring microorganisms. Access of drugs to the target can also be prevented because of gross anatomical barriers. Penetration of the blood–brain barrier by enzymes for instance would be desirable in the treatment of some lysosomal storage diseases[1].

There are at least two options open to us in pursuing optimal drug action. (By drugs I mean not only conventional drugs, enzymes and proteins used in medicine, but also substances used in biological research.) In the conventional one, efforts are directed towards the creation of specialised molecules. Usually a therapeutically profitable target–agent relationship is far from ideal, and undesirable side effects are almost always present. The alternative could prove simpler: functional molecules, not necessarily target-specific, could be transported by a carrier to the site of action and released to perform their task. Transport should be effected in isolation from the biological space between the site of application and the site of action because this might be important in where agents are either prone to inactivation or detrimental to the non-target space in the host. The carrier itself should be non-toxic, biodegradable and of the appropriate shape and size to accommodate a wide variety of substances. It should preferably ignore, or be ignored by, irrelevant areas and have a pronounced affinity for, and easy access to, the target site within which there should be a mechanism for the release of agents from the carrier. The latter, having accomplished its function, would then be disposed of.

In searching for the ideal carrier, one is tempted to look for systems which can intrinsically 'recognise' the target (Table 1). Thus, antitumour drugs complexed to antibodies have been shown to improve cytotoxicity to malignant cells possessing antigens corresponding to the immunoglobulin carrier[2]. As binding to the immunological determinants of the membrane is believed[80,81] to initiate endocytosis, the action of the antibody-bound drug is likely to be lysosomotropic (Fig. 1*b*). In spite of its appeal the antibody carrier approach is associated with a number of difficulties among which the isolation of target specific antigens for the producton of antibodies and the purification from these of immunoglobulin molecules specific for the antigen, are prominent. In addition, drugs attached to immunoglobulins may mask[83] the antigen recognition site of the protein or alter its tertiary structure and render it prone to rapid removal by the reticuloendothelial system. Assuming that target–carrier contact can be made one may ask whether the immunoglobulin–drug complex will allow the active moiety (drug) to perform its task. Severance of the bond (usually an ester) between carrier and agent may be necessary and as there could be a variety of linkages to suit a variety of agents, there should be a corresponding number of esterases. Other difficulties include inhibition of the immunoglobulin–antigen (target) interaction by circulating antibodies raised by the host against the antigen and also the possibility of allergic reactions to the carrier itself.

An interesting group of macromolecular carriers, only modestly pursued, is asialoglycoproteins (Table 1). These exhibit *in vivo* a highly specific affinity for the hepatic parenchymal cells[84] by which they are taken up into the lysosomal apparatus[85]. Using asialofetuin it was possible[10] to direct to the liver lysozyme and albumin cross-linked to the protein, and a similar use could perhaps be made of agalactoglycoproteins and ahexosamine glycoproteins which possess specificity for the liver and kidney respectively[86]. Other potential carrier molecules are trophic hormones, lectins[82] and some lysosomal enzymes[87]. In contrast to antibodies, many of these substances are readily available and complications in target recognition are less likely to occur *in vivo*. However, they lack the breadth of target choice of immunoglobulins as a group.

In a different approach for target selectivity advantage is taken of the ability of a number of cell types (for example phagocytes and certain malignant cells) actively to endocytose macromolecules. Among the latter (Table 1) a notable example[15] is DNA, to which cytotoxic drugs such as daunomycin and adriamycin bind tightly upon contact. Experiments with DNA-bound daunomycin and adriamycin have shown that reduced toxicity[88] of the bound drug and, presumably, increased uptake of the DNA–drug complex by tumour cells contribute to cures of tumour-bearing animals[15,17] and to remissions of certain malignancies in man[16]. In another example[11], β-amanitin coupled to albumin was found to induce *in vivo* selective damage of the sinusoidal liver cells and kidney proximal tubule cells, both very actve in the endocytic uptake of proteins. As with most macromolecules discussed, these lysosomotropic (Fig. 1) carriers can be vulnerable to the biological milieu (for example

Table 1 Drug carriers in biology and medicine

Carrier	Associated drugs
Macromolecules	
Immunoglobulins[2]	Methotrexate[3], daunomycin[4], adriamycin[4], chlorambucil[5,6], radioactive iodine[7], diphtheria toxin[8], glucose oxidase[9]
Desialylated glycoproteins	Lysozyme[10], albumin[10]
Albumin	Amanitin[11], phalloidin[12], deoxycholic acid[13]
Fibrinogen	Dichloroethylphosphoramide[14]
Deoxyribonucleic acid	Daunomycin[15,16], adriamycin[17]
Dextran	Insulin[18], noradrenaline[18], amphetamine[18], novocaine[18], coenzyme B_{12}[18]
Cells	
Erythrocytes	β-glucosidase[19], β-galactosidase[19], glucuronidase[20], asparaginase[21], glucose oxidase[22], methotrexate[23], adriamycin[23]
Leucocytes	'Corrective' enzyme[24]
Hepatocytes	Uridine diphosphate glucuronyltransferase[25]
Synthetic systems—non-biodegradable[26]	
Nylon semi-permeable microcapsules	Carbonic anhydrase[26], uricase[26], asparaginase[26], urease[26], catalase[26]
Polyacrylamide gel	Asparaginase[27]
Liquid surfactant membranes	Urease[28]
Glass beads	Uricase[29]
Synthetic systems—biodegradable	
Albumin microspheres	6-mercaptopurine[30], actinomycin D[31]
Multiple oil emulsions	Naltrexone[32]
Lactic acid polymers[33]	Cyclazocine[33]
Ufasomes (unsaturated fatty acid spheres)[34]	
Liposomes[35]	Lysozyme[36], amyloglucosidase[37,38], neuraminidase[39,40], α-mannosidase[41], glucocerebroside:β-glucosidase[42], hexosaminidase A[43], asparaginase[44], peroxidase[45-47], glucose oxidase[48], lectins[49], immunoglobulins[46,50-53], insulin[54,55], diphtheria toxoid[56], Poly(I):Poly(C)[57], actinomycin D[58-61], 5-fluorouracil[62], methotrexate[63,64], bleomycin[48,50,65], cytosine arabinoside[66], 8-azaguanine[67], mechlorethamine[68], bichloroethyl nitrosourea[68], colchicine[69], penicillin G[70], steroids[71,72], cyclic AMP[73], pepstatin[74], glutamate[75], nitroblue tetrazolium[76], EDTA[77], DTPA[77], TcO_4[78,79]

Association of drugs with carriers can be effected through covalent, hydrophobic, hydrogen or other types of bonding. In synthetic systems passive entrapment of drugs is also possible. Only representative bibliography is shown for antibody[2], non-biodegradable[26] and liposomal[35] carriers. For more information see respective references.

blood nucleases in the case of DNA) and are limited in both range of agent accommodation and target choice.

A number of three-dimensional systems (Table 1) have been proposed as alternatives to the 'linear' macromolecular carriers. Depending on their composition, such systems can be biodegradable or non-degradable. Of the latter, a well-known example is the nylon semipermeable microspherule[26] within which various enzymes have been entrapped and found capable of acting on inwards diffusing substrates. Like most non-biodegradable carriers, however, these are unsuitable for parenteral (chronic) use. Of the biodegradable systems on the other hand, whole cells could prove of considerable value. Erythrocytes (Table 1) for instance could be useful in delivering agents to the reticuloendothelial system[19] into which these cells eventually find their way. Furthermore, and assuming that their life span *in vivo* is largely unchanged by the procedure of agent entrapment, erythrocytes could serve as devices for the slow release of drugs into the circulation. Alternatively, undesirable substrates could enter erythrocytes to be degraded by entrapped enzymes[21]. While erythrocytes are limited in both range of agents which they can carry and target accessibility, this is even more so for other cells (for example leukocytes, hepatocytes) which function as vehicles of agents they contain naturally (Table 1). Nonetheless, Brady's suggestion[89] of transporting enzymes past the blood-brain barrier in leukocytes (known to percolate through the cerebral tissue after emigrating from post-capillary venules) may render such cells valuable therapeutic tools.

How realistic then is the concept of an effective multipurpose carrier? For reasons outlined earlier, it is apparent that there is indeed a requirement for a three-dimensional system capable of containing agents within a well-protected space and amenable to modifications, both structural and functional. In retrospect, it seems unlikely that any other natural materials would have been as appropriate building blocks for the carrier as insoluble polar phospholipids. These, when confronted with water, form highly ordered assemblages of one or several concentric lipid bilayers known as liposomes[90,91] and which by the use of simple techniques[92] can accommodate a wide variety of water soluble substances (Table 1). Alternatively, lipid soluble materials including the hydrophobic regions of macromolecules such as proteins, can be inserted into the lipid space in the bilayers[93]. Several of the physical properties of liposomes can be varied at will: size (radius) can be adjusted from about 12 nm for monolamellar liposomes to up to several microns for the multilamellar version, and a negative or positive surface charge can be imposed by the incorporation of charged amphiphiles[92]. Control of permeability to entrapped substances, and of stability is also feasible by the addition of a sterol or other lipids into the liposomal structure[92]. Finally, manipulation[35] of the surface characteristics of liposomes (see below) will enable them to recognise specific cells.

Following the demonstration[94,37] that injected liposomes control both the rate of elimination from the circulation and tissue distribution of entrapped agents, a considerable amount of work has been carried out in regard to the possible role of liposomes as carriers in biology and medicine[35]. For example, intravenously given liposomes by and large remain intact in the blood and entrapped non-diffusable agents (for example enzymes) are transported predominantly into the liver and spleen[37,95]. Entrapped small molecules such as 5-fluorouracil[62] and penicillin[70] diffuse from the carrier into the blood while others (for example actinomycin D[70], colchicine[69]) are retained and follow the carrier to its destination. We have found that retention of daunomycin and melphalan by liposomes is greatly augmented when the two drugs are bound to DNA and polyglutamic acid respectively (G. Gregoriadis, S. C. Scott and P. N. Davisson, unpublished work). Rates of liposome clearance from the site of injection as well as penetration of target areas can easily be varied by controlling liposomal size, surface charge and lipid composition. Thus, intravenously injected small liposomes circulate in the blood for longer periods[69] and, because of their size, can reach malignant tissues[48]. Similar liposomes given intramuscularly enter the lymphatic nodes draining the injected tissue[96]. On the other hand, liposomes composed of phospholipids resistant to gut phospholipases at the body temperature are capable of transporting insulin from the gut into the blood circulation and of reducing blood glucose levels in normal and diabetic rats[51]. Indeed a considerable body of experimental evidence, discussed in detail elsewhere[35], has now made possible a realistic appraisal of the carrier potential of liposomes in the treatment of diseases as diverse as cancer, diabetes and lysosomal storage diseases and also in preventive medicine (for example as immunological adjuvants).

Although manipulation of the physical parameters of liposomes can modify to some extent the pattern of their tissue distribution[35], a method for targetting liposomes would vastly expand their potential. A few attempts for improving target selectivity have already been made: after *in vitro* exposure of phagocytes from *Mustelus canis* and a Tay Sachs disease patient to liposomes coated with aggregated isologous immunoglobulin, there was considerable improvement in the cellular uptake of the liposome-associated horseradish peroxidase[46] and hexosaminidase A (ref. 43) respectively. It was assumed that association of liposomes and their enzyme contents with phagocytes was mediated through the Fc portion of the extraliposomal immunoglobulins. Other workers[97] found that incorporation into the liposome structure of a sialoglycoprotein extracted from the erythrocyte membrane, could facilitate *in vitro* binding of such liposomes to erythrocytes in the presence of lectins. Our studies have shown that homing of liposomes is also possible *in vivo*. Thus, desialylated fetuin (which, as mentioned earlier, exhibits affinity for the hepatic parenchymal cells) incorporated on to the liposomal surface was found[50] to mediate uptake of the liposome-associated bleomycin by the relevant receptors on the liver cell surface.

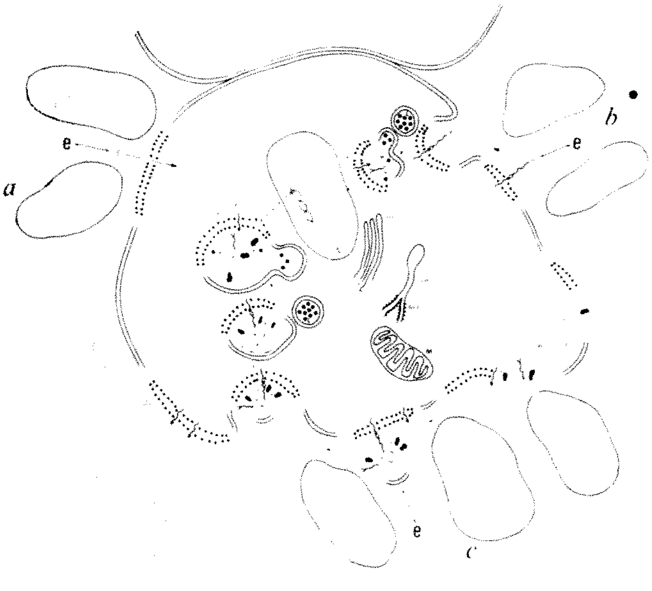

Fig. 1 Interaction of carrier-associated drugs with cells. A drug molecule (*) presented to a cell in its free form can enter the interior non-specifically by mechanisms such as diffusion and endocytosis[82] (*a*). Untoward reactions may occur because of the availability of the free drug to, and its interaction with, the environment (e). In *b*, interaction of the carrier–drug complex (α–α) with a carrier-recognising receptor (→) on the cell membrane induces endocytosis of the complex and its subsequent interiorisation into a lysosome where lysosomal exterases (●) liberate the drug. Other mechanisms of action of the carrier-bound drug are also possible[2]. Carrier-bound drug molecules are again available to, and can interact with, the environment but owing to the size of the complex and its affinity for the target, diffusion to non-target areas is reduced. *c*, A drug-containing monolamellar liposome recognises the target cell through a homing macromolecule (—<) inserted on the liposomal surface and which binds to the relevant cellular receptor (→). Contact with the cell is followed by endocytosis of the carrier (arrow pointing to the left) and its subsequent localisation in the lysosomes. Lysosomal esterases (phospholipases?) disrupt the bilayer and free the drug which can either act locally or, after escape from lysosomes, reach other cell compartments and interact with molecular targets (for example interaction of actinomycin D with DNA in the nucleus). Alternatively the liposome, upon fusion with the cell membrane (arrow pointing to the right), introduces its water-soluble contents into the cytoplasm and makes them available to the remainder of the cell. Lipid-soluble agents (▮) carried by the lipid bilayer of the liposome are transferred after fusion into the framework of the cell membrane. Liposome associated drugs, being surrounded by the lamellae, are not available to the environment. N, nucleus; GA, Golgi apparatus; SER and RER, smooth and rough endoplasmic reticulum; M, mitochondrion; L, lysosome.

The possibility of a more general method for the selective uptake of liposomes by cells is under investigation in my laboratory. Our approach[50] is based on the anchoring of native anti-target IgG immunoglobulins, through their Fc portions, into the liposomal lipid phase. The Fab moiety seems to extend extraliposomally (G. Gregoriadis and E. D. Neerunjun, unpublished work), and is capable of recognising, and associating with, the respective antigens on the target cell surface. Before trying to raise antibodies to cell specific antigens we experimented with the possibility of using whole cells for antibody production. It was hoped that the presence of cell-specific strong antigenic determinants on the cell surface would produce antisera rich in antibodies to such antigens and therefore reasonably specific for the parent cells. Indeed, after exposure of HeLa cells and human skin fibroblasts to liposomes containing ^{111}In-labelled bleomycin and bearing on their surface ^{125}I-labelled IgG raised against whole HeLa cells, the uptake of both radioactivities by HeLa cells was 25 times greater than that with fibroblasts[50]. On the other hand, after exposure of fibroblasts to the same liposomes now bearing anti-fibroblast-labelled IgG, uptake of the two radioactivities was five-fold greater than with HeLa cells[50]. As both cell types exhibited similar rates of uptake of bleomycin-containing liposomes coated with nonspecific IgG, it was concluded that cell-specific IgG on the liposomal surface was mediating selective uptake of the carrier and its drug contents. In practical terms, this approach has not only made the need for production of IgG against purified cell-specific antigen doubtful, it also suggests that purification of anti-target IgG from the multitude of other IgG molecules in the serum may be unnecessary; assuming a random distribution of the IgG molecules within the liposomal population, each individual liposome would be expected to possess on its surface some of the target-specific IgG. These specific molecules would then mediate the interaction of the associated carrier and the target. With regard to allergic reactions to the IgG used for homing, it is conceivable that insertion of the Fc portion of the immunoglobulin molecule into the lipid bilayer (which still allows the Fab portion to recognise its antigen) could mask this strongly antigenic site of the protein itself and thus prevent its interaction in the circulation with the respective anti-IgG (Fc) antibodies. Such avoidance of antigen–antibody interaction has been already observed for liposome-associated diphtheria toxoid[58], asparaginase[44] and insulin[54].

Effective direction of liposomes to target areas in the body will depend crucially on the circumvention of at least two obstacles. First, and when the target is not the hepatic parenchymal cells or in the confines of the reticuloendothelial system, for which conventional liposomes show preference, it will be necessary to reduce hepatic and splenic interference. Modest attempts[98,99] have shown that this is possible. Second, the size and composition of liposomes must be manipulated in a way that will allow passage of the carrier through a variety of anatomical barriers. This too is under investigation[48] but as there is a minimum (12 nm) in the radius of liposomes, there will be limitations. Other mechanisms, however (for example the use of leukocytes[43]), by which liposomal contents can be somehow transported into restricted areas cannot be excluded.

Provided that such difficulties can be overcome, it would be possible for specialised liposomes to seek and reach their cellular target site, become associated with it and deliver their contents. Two mechanisms of cell–liposome association are currently recognised[35], namely endocytosis[100–102] and fusion[45,73,103–105] (Fig. 1*c*). Direct as well as circumstantial evidence[35] suggests that the former mechanism occurs both *in vitro*[106,38] and *in vivo*[101,102,107] with a variety of actively or not so actively endocytosing cells. Because of this process, liposome-associated agents end up in the lysosomes where they are liberated and assuming such agents retain their activity in the lysosomal milieu, they can then act locally[106,38,108]. Alternatively, and when the physical properties of the agents allow it, these can escape by diffusion and reach other cell regions[61]. There is now considerable evidence[73,103–105,109] to suggest that under certain conditions *in vitro* the liposomal bilayers can, in addition to being endocytosed, fuse with the cell membrane (Fig 1*c*). This can either mediate incorporation of lipid soluble substances (located within the lipid phase of liposomes) into the cell membrane[110] or introduction of water soluble substances (entrapped in the aqueous space) in the cytoplasm[73].

Selective association of liposomes with cells could bring agents with their own selectivity for action near intracellular molecular targets. For instance actinomycin D or daunomycin originating from lysosomes (endocytosis) or from the cytoplasm (fusion), could enter the nucleus, bind to DNA and inhibit DNA directed RNA synthesis[61]. Similarly, agents in the vicinity of mitochondria or other organelles could, because of a specific affinity, bind to respective components and exert their effect. It thus appears that targetting of drugs with liposomes could proceed in two steps. In the first, the carrier would recognise the general area of action and subsequently enter it. Following their liberation from liposomes, drugs could then proceed for a finer target recognition at the molecular level (Fig. 1).

Additional results on palaeomagnetic stratigraphy of the Koobi Fora Formation, east of Lake Turkana (Lake Rudolf), Kenya

J. W. Hillhouse
US Geological Survey, 345 Middlefield Road, Menlo Park, California 94025

J. W. M. Ndombi, A. Cox
Department of Geophysics, Stanford University, Stanford, California 94305

A. Brock
Department of Physics, National University of Lesotho, Roma, Lesotho

The magnetostratigraphy of the hominid-bearing sediments exposed east of Lake Turkana has been strengthened by new palaeomagnetic results. Ages obtained from several tuffs by the ^{40}Ar/^{39}Ar method suggest an approximate match between the observed magnetozones and the geomagnetic polarity time scale; however, the palaeomagnetic results are also compatible with a younger chronology suggested by conventional K–Ar dating of the KBS Tuff.

BROCK and Isaac[1] have reported palaeomagnetic polarity determinations from the Koobi Fora Formation, exposed on the north-east side of Lake Turkana (formerly named Lake Rudolf), Kenya (Fig. 1). Because these Pliocene and Pleistocene deposits have yielded rich assemblages of fossil vertebrates, including the remains of very early humans, the ages of these beds have received considerable attention[2–4]. The Koobi Fora beds have also yielded a large collection of stone artefacts representing at least two toolmaking industries[5,6]. The palaeomagnetic study complemented a framework of radiometric ages determined from five tuffs interbedded within the Koobi Fora formation[7]. After Brock and Isaac's results were published, one of the tuffs, the KBS, was redated in another laboratory using the conventional K–Ar method, and a younger age was reported[8]. We have now obtained additional palaeomagnetic results which warrant a reevaluation of the magnetic stratigraphy.

The palaeomagnetic study of Brock and Isaac included 247 oriented specimens collected from four stratigraphic sections within the Koobi Fora Formation. The sedimentary deposits consist of fluvial sandstones and siltstones interbedded with lacustrine mudstones that formed near the eastern shore of ancient Lake Turkana. The palaeomagnetic results were tied to local, discontinuous outcrops of tuffs, each of which has been tentatively correlated with one of five ash beds that are believed to be widespread marker units within the Koobi Fora area. Listed from oldest to youngest, these tuff horizons have been named: Suregei, Tulu Bor, KBS, Koobi Fora and Chari. The proposed correlation of tuffs should be considered as a working hypothesis subject to revision. Further work is now in progress and it is evident that some amendments to the published correlations[9–12] are called for (I. Findlater, J. M. Harris, T. White and R. E. F. Leakey, personal communication.).

A consistent sequence of polarities was established from the four stratigraphic columns, and using the previously published age of 2.6±0.26 Myr for the KBS Tuff[13] as a fixed point, this sequence was matched with parts of the geomagnetic polarity time scale. In this interpretation part of the lower member of the Koobi Fora Formation, bracketed by the KBS and Tulu Bor Tuffs, was assigned an age of 2.6–3.2 Myr, while the upper member was assigned an age between 1.2 and 1.8 Myr. As reversed rocks were not found between the Koobi Fora Tuff and the KBS Tuff, the interpretation required that sediment representing 600,000 yr of the early Matuyama epoch had been removed from the section, possibly by uplift and erosion after deposition of the KBS Tuff. The subsequent publication[7] of ages for the other tuffs, namely, Tulu Bor (3.18±0.09 Myr), Koobi Fora (1.57 Myr) and Chari (1.22±0.01 Myr) provided strong support for the palaeomagnetic interpretation.

The basis of the initial polarity interpretation was the KBS Tuff, the age of which is now disputed. An age of 2.6±0.26 Myr was initially assigned to the KBS Tuff on the basis of apparent age spectra determined by the ^{40}Ar/^{39}Ar method, which entails step-wise heating of specimens. It was thought that the conventional K–Ar method could not be applied successfully to the Koobi Fora tuffs because the ash had lost some argon, due possibly to widespread hydrothermal events[14]. Conventional K–Ar

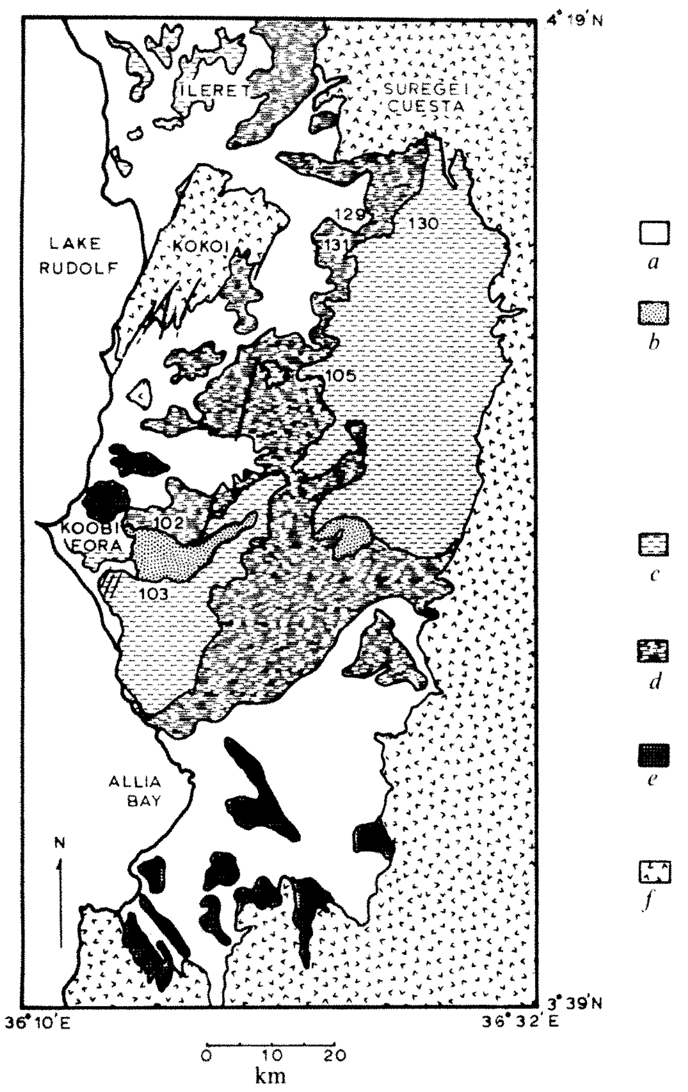

Fig. 1 Geological map of the Koobi Fora region in northern Kenya, showing palaeomagnetic sampling area (after Vondra and Bowen (ref. 11). *a*, Alluvium, beach sand; *b*, Galana Boi beds. *c*–*d* Koobi Fora Formation. *c*, Upper member; *d*, lower member; *e*, Koobi Algi Formation; *f*, volcanic rocks undifferentiated.

dating has now yielded significantly younger ages[8]. Glass and sanidine separates taken from the same sample have remarkably similar ages; nine specimens from areas 105 and 10 gave an average age of 1.60±0.05 Myr and six specimens from area 131 gave an average age of 1.82±0.04 Myr. These results combined with trace element analysis indicated that the tuffs exposed in areas 105 and 131 might be from two eruptions separated in time by 200,000 yr. The high precision and concordancy of these dates determined from two materials with different crystal structures provide strong evidence that the tuff has not lost radiogenic argon. Additional ^{40}Ar/^{39}Ar measurements[15] and fission track age determinations[16], however, provide evidence in favour of the earlier date for the KBS Tuff. Thus the chronology of the Koobi Fora Formation remains open to discussion, and alternate interpretations of the magnetostratigraphy, enhanced by 800 additional samples, are presented here.

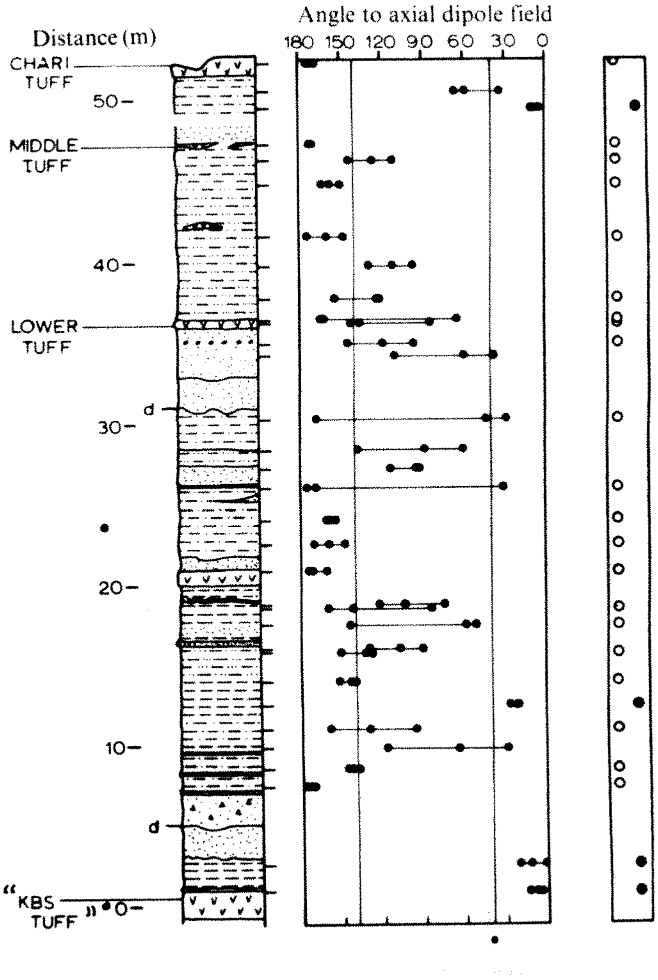
Additional palaeomagnetic results

We have determined magnetic polarities of six new stratigraphic sections, spanning the following stratigraphic intervals (Figs 1 and 4): (1) area 131: 'Tulu Bor'–'KBS Tuff'; (2) area 105 and 116: 'Tulu Bor Tuff'–KBS Tuff (type section); (3) Ileret: 'KBS Tuff'–Chari Tuff (type section); (4) area 129 and 15: Suregei Tuff–Tulu Bor Tuff (type section); (5) area 102: 'Suregei Tuff'–Koobi Fora Tuff; (6) area 103: 30-m column just below the Koobi Fora Tuff (type section).

Because the identities of tuffs in localities other than the type areas are hypothetical, the above list indicates whether or not the palaeomagnetic column is attached to a type section. In the remainder of this paper, tuffs which have not been traced back to the type section with certainty are flagged with quotation marks.

The sampling technique has been described by Brock and Isaac[1]: The magnetic polarity of each horizon was determined from three oriented cubes (2 cm × 2 cm × 1.5 cm) with a 5 c.p.s. flux-gate spinner magnetometer. One sample from each horizon was progressively demagnetised with an alternating-field (AF) up to 300 Oe, then the optimum field was selected as that which minimised the change in magnetic direction between successive demagnetisation steps. The remaining samples were demagnetised at the optimum field determined from the pilot sample. Typical optimum fields of these samples ranged between 100 and 200 Oe, with the remaining magnetisation averaging 10–25% of the initial natural magnetisation. Almost all of the specimens had acquired

Fig. 2 Palaeomagnetic results from the Ileret section. The angular difference between the cleaned palaeomagnetic direction and the normal axial dipole field is plotted for each sample. On the right the polarity of each horizon has been interpreted as normal (dot) reversed (open circle), or indeterminate (no symbol) from analysis of three samples. Disconformities are indicated by d. The tuff correlated as the 'KBS' is the uppermost of a pair of tuffs separated by several metres of sediment. This same upper tuff was dated by Curtis *et al.*[8] at 1.60±0.05 Myr.



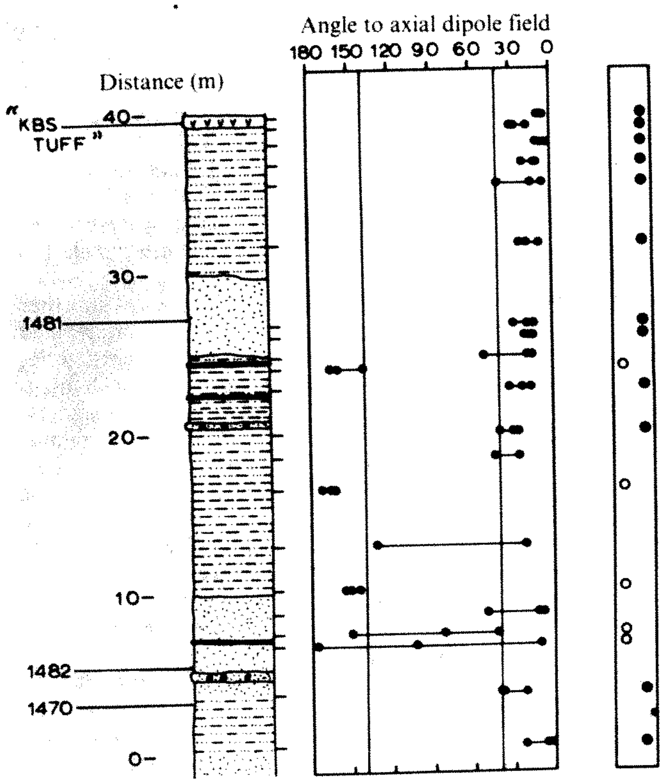


Fig. 3 Palaeomagnetic results from the lower member of the Koobi Fora Formation in area 131. Stratigraphic positions of hominid sites ER-1470, ER-1482, and ER-1481 are indicated[3]. The Tulu Bor Tuff is believed to be located approximately 6 m below the base of this section. The tuff correlated as the 'KBS Tuff' in this column was dated by Curtis *et al.*[8] at 1.82±0.04 Myr. The possibility cannot be eliminated that this tuff is the lateral equivalent of a minor tuff that occurs below the type KBS Tuff in area 105.

viscous magnetisation parallel to the normal axial dipole field, and this component was effectively removed by AF demagnetisation of 50–100 Oe.

In the treatment of the preliminary columns, Brock and Isaac[1] defined normal and reversed magnetic directions as those which deviated less than 50° from the axial dipole ($D=0°$, $180°$; $I=\pm 8°$). Directions lying outside these 50° cones were regarded as intermediate. In a few cases the cleaning procedure produced erratic changes of direction between successive steps, so these samples were classified as giving no clear result. In order to give a better representation of the range of dispersion within horizons we have modified this analysis by computing for each sample the angle between the cleaned palaeomagnetic direction and the normal axial dipole field ($D=0°$, $I=8°$). Because all of the sampling localities are located within a 30-km radius, magnetic directions rather than virtual geomagnetic poles (VGP) were analysed. As examples, the palaeomagnetic results from columns in areas 131 and Ileret are shown in Figs 2 and 3.

We have defined the polarity of each specimen using cones of confidence centred about the normal and reversed axial dipole directions. Given a period of 10^5 years or more, the time-averaged direction of the Earth's field at a given site is very close to the axial dipole direction, although at a given instant changes in the non-dipole field may displace the field vector away from the axial direction. At the latitude of Koobi Fora (4 °N) the angular standard deviation is 18°, based on a model which assumes non-dipole dispersion similar to that of the present field[17]. Palaeomagnetic evidence from Tertiary lavas indicates that this value of the standard deviation is in accord with ancient field behaviour[18,19]. We have used an angle (40°) slightly larger than two standard deviations as the radius of the 95% confidence cone centred on the axial dipole in order to define the polarities as follows: (1) If the angle to the axial dipole lies between 0° and 40° the specimen has normal polarity. (2) Between 140° and 180°, the specimen has reversed polarity. (3) Between 40° and 140° the specimen has intermediate polarity.

Even after AF cleaning, some horizons gave three widely scattered directions, and in extreme cases the horizons contained normal and reversed polarities. This inconsistency indicated that some samples had acquired secondary remanence which was not completely removed by AF demagnetisation. Therefore the polarity of each horizon was interpreted from three specimens according to the following rules: (1) If one or more specimens had reversed directions, the horizon was assigned reversed polarity. (2) If all three specimens had normal directions, the horizon was assigned normal polarity. (3) If a horizon had one or more intermediate specimens and no reversed specimens, the results were rejected and the horizon's polarity was said to be indeterminate. Intermediate directions may record true palaeofield directions during polarity transitions or excursions, or they may be due to the superposition of primary and secondary magnetic components with opposite polarities. Because of this ambiguity, intermediate directions were ignored in the interpretation of the magnetic stratigraphy.

This scheme deliberately favours reversed directions. Our reason for adopting it is that many Koobi Fora specimens have acquired an overprint of stable secondary remanence with normal polarity. This normally polarised secondary remanence may have been acquired by two processes; it may have originated as viscous remanence due to recent exposure in the Earth's field or it may have originated as chemical remanence by oxidation of magnetite during weathering. Because the Earth's field has been normally polarised essentially all of the time since 700,000 BP we would expect the viscous magnetisation to be normal. Recent weathering of outcrops may cause chemical changes that also impart normally polarised chemical remanence. For these reasons, reversed magnetisation is less likely to represent overprinting due to viscous magnetisation or weathering and therefore is more reliable for purposes of palaeomagnetic stratigraphy. Some specimens may have acquired post-depositional chemical remanence during periods of reversed polarity; however, at Koobi Fora long intervals of normally polarised rocks contain only a few intermediate and reversed specimens; they tend to be entirely normal. On the contrary, horizons with widely scattered directions are confined almost entirely to beds that have reversed polarity. This indicates that for the most part secondary remanence is normally polarised. In short, reversed magnetisation indicates that the rocks formed when the field was reversed whereas the converse is not always true for normal magnetisation. Good examples of the relations defined above can be seen in the Ileret and area 131 sections (Figs 2 and 3). It was for the above reasons that reversed directions were given more weight than normal directions in the interpretation of the magnetic stratigraphy.

Figure 4 summarises the magnetic stratigraphy of the Koobi Fora Formation, including the preliminary results[1] in columns marked with arrows. Two incomplete sections, Ileret 6A and area 103, which were presented by Brock and Isaac, have been superseded. Although some inconsistencies are apparent between the sections, a coherent pattern may be seen which provides a basis for making correlations with the geomagnetic polarity time scale. Besides extending the magnetostratigraphy down to the Suregei Tuff, the new results have led to some revisions of the preliminary magnetozones. For example, in area 105 between the 'Tulu Bor' and the type KBS Tuffs, Brock and Isaac found evidence for two reversed zones separated by a short

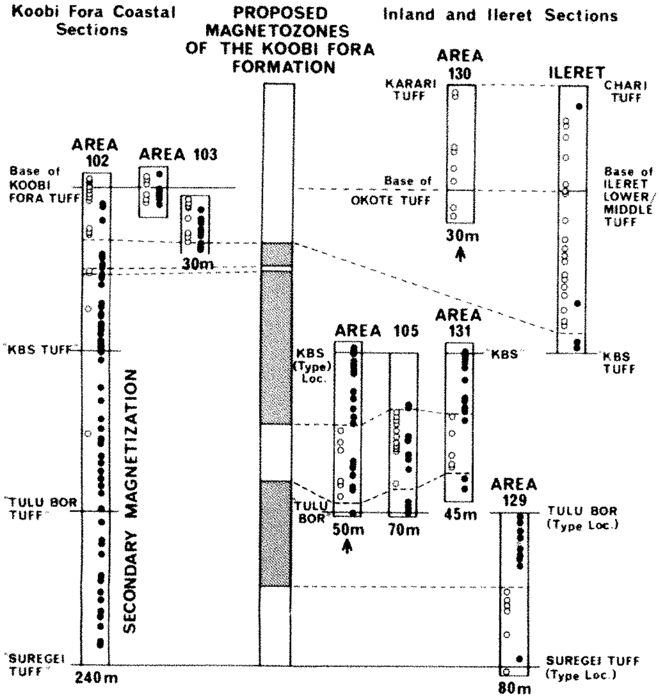

Fig. 4 Summary of palaeomagnetic stratigraphy of the Koobi Fora Formation. The stratigraphic sections are correlated by several key tuffs, placed on an arbitrarily spaced grid. The actual thicknesses are shown at the bottom of each stratigraphic section. Because the correlations of tuffs outside the type localities are provisional these correlations are flagged with quotation marks. Normal polarities (dot) and reversed polarities (open circle) define magnetozones shown in the generalised column. Columns previously reported by Brock and Isaac[1] are marked with an arrow.

normal zone. Resampling of the same interval in areas 105 and 131 showed the presence of sporadic normal horizons within the thick reversed zone. In keeping with our assumption that reversed magnetic directions are more reliable than normal ones, we have disregarded those isolated normal horizons in constructing the generalised magnetic column in Fig. 4. Therefore, we now regard the reversed horizons below the KBS Tuff as part of one magnetozone.

The inconsistencies serve as a warning that palaeomagnetic dating, like K–Ar dating, is subject to errors due to geochemical processes. For example, the lower portion of the Area 102 column (Fig. 4) is normally polarised, whereas sections of overlapping age in areas 129, 131 and 105 have several bands of reversed polarity. In area 102 the oldest sediments consist of brittle, grey claystones deposited in deep water within a rapidly subsiding graben. In contrast the equivalent deposits exposed in areas 105 and 131 are composed of fluvial and shallow lacustrine sediments. Apparently, the original palaeomagnetic signal carried by the area 102 clays was erased, perhaps by chemical alteration of the detrital magnetic minerals during burial. In recent time the clays may have acquired stable chemical magnetisation of normal polarity. Palaeomagnetic results from the lower portion of the area 102 column were therefore largely discounted. As a general rule, the least reliable palaeomagnetic columns of the Koobi Fora formation were located in hard lacustrine clays exposed near the present shoreline. The most consistent results were obtained from deltaic and shallow lacustrine sediments exposed near the eastern margin of the Koobi Fora beds.

In all columns, however, mixed polarities and scattered magnetic directions were most apparent in poorly consolidated sandy beds where the mean grain size exceeded 50 μm. For example, the reversed magnetozone from area 103 is interspersed with isolated normal horizons and many of the reversed horizons include one or two specimens with normal or intermediate polarity. Most of these unreliable results were determined from friable, coarse-grained sediments. In the area 102 column, scattered magnetic directions occur between the 'KBS' and 'Tulu Bor Tuffs'. This part of the column largely consists of sandstone. It is possible that the entire column from area 102 is affected by remagnetisation, and that in Fig. 4 we have overestimated the true thickness of the normal magnetozone which lies above and includes the 'KBS'.

Post-depositional normal polarity may be present in other areas, so the magnetic stratigraphy should be interpreted cautiously, especially where short normal magnetozones are present. We have attempted to determine which magnetozones correspond to real changes in geomagnetic polarity by repetitive sampling of palaeomagnetic columns throughout the Koobi Fora Formation.

There is an element of ambiguity in palaeomagnetic dating because it involves recognition of a pattern composed of only two elements; the identify of a particular time interval is determined from the relative thicknesses of adjacent polarity zones. Where deposition has been steady and where the magnetic recording process has been of good fidelity, palaeomagnetic ages can be assigned with the known reversal time scale. Hiatuses and changes in the deposition rate, however, which are common in the fluvial and lacustrine facies of the Koobi Fora Formation, have distorted the polarity sequence. Additional age controls provided by the fossil record and by K–Ar dating are needed to provide an approximate match with the known reversal time scale. The palaeomagnetism can then be used to define the ages of some of the key strata.

Interpretation of magnetic stratigraphy

We have constructed a generalised stratigraphic column which shows the relative positions of the tuffs and the observed magnetozones of the Koobi Fora Formation (Fig. 5). With control provided by the framework of radiometric ages of the tuffs, the magnetozones are correlated with the geomagnetic polarity timescale[20–22]. As the age of the KBS Tuff remains under discussion we propose two possible interpretations of the Koobi Fora magnetic stratigraphy. Interpretation 1, proposed originally by Brock and Isaac[1], is based on a KBS age of 2.6 Myr obtained by the ^{40}Ar/^{39}Ar step-heating method. Interpretation 2 is an alternative which is in accord with the KBS complex age of 1.60–1.82 Myr obtained by Curtis and others[8] who used the conventional K–Ar technique.

In both interpretations the age of the upper member, which lies above the KBS Tuff, is between 1.2 and 1.8 Myr; however, the age of the top boundary of the lower member differs by 1 Myr. If interpretation 1 is accepted, the first reversed magnetozone below the KBS Tuff correlates best with the combined Mammoth and Kaena events, 2.8–3.1 Myr. Accordingly, the reversed interval below the Tulu Bor Tuff correlates with the end of the Gilbert epoch, 3.3–3.7 Myr. Because a substantial interval of reversed polarity is missing between the KBS Tuff horizon and the 1.61 Myr polarity boundary, this interpretation requires that sediments of early Matuyama age, 1.8–2.4 Myr, are not present in the Koobi Fora area. It has been proposed by Brock and Isaac that this time gap is due to uplift and subsequent erosion. Indeed, a disconformity was mapped in area 105, area 103, and Ileret just above the 'KBS Tuff'[5]. Whether the corresponding hiatus is as long as the required 600,000 years is uncertain, however, and this uncertainty remains a major weakness of the chronology.

Interpretation 2, which is consistent with an age of 1.6–1.8 Myr for the KBS Tuff complex, assigns an age of 1.8–2.4 Myr to the first reversed magnetozone below the KBS Tuff. Reversed horizons below the Tulu Bor Tuff are in accord with the combined Mammoth and Kaena events

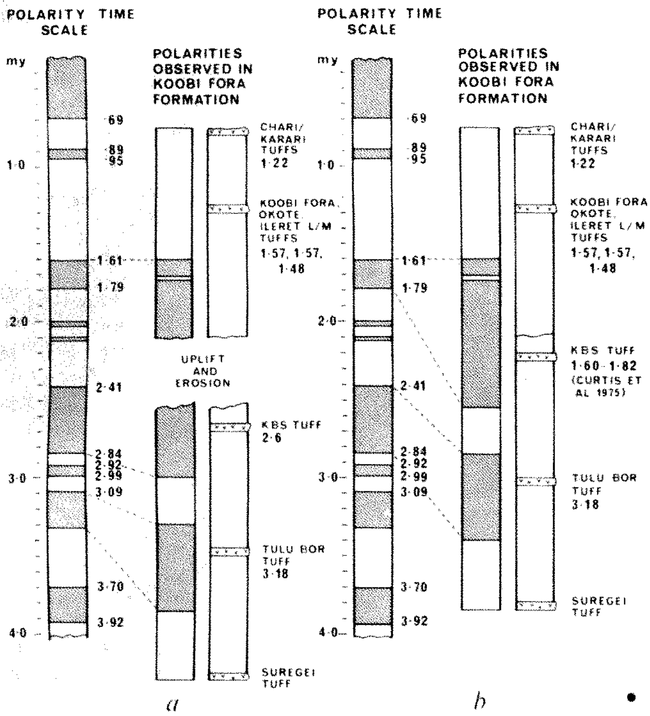

Fig. 5 Two possible correlations of the magnetozones observed in the Koobi Fora Formation with the geomagnetic polarity time scale. *a*, Interpretation 1 is based on ^{40}Ar/^{39} dating of the KBS Tuff (2.6 Myr) by Fitch and others[7]. *b*, Interpretation 2 is based on conventional K–Ar dating of the KBS Tuff, which gave two ages, 1.60 Myr in area 105 and 1.82 Myr in area 131[8]. All other ages were determined by the ^{40}Ar/^{39} Ar method.

(2.8–3.1 Myr). In contrast with the original chronology, interpretation 2 reduces the age of the reversed magnetozone between the Tulu Bor and KBS Tuff by 0.7–1.0 Myr and increases its duration from 0.3 to 0.6 Myr. Interpretation 2 also suggests that the Tulu Bor Tuff is younger than 2.8 Myr, contradicting the tuff's radiometric age of 3.18±0.09 Myr, and this must be accepted as a major weakness of the interpretation.

Fossil mammal assemblages offer another means of calibrating the polarity sequence at Koobi Fora against other well-dated localities in East Africa. Palaeontologic, palaeomagnetic, and radiometric ages have been obtained from the Pliocene and Pleistocene Shungura Formation, located along the Omo River in southern Ethiopia[23]. The occurrence of the fossil pig *Mesochoerus limnetes* in both the Koobi Fora and Shungura Formations helps in the correlation of the magnetozones between the two areas. Cooke and Maglio[24] reported that *Mesochoerus limnetes* from below the KBS Tuff at East Turkana correlates best with Shungura Member F which has a K–Ar age of approximately 2.0 Myr (ref. 23). The biostratigraphic range of a single species can vary between regions depending on palaeoecological conditions, so the above correlation must be weighed against other lines of evidence. Recent collecting in these areas has provided a larger sample of the fossil fauna which is now being analysed (J. M. Harris, personal communication). Note that neither geophysical methods nor biostratigraphy yet provide an unequivocal chronology for the Koobi Fora Formation.

We thank R. E. F. Leakey, Ian Findlater, Kay Behrensmayer, Bruce Bowen and Robert Raynolds for assistance. This study was supported by grants from the NSF.

Note added in proof: Continuing studies show partial error in tuff correlations (Fig. 4): (1) Identities of tuffs are unknown in the lower portion of area 102 column, so we can no longer assume that this section was overprinted with normal polarity. (2) A stratigraphic gap could exist between the bottom of column 105 and the top of column 129 because area 105 basal tuff cannot be firmly correlated with the type Tulu Bor Tuff of area 129. 'Area 129' column is a composite: the upper portion was from area 129, the lower, from the adjoining area 15.

Aggregation, migration and population mechanics

L. R. Taylor

R. A. J. Taylor
Imperial College Field Station, Silwood Park, Ascot, Berkshire, UK

A concept is developed for the regulation of populations by density-dependent movement, rather than by overt competition alone. Fitness is seen as maximising the reproductive advantage of a balance between migratory and congregatory behaviours. Population density is shown to be spatially, as well as temporally dynamic and a mechanism is proposed that accounts for observed spatial behaviour.

THE Malthusian concept of population is contained in the basic proposition that, with full census information, population change can be assigned to either reproduction or mortality[1]. This proposition is consequently the basis of Darwinian fitness measured in terms of reproduction and survival[2], and of population models for competition[3,4] and predation[5,6] that are primarily concerned with equilibrium conditions[7,8]. Populations are seen as persisting through time owing to the check on multiplication imposed by such familiar Malthusian[9] restraints as disease, predation and resource limitation. Key factors[10,11] direct our attention to the causes and time of death, but not to the place of death nor to its distance and direction from the place of birth. Lacking this component of movement in real space, it seems to us that populations are static[12], not dynamic. They can neither function nor evolve unless they include the controlled mobility that enables organisms to select a place to live and so survive and reproduce. This mobility we shall equate largely, but not entirely, with internal or external migration using the word in a wider sense than that familiar in ornithology.

Migration and static population concepts

Until recently migration has often been regarded as an idiosyncrasy to be included with unaccountable mortality in life tables based on census information from a restricted area. Yet migration is not synonymous with mortality. Re-examination of old census records now reveals more extensive, successful, internal migration in man than was formerly appreciated[13,14]. Among insects, many species formerly regarded as sedentary have been found to be vagile[15]. For example, *Drosophila* seem non-migratory as compared with the monarch butterfly[16], and their flight behaviour is well adapted to minimising dissemination[17,18]. Even so, their migratoriness is now known to be considerably underestimated in the Dobzhansky–Wright models that so influenced concepts of population mobility in genetics[19,20]. New evidence from bird ringing shows long distance movements in territorial species formerly considered extremely sedentary, the European blackbird, for example[21], and, since young birds rarely occupy their parents' nests, they must migrate to establish a new territory. Dispersal in small mammals has been related to population cycles[22] and the zoo syndrome has been called "frustrated dispersal"[23] in species not commonly thought of as migratory.

Segregation of migration from dispersal obscures their common population function. In birds, fish and especially in insects, whose complex life-histories enable the various aspects of migration to be analysed in most detail[24,25], much is now known about ontogenetic[25], physiological[26] and behavioural[27] processes that initiate movement and about its evolutionary origins[28] and ecological function[29], as well as about the more striking, but in this context less relevant, orientation[30,31] and navigation[32] behaviour. Gene migration models[33-35], like population models[36], have not yet made due allowance for the sophisticated migration control mechanisms in which the experience of parents and grand-parents[37], as well as population density[38], affect the migrant status of the individual. These are most clearly evident in the labile[39] migratory polymorphisms, remote from genetic heterogeneity, in clonal populations of aphids[40]. As a result, little light has been shed on the role of migration in the dynamics, and hence in the fundamental concept, of population.

Concepts of population are not consistent[11]. A lack of rigour in distinguishing total population from population density can imply uniform distribution of density in space, whereas the actual spatial distribution of few organisms is known[42]. Again, key factors differ for the same species in different places and affect different stages in the life history. This makes models for the whole species population incomprehensible. If, however, a model is considered to represent a separate element of the population, equivalent to the mean density at a certain place, then growth rate can be equated with unity, as required by basic theory[9,43], only if there is no population flow between such places.

But we doubt that populations are often like that. All populations are spatially fluid in some measure because movement is a fundamental biological response to adversity. Nor is population density distributed uniformly in space. A valid concept of population must encompass both the more settled species, like the red grouse say[44], to which the current models appear to be most suited, and the highly volatile species, like aphids, for which local stability in time seems almost irrelevant because of the persistent change of place.

A spatial concept for population and some evidence

The classical model for the whole population of a species changing only through time was the phylogenetic tree. If we treat the anatomy of a real population as being in three dimensions, latitude × longitude through time, we visualise its internal structure to be reticulate, not unlike the fern stele in Fig. 1 in which density changes constantly through time and space. So, spatial sections through this anatomical model at successive time intervals differ slightly, or markedly, depending upon the time scale. (This has much in common with MacArthur's[45] r–K continuum, and with Southwood's[46] τ/H ratio.)

After monitoring the changing distribution of density of hundreds of species of Lepidoptera throughout Great Britain for almost a decade[47], we can show that growth cycles in different local population elements are normally asynchronous, as in Ford's marsh fritillaries[48], combining with movement to change the pattern of density in space like serial sections through the fern stele model, even when overall abundance remains relatively constant (Fig. 2). The moths we have sampled range from known migrants to species considered localised, but density distribution is always changing. The time-scale is, of course, short compared with vertebrates. Our conceptual model predicts that once a density element has been defined in space, its life-span is limited. Our field samples confirm this,

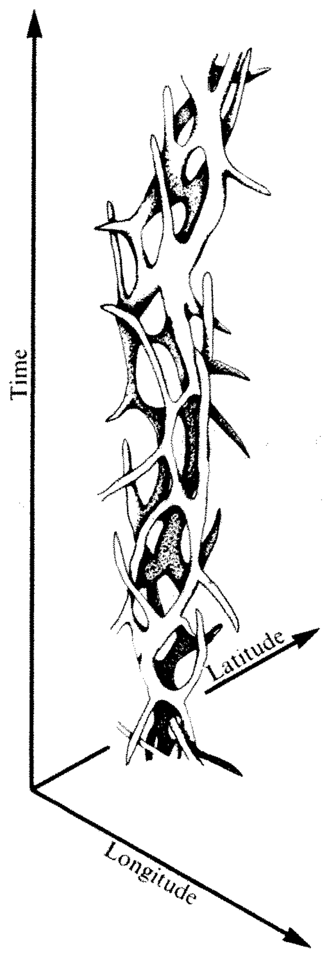

Fig. 1 Conceptual model for population anatomy based on Rostowzew's[75] drawing of the stelar structure of the adder's tongue fern. The stele represents the space-time reticulum created by the distribution of an arbitrary density level through time.

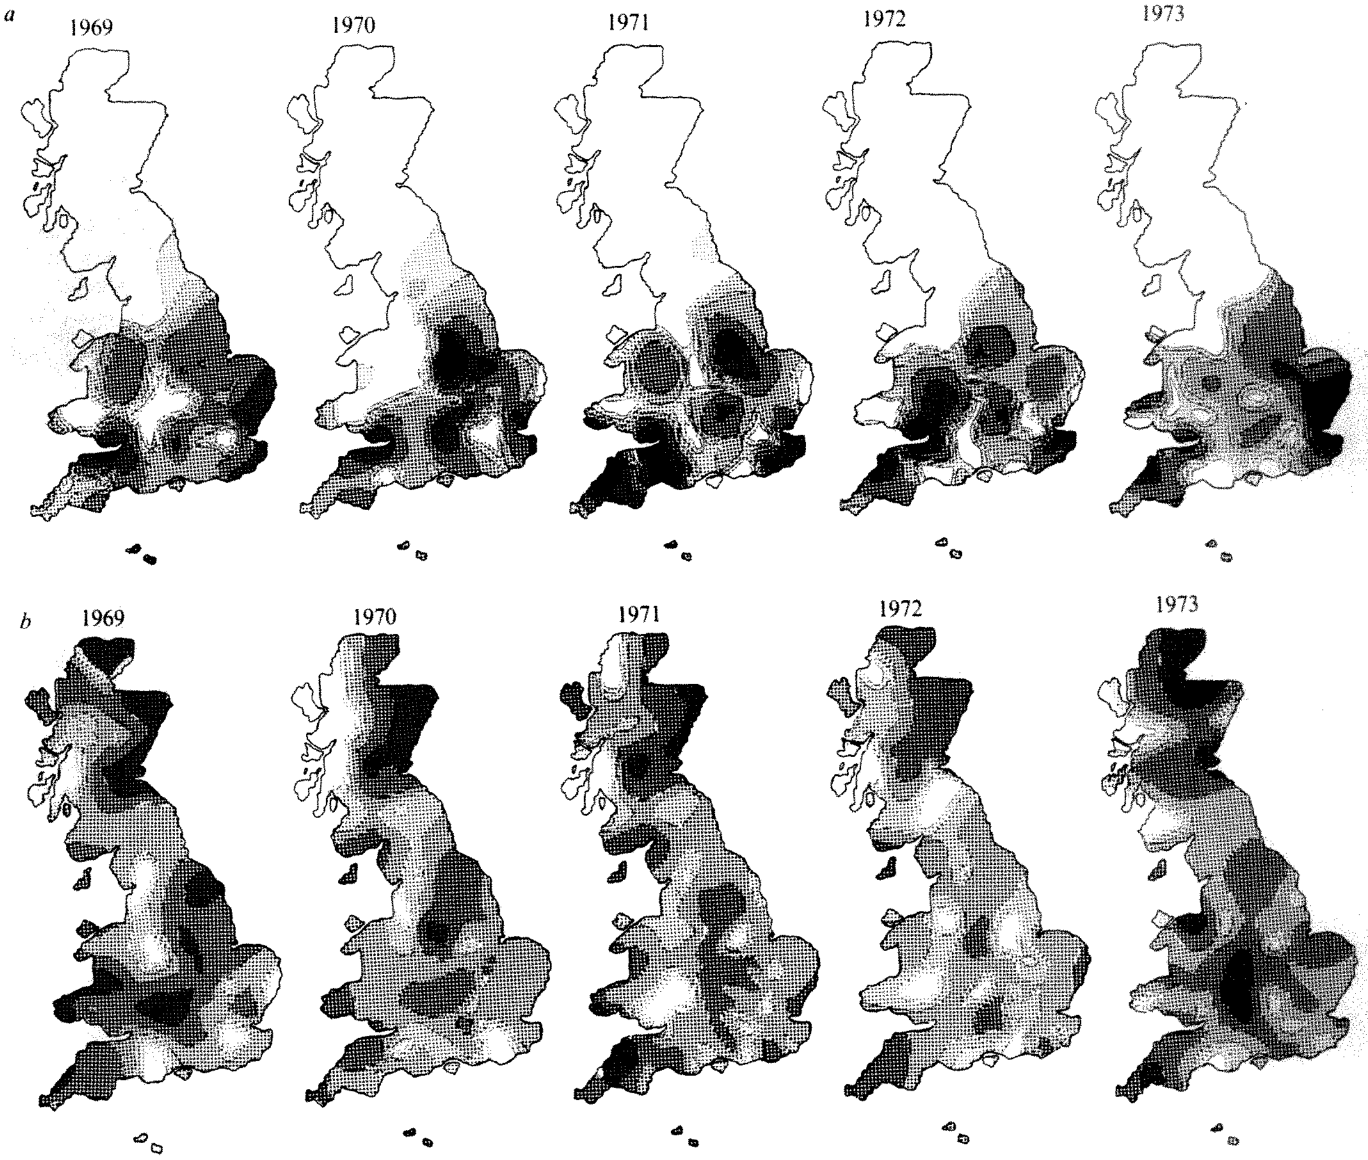

Fig. 2 Measured annual (1969–73) adult population density distribution of two moth species showing the changing patterns typical of the 623 species sampled by the Rothamsted Insect Survey[17]. Each map is based on 62–88 sample points; there were inadequately distributed in Scotland, hence the poor definition there in (*b*). Density layers 0, 1–2, 3–9, 10–31, 32–99, 100–315, 316–999, individuals per sample unit. *a*, *Agrochola lychnidis* (Denis and Schiff.) a marginal species near its northern limit. *b*, *Xanthorhoe fluctuata* (L.) has a very stable total population. The maps are visualised as serial sections through the conceptual model in Fig. 1. In both instances the appearance and disappearance of 'holes' in the population is clearly visible so that all parts of the population are essentially 'marginal'.

and hence that the use of spatial averages, in fitness say[35], makes questionable assumptions about the nature of spatial distribution, for density can diminish locally to create what are usually regarded as marginal conditions[49,50] even in the heart of a population (Fig. 2).

The individual's dilemma and the population consequence

In an environment changing through time and space, the most probable strategy for a new individual to adopt to survive and reproduce is not necessarily to stay to compete with its parents or congeners[51] but may be to go elsewhere, to find an empty environmental hole to inhabit. Its ability to do this depends on its malleable migrant status. In a doomed habitat, one offspring capable of migrating at the right time may well have more survival value than a litter of more sedentary morphs[40]. Thus the migrant status of offspring is an essential component of fitness controlling the production of grandchildren, which we take to be the relevant criterion. This point was originally made by Grinnel[52] but he assumed population centres to remain static and, like Gadgil[53] and others[35], regarded migration as compulsive for a genetically fixed proportion of the population. MacArthur[54] argued, legitimately, that such migration would be from an equilibrium population to a less hospitable place and involve a loss of fitness. Much environmental hostility which results in death or dispersal is transient, however, especially that due to biological restraints such as predation and disease or the loss of nesting sites or food supply. This creates vacant holes in the environment which subsequently recover their hospitality and are re-occupied by searching migrants so that population centres are mobile when seen at the appropriate time scale. These more fluid populations make MacArthur's argument unconvincing and, from the individual viewpoint, offer alternative courses of action. It was to an apparently social option that Hamilton[55] addressed his attention which he so graphically illustrated by his selfish frogs. The environmental menace was a predator and the choice considered was where to go within the herd so as "not to be nearest the snake". There is an additional option which Hamilton precluded, to abandon the herd and find a pond

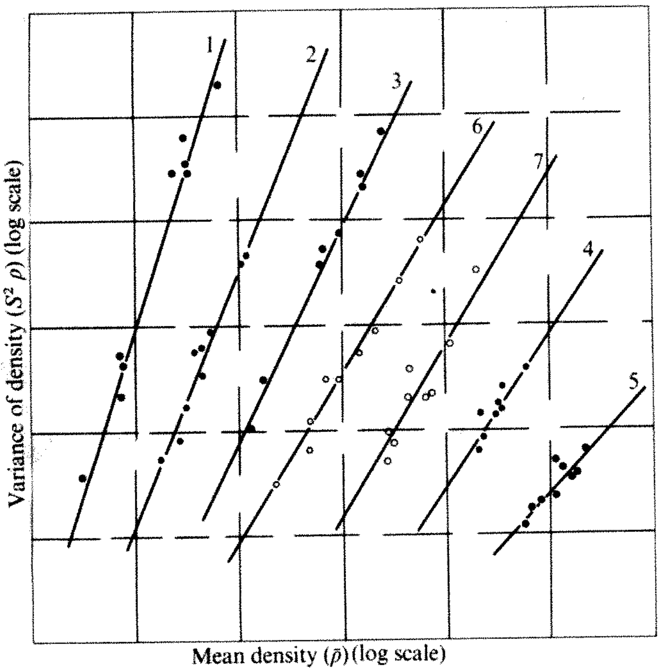

Fig. 3 The relation between variance of spatial disposition and annual mean density for five moth species from the same source as in Fig. 2, and two simulated quasi-stable populations. Each point is one years sample, equivalent to a map in Fig. 2. The fitted regression is $\log S_\rho r^2 = a + b \log \bar{\rho}$. The range of aggregatory response to overall population level differs widely between species but is highly consistent within species. 1, *Lycophotia varia* (Villers) ($a = 0.02$; $b = 3.02$). 2, *Xanthorhoe ferrugata* (Clerck) ($a = -0.29$; $b = 2.41$). 3, *Malacosoma neustrie* (L.) ($a = 0.94$; $b = 1.98$). 4, *Xestia xanthographa* (Denis & Schiff) ($a = 1.16$; $b = 1.48$). 5, *Epirrhoe alternata* (Müller) ($a = 1.56$; $b = 1.04$). 6, From Fig. 5*a*; heterogeneous environment ($a = 1.38$; $b = 1.65$). 7, From Fig. 5*b*; homogeneous environment ($a = 1.35$; $b = 1.66$). Axes are staggered to save space. Grid is at ×10 intervals. Symbols are (●) real samples, (○) from simulation.

without a snake. This individual choice creates recognisable spatial properties at population level which we suggest lead to population homeostasis without group selection[56,57].

A dynamic mechanism and a postulate

We would argue that all spatial dispositions can legitimately be regarded as resulting from the balance between two fundamental antithetical sets of behaviour always present between individuals. These are, repulsion behaviour, which results from the selection pressure for individuals to maximise their resources and hence to separate, and attraction behaviour, which results from the selection pressure to make the maximum use of available resources and hence to congregate wherever these resources are currently most abundant. The balance between these two conflicting behavioural tendencies operating on each individual determines its movements and hence the resulting spatial pattern of the population at any instant in time. It is the response of this balance to changing internal and external environmental conditions that, we suggest, constitutes the dynamic element in populations.

From this basis we have sought to bridge the gap between models and real data with a functional mechanism for the distributive processes in a population that would lead to the diffusion rates and spatial dispositions observed in nature.

The only hard spatial evidence we know of, that relates equally to populations of all kinds of organisms, is the statistical measure of fine-scale spatial disposition of individuals[58]. Randomness is by definition atypical of the microdistribution of living organisms and one of us has previously shown empirically[59] that the spatial variance ($S_\rho{}^2$) characteristic of species, at a particular point in the environment, is proportional to a fractional power of mean population density ($\bar{\rho}$) at that place;

$$S_\rho{}^2 = a\bar{\rho}^b, \qquad (1)$$

where b is a measure of the density dependence of aggregation. Our field monitoring now yields convincing evidence that macrodistribution, at least in Insecta, still has the same property of density-dependent aggregation when mean density relates to an area the size of Great Britain instead of a few square metres (Fig. 3). From this it is clear that, to return to the ferne stele model, successive stelar sections characterise the species spatial behaviour on a geographical as well as on a local scale.

The other relevant experimental evidence relates to rates of diffusion, or migration, of individuals from population concentrations, but for this there has yet been no generally accepted functional relation[60,61]. Biological diffusion is no more random than spatial disposition, for it is the outcome of equally

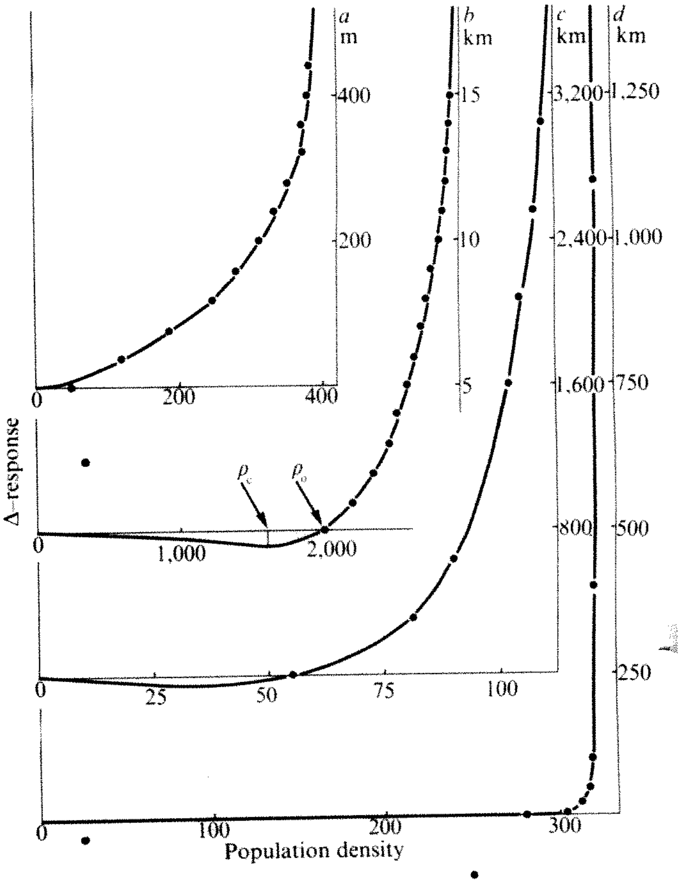

Fig. 4 Δ-functions reflecting different life styles with superimposed density × distribution data from *a*, sedentary insect, *Drosophila pseudoobscura*; fluorescent dust recoveries at attractant traps in California[20]. *b*, Social primate, man; census data from Sweden[13]. *c*, Migrant insect, monarch butterfly; wing-label recoveries in North America[16]. *d*, Territorial bird, blackbird; leg-ring recoveries in Great Britain[21].

Parameters

	ε	ρ_0	p	q
a	0.03	6	0.97	0.72
b	5.2	2000	7.3	6.7
c	11.0	54	7.2	1.1
d	7.3×10^{-22}	225	151	2.1

ρ_0 is the population density at which migratory and congregatory behaviour balance and no net movement ensues. At $\rho > \rho_0$ the population is over-dense and migratory behaviour predominates; at $\rho_c < \rho < \rho_0$ density is below par, congregatory behaviour predominates and leads to rapid recovery; at ρ_c, minimum Δ, congregatory behaviour is maximised; at $\rho < \rho_c$ spatial recovery is greatly impeded, T_R is prolonged and relies on high reproductive rate. Density units are arbitrary as in the original data. Densities below ρ_0 are difficult to measure and short-lived, hence the data points are inadequately represented.

sophisticated behaviour, and the problem has been to find a distance function common to such diverse organisms as, for example, the migrant monarch[16] and the sedentary *Drosphila*[20], the territorial blackbird[21] and social man[13].

The working model does not deal with the underlying complexities of social behaviour[62] and bizarre adornment associated with sex[63], which can be regarded largely as visible evidence of the congregatory behaviour, nor with the equally complex behaviour and locomotory mechanisms associated with migration[25], for they are too difficult to measure. It deals with the net displacement resulting from these. When the motion is centrifugal to the nearest population concentration it is here classified as 'migratory' to distinguish it from the random motion implied by 'dispersive'. Alternatively, when the motion is centripetal fulfilling the function of "gravitational attraction" in Skellam's[64] population concept, but missing from Lidicker's[65], it is here called 'congregatory' to distinguish its active motion from the resulting instantaneous static condition or aggregation. Migratory motion, like congregation, is overlaid by elaborate behaviour patterns and can be almost obscured by movements concerned with reproduction, fighting and feeding, especially daily and seasonal commuting in man and certain highly mobile and long-lived birds whose feeding and reproductive sites are far apart[60-66]. Nor does it necessarily imply displacement right outside occupied territory, for much migration is internal. The displacement crucial to fitness is that between the birthplace of one generation and that of the next and it is the distribution of sexually mature adults as in Fig. 2 that is, therefore, relevant.

We postulate that the net centrifugal displacement of an individual (Δ_m) generated by migratory behaviour as defined above, is proportional to a fractional power of the population density (ρ) it experiences; $\Delta_m = G\rho^p$. So also is net centripetal displacement (Δ_c) due to congregatory (i.e. anti-migratory) behaviour; $\Delta_c = H\rho^q$. The exponents p and q are rate constants for density-dependent migration and congregation respectively which may be specific. G and H are constants of proportion for which we offer no biological interpretation.

If we adopt the sign convention that any tendency to increase the mean distance between individuals is positive while reduction in mean separation is negative, the intuitive sum of the two conflicting density-dependent behaviour sets is

$$\Delta = G\rho^p - H\rho^q \tag{2}$$

Equation (2) may be written in the parametric form

$$\Delta = \varepsilon\left[\left(\frac{\rho}{\rho_0}\right)^p - \left(\frac{\rho}{\rho_0}\right)^q\right] \tag{3}$$

where G and H are replaced by the biologically identifiable parameter ρ_0, the density at which migration exactly balances congregation[67], and

$$\varepsilon = (H^p G^{-q})^{1/(p-q)} \tag{4}$$

which is a scale factor containing the dimensional units. Congregation (negative displacement) now occurs when $\rho < \rho_0$, and migration when $\rho > \rho_0$ (see Fig. 4). The condition $p < q$ cannot evolve because growing populations would continue to congregate indefinitely and condense into a point in space.

Simulation and interpretation

For simplicity in the primitive simulations presented here (Fig. 5), reproduction is by binary fission at random in space among those individuals reproductively mature, and at regular intervals in time. In an environment consisting of a permanent two-dimensional random mosaic of areas that are lethal, or tolerable but prevent reproductive maturation, or hospitable, the individuals of a founder population divide and each daughter organism responds, by movement, to the population density at the time of birth. This Δ-response is to the density at a fixed population centre and is assumed to be radial. Mortality occurs only when movement ends in a hostile part of the environment. In practice the Δ-response may be to the individual's or to its parent's experience, to the distance from the nearest neighbour, or to number of social contacts, level of aggression or competition, or to other epideictic[56] or environmental cues relating to population density, and may not be radial. In a few generations population nuclei on hospitable areas reach a quasi-stable condition when migration balances natality (Fig. 5*a*). Satellite populations, repeating the process by responding to their own population centres, would ultimately occupy all the habitable areas.

Successive simulations with the environmental mosaic changing between generations (not shown here) generate additional movement and mortality. The resulting redistribution

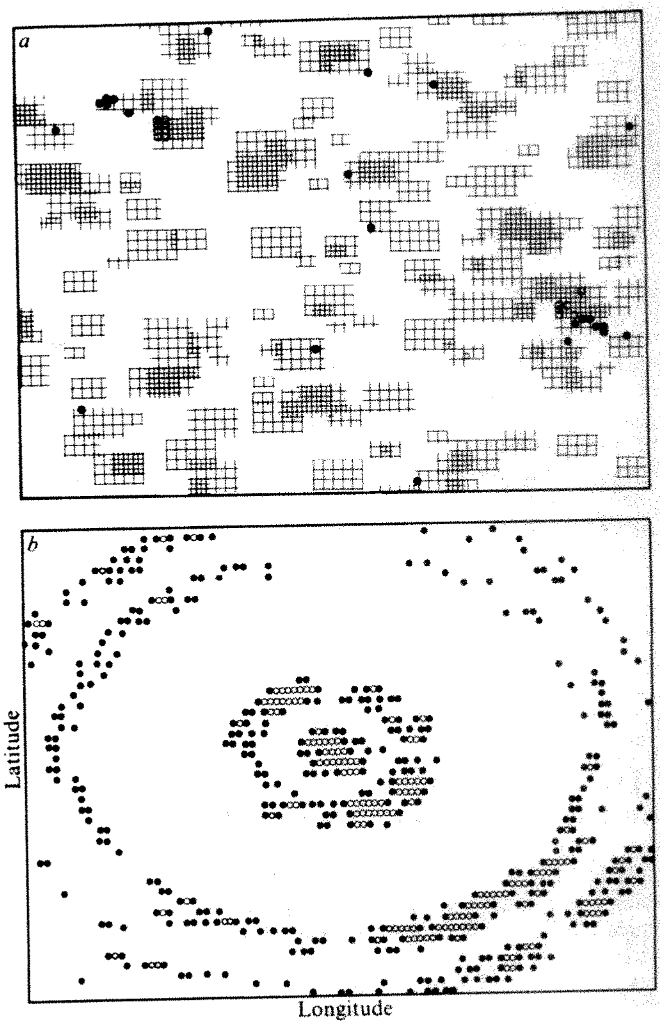

Fig. 5 *a*. Simulated population complex of a highly migrant species, something like an aphid, founded by three individuals and quasi-stable after five generations: Δ-response parameters, $\varepsilon = 0.333$; $\rho_0 = 40$; $p = 4$; $q = 2$, in an unchanging heterogeneous, mainly hostile, environment. Blank background is hostile, faint hatching tolerant but unproductive, denser hatching permits reproduction. At this stage two nuclei are reproducing and excess offspring migrate. Individuals on non-reproductive sites await an environmental change that will either release reproduction or kill them; their prospects depend on Southwood's[46] τ/H ratio, currently being held in suspense by the models fixed environment. *b*, When the environment is homogeneous and the universe unlimited, density annuli radiate outwards from a point source in successive synchronised generations; parameters similar to (*a*). In this form the model describes the annular pattern of movement familiar, on a short time scale, as the radar ring angels[76] produced by the commuting flight of starlings in response to a daily cycle in the changing balance between feeding and flocking behaviours. The figures are distorted to conserve space. Hollow circles are occupied by more than one individual.

of population centres becomes a game of hide-and-seek, emulating the response of local population elements to predation, disease and other restraints, akin to Huffaker's survival by refuge[68]. The net area population density now depends on the balance between rates of environmental change, and the movement and reproductive rates of the organism, which fails to use some resources because they are not disovered in time. Hence the population is stabilised below carrying capacity. Environmental change releases the reproductive potential of surplus individuals that wait in survival areas to mature if conditions improve, or to die if they worsen. The balance is set by the parameters in the Δ-function with respect to the environment into which further non-random elements are introduced because the Malthusian restraints are themselves biological and hence non-random[36,69]. This now generates further local contraction[70] and small-scale geographical shifts of density like those clearly visible in successive years in Fig. 2.

The simplifying conditions adopted for simulation appear not to be restrictive. Age-dependent or facultative Δ-behaviour and sexual reproduction add complexity in the computing but without fundamental change in the outcome, so far as we can tell, for the resulting distance function appears to apply quite well to sexual animals with high levels of organisation (Fig. 4). Behaviour inherited or imprinted from the parents' or grandparents' experience or modified by experience throughout life, further complicates the computing but seems not to affect the outcome. Refinements of social and migratory behaviour, together with increase in size, minimise migratory risks by providing more accurate sensory information on which to make the choice. Again parental care and altruism add sophistication but seemingly make no fundamental change in the logic. Non-radial migration, by controlled orientation or navigation, or even environmentally assisted motion, affects individual migratory risks and hence proportionate mortality. It affects the ultimate spatial disposition only in large-scale geographical trends, because final settling place depends on the successful location of environmental holes, not just on navigation[71]. Death due solely to aging is a minor factor and all other causes are included in environmental adversity.

If each new recruit responds independently to density, a continuous generation model is formulated; synchronous response generates a discrete system as in the examples shown here.

The ecological results and the evolutionary consequences

Analysis of the spatial dispositions generated by simulation yields the power relation between variance and mean population density in equation (1) that is required by the field evidence (see Fig. 3). While the power relation could arise from mathematical models based on other functional mechanisms, this result suggests that our conceptual model for a balance between specific distributive behaviours is reasonable.

The Δ-function for individuals results in a density distributing process which generates a hollow frequency distribution of numbers against displacement in a population which matches the experimental evidence on dispersal for organisms as disparate in behaviour as *Drosophila* and man (see Fig. 4). Again, other functional mechanisms could generate appropriate distributions but no previous model has comprehended spatial behaviour over so wide a range of distances or organisms. We suggest that, if migration and congregation are seen in the collective sense used here, the dispersive behaviour of other animals and plants[72,73] will be found to fit the pattern. The non-migratory condition when $\rho < \rho_o$ is perhaps most readily recognised in island life where ρ_o is high due, for example in insects, to flight-inhibiting behaviour and even morphological adaptation such as brachyptery.

The only biological premises involved are that an organism can move at some stage in its life history before reproduction and can detect directly or indirectly, by any means, including those listed by Wynne-Edwards[56] and Wilson[62], the presence of another of its own kind and hence can respond to it. Reproductive success then often lies in the avoidance of overt competition by movement and goes to the individual with the best Δ-adaptation, rather than to the more superficially successful competitor, and so provides an essential[70,74] counterbalance to excessive competitiveness.

As with other population models, migration and mortality can in some respects be equated. The emphasis is here shifted from the key factors that cause death to the place where they operate, because this reflects the real space hostility pattern of the total environment, including other organisms, and to the subsequent replacement of individuals by movement as well as by birth. Thus the return time for populations displaced from equilibrium, T_R (ref. 8), can be short-circuited by migration. A demon with perfectly developed Δ-response and ability to locate environmental holes could survive almost any catastrophe. If survival is thus seen as a spatial exercise in eluding adversity, evolution depends on learning the geometry, not just of Hamilton's selfish herd[55], but of the changing Darwinian landscape of which the herd is a part.

Epidermal growth factor and the multiplication of cultured human epidermal keratinocytes

James G. Rheinwald & Howard Green

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The culture lifetime of epidermal cells of newborn humans is increased from 50 to 150 generations by adding to the medium epidermal growth factor, a polypeptide mitogen. EGF seems to delay senescence of the cells by maintaining them in a state further removed from terminal differentiation. This effect is revealed by a greater ability of the cells to survive subculture and initiate new colonies, but not necessarily by an increased growth rate.

MAMMALIAN epidermis is composed principally of a single cell type, the keratinocyte, in various stages of differentiation. The basal layer, separated by a basement membrane from the fibroblasts of the underlying dermis, contains the dividing keratinocytes. These give rise to progeny, some of which no longer divide but move outward from the basal layer, terminally differentiate, and eventually are shed from the surface.

In cell culture conditions, keratinocytes depend on the support of fibroblasts in order to initiate colony formation[1,2]. When human diploid epidermal keratinocytes obtained from foreskin of newborns are inoculated together with lethally irradiated 3T3 cells, the keratinocytes grow from single cells into macroscopic colonies. Colonies can be disaggregated to single cells with trypsin and EDTA and the cells subcultured with fresh irradiated 3T3 cells. A fraction of the keratinocytes undergoes terminal differentiation even in growing colonies; these cells leave the basal layer, increase in size, and develop an envelope resistant to detergents and reducing agents[3]. At least partly because of this terminal differentiation, colony-forming efficiency on transfer is lower than that of fibroblasts. Keratinocytes derived from foreskin of newborn humans were cultivated serially through a total of about 50 cell generations but those of older donors had a reduced culture lifetime (ref. 2 and unpublished observations). This behaviour resembles that of cultivated human fibroblasts, whose restricted culture lifetime has suggested an analogy to the process of ageing[4].

Epidermal growth factor (EGF), a polypeptide with molecular weight 6045 and a known amino acid sequence[5] was first isolated from the male mouse submaxillary gland by S. Cohen, and found to enhance growth and maturation of epidermis in newborn mice[6,7], and in organ cultures of epithelial tissues[8,9,10,11]. It has more recently been found to be an extremely potent mitogen for fibroblasts[12,13,14], and for some other cell types (refs 15, 16, and R. Holley, personal communication). Most cells bind EGF with a K_m of ~ 1 ng ml^{-1}, a concentration similar to that present in mammalian plasma[17].

We describe here experiments on the effect of mouse EGF on cultivated epidermal keratinocytes derived from foreskin of newborn infants. The culture methods, including the use of irradiated 3T3 cells, have been described earlier[1,2,3]. For the first experiments, the EGF was kindly donated by Dr Cohen; later experiments were carried out using EGF purified by Dr T.-T. Sun according to Savage and Cohen[18]. The effects we describe have a bearing on the general problem of the lifetime of serially cultivated cells, and on possible relations between this phenomenon, ageing and terminal differentiation.

Effect of EGF on colony expansion

Culture dishes (50 mm) were inoculated with 5×10^3 epidermal keratinocytes and one-third the confluent density of lethally irradiated 3T3 cells (x3T3). As EGF was found

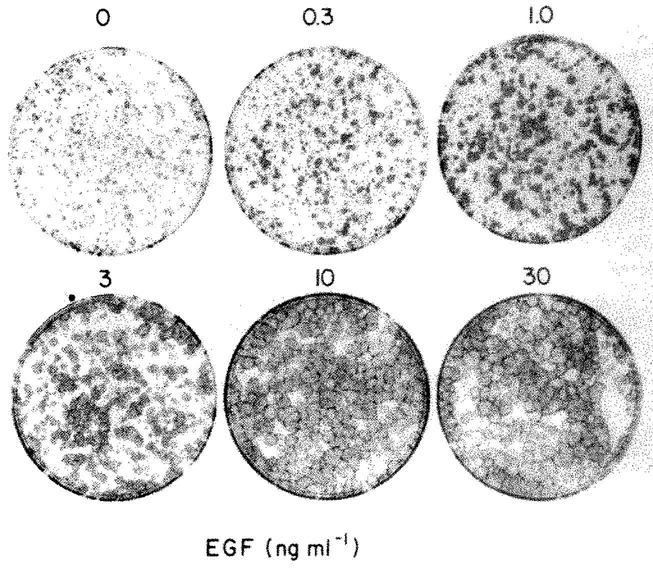

Fig. 1 Effect of EGF on the morphology and size of growing keratinocyte colonies. Dishes (60 mm) were inoculated with 5×10^3 keratinocytes of strain N at their 43rd culture generation and the Dulbecco-Vogt modification of Eagle's medium supplemented with 20% fetal calf serum and hydrocortisone, 0.4 µg ml^{-1}. EGF was added at various concentrations beginning on d 4. Cultures were fixed on d 13 and stained with Rhodanile blue[1]. Colonies grown in the presence of EGF are larger, but also thinner and the intensity of their red staining by Rhodanile blue is reduced. At higher concentrations of EGF, the colonies sometimes acquired a shredded appearance, and growth was retarded.

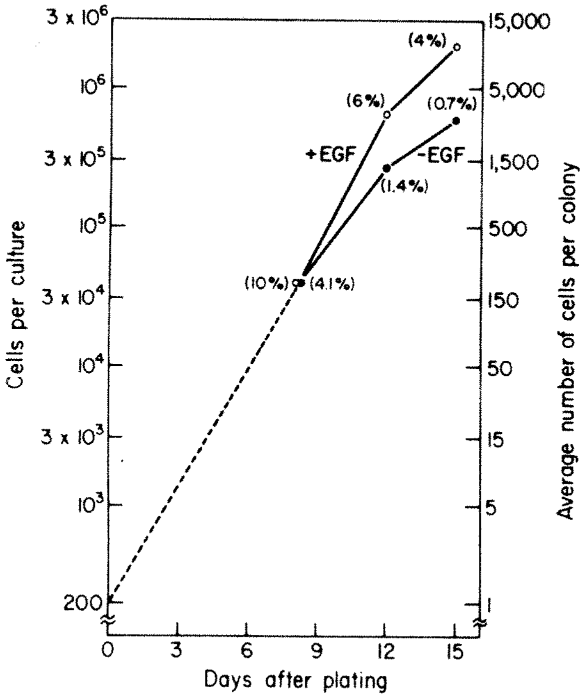

Fig. 2 Effect of EGF on growth rate and colony-forming ability of cultured human epidermal keratinocytes. Strain M. keratinocytes, at their 20th generation in culture, were plated at 1.9 × 10^4 cells (200 colony-forming units) per 60 mm dish, together with lethally irradiated 3T3 cells. Beginning at the first medium change 5 d after plating, EGF was added at 30 ng ml^{-1} to half of the cultures. Cultures were refed every 3–4 d thereafter. On d 8, d 12, and d 15 after plating, the x3T3 cells of a culture were removed with EDTA; the epidermal colonies were then dispersed to single cells with a mixture of trypsin and EDTA and counted in a haemocytometer. Aliquots were replated with x3T3 to determine colony-forming ability. ○, Cultures to which EGF was added beginning on the 5th day after inoculation; ●, no EGF. Values in parentheses give the colony-forming ability of the cells upon subculture. Cells growing in the presence of EGF have a higher colony forming ability and maintain exponential growth for a longer period.

to reduce colony-forming efficiency slightly when added at the time of inoculation, it was routinely added to cultures at the time of the first medium change, 3–5 days later. Figure 1 shows the appearance of colonies fixed and stained on the 13th day after inoculation. Colonies growing in the presence of EGF were larger, less stratified, and stained less intensely red with Rhodanile blue. These effects were evident at EGF concentrations as low as 0.3 ng ml^{-1} and increased in magnitude up to concentrations of 10 or 30 ng ml^{-1}. Part of the increase in colony size is due to enhancement of growth and part to the spreading and flattening of the cells. When EGF is added to cultures of large colonies grown in the absence of EGF, change in colony morphology is often evident as soon as 24 h later.

In contrast to the effects of EGF, fibroblast growth factor (FGF), kindly provided by Dr Denis Gospodarowicz, produced no changes in colony morphology or growth at concentrations of 1–100 ng ml^{-1}, in keeping with its activity as a growth factor only for mesenchymal cells[19].

Effect of EGF on the growth rate and colony-forming efficiency of keratinocytes

Early passage human keratinocytes were plated at low density and grown in the presence or absence of EGF at 30 ng ml^{-1}. Figure 2 shows that while the colonies were still small, they did not grow more rapidly in the presence of EGF, but as the colony size increased, exponential growth was maintained longer and by the end of the experiment (d 15) the number of cells was about four times greater in the presence of EGF. The average doubling time for the cells while in exponential growth was about 24 h, both in the presence and absence of EGF.

Some of the cells harvested for each count were replated with fresh x3T3 cells to determine their ability to start new colonies (Fig. 2, values in parentheses). The colony-forming ability of the cells fell as colonies grew larger and as their average growth rate declined, but was always greater for the cells derived from cultures grown in the presence of EGF. The difference was small at first but became progressively larger as the colonies became larger. At the end of the experiment (d 15) the difference was about sixfold.

The effect of EGF on small colonies was more closely examined by using two other strains of newborn keratinocytes. Cultures were plated with 10^5 cells of strain N or strain K, previously grown through one subculture in the absence of EGF. EGF was added to some cultures 2 d after inoculation and the growth and colony-forming ability of the cells of the two sets of cultures were compared during the following 4 d. EGF had no significant effect on growth rate (Table 1), but increased the colony-forming efficiency of the cells by 50% within 2 d of its addition and by 60% to twofold within 4 d.

These experiments suggest that the effect of EGF on the growth rate of large colonies is due to its ability to oppose inhibitory influences that begin when the cells become crowded. There are several possible ways by which this effect might be brought about, but all would have to alter either the generation time or the relative magnitude of the dividing fraction. (These alternatives are not completely independent, since an increase in the growth rate of the dividing fraction would, if the time required for terminal differentiation were unchanged, lead to an increase in the relative size of the dividing fraction.)

The fact that EGF increases colony-forming ability before the growth rate is detectably increased indicates that, even while the magnitude of the dividing fraction is unaltered, there is a change in the state of the dividing cells

Table 1 Effect of EGF on the cells of small keratinocyte colonies

Strain	Days after Inoculation	Cells per culture (x10^{-5})		Colony forming efficiency on subculture (%)	
		−EGF	+EFG	−EGF	+EGF
N (23 gens.)	2	0.74	—	9.7	—
	4	2.6	2.1	13.3	19.5
	6	11.0	9.8	7.0	11.5
K (25 gens.)	2	0.56	—	5.2	—
	4	3.4	2.7	7.6	11.3
	6	16.0	13.0	3.5	7.2

Cultures were inoculated with 10^5 keratinocytes and x3T3 cells on day zero. Cultures were refed on d 2 and EGF was added to 10 ng ml^{-1} At intervals the 3T3 cells were removed from a culture with EDTA and the keratinocytes were harvested in trypsin and EDTA. After counting the cells, some were reinoculated with x3T3 cells to determine their colony forming ability. Values are means (±15%) obtained from duplicate cultures.

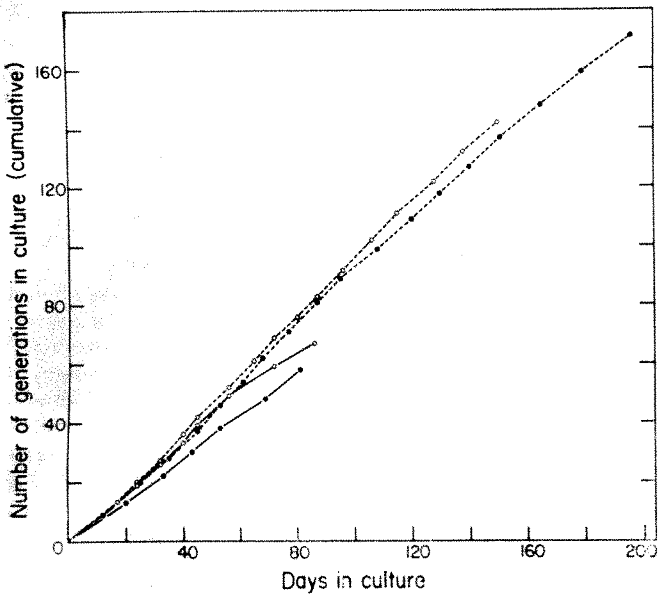

Fig. 3 Effect of EGF on the culture lifetime of human epidermal keratinocytes. The number of cell generations was calculated from the number of colonies formed and the number of cells harvested at each transfer. Each point represents a single transfer. The last point was obtained from the harvest of the last culture in which colonies formed. The average growth rate is given by the slope. – – –, Cultures grown in the presence of EGF; ——, controls grown on the absence of EGF. ●, Strain HFE; ○, strain E.

better enabling them to survive disaggregation and form new colonies. In order to have this effect, it was found that EGF must interact with cells able to proceed through the growth cycle. For example, if keratinocytes were prevented from growing by suspending them in medium stabilised with methyl cellulose, they lost their colony forming ability with a half life of 3–4 h, and later acquired markers characteristic of the terminally differentiated state. This extremely rapid loss of colony forming ability by keratinocytes, so different from the behaviour of fibroblasts, did not seem to be affected by the presence of EGF, or by growing the cells in the presence of EGF immediately before inoculating them into suspension cultures. Clearly then, keratinocytes can respond to EGF only if they are able to grow. Further data on this effect of EGF were obtained from the studies of serially cultivated cells described below.

Effect of EGF on the culture lifetime of keratinocytes

As reported earlier, the culture lifetime of newborn human epidermal keratinocytes in the absence of EGF did not exceed 50 cell generations[2]. As cultures maintained a higher proportion of colony forming cells in the presence of EGF, we examined the effect of EGF on the culture lifetime. In this experiment, contaminating dermal fibroblasts were selectively removed[3] during the first two subcultures, and therefore never overgrew the keratinocytes in later subcultures. The cultures were always transferred while the cells were in exponential growth. For these reasons the values for culture lifetime were more reproducible than those obtained in conditions used earlier[2].

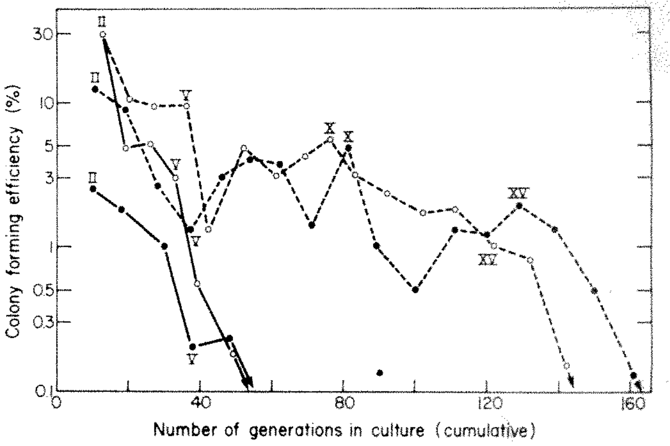
Two independent human keratinocyte strains, HFE and E, were serially transferred by inoculating 2×10^4–2×10^5 cells per 60 mm dish and subculturing 7–11 days later. EGF was added beginning with the first refeeding at 3–5 days after each inoculation. The colony forming efficiency of the cells at each subculture was determined by plating 3×10^3–3×10^4 keratinocytes and counting the number of colonies produced. All inoculations were made together with the standard density of irradiated 3T3 cells. The number of generations in each subculture was derived by relating the number of colonies (assuming each to be initiated by a single cell) to the total number of cells harvested. The number of generations so calculated is an average for the descendants of each colony-forming cell; but because of terminal differentiation in growing colonies, the dividing fraction undergoes more than the average number of doublings.

The maximum culture lifetime, as found earlier, of the two keratinocyte strains derived from newborns, and grown in the absence of EGF, was 6–7 transfers and about 50 cell generations. Addition of EGF to the medium increased the culture lifetime to 17–18 transfers and over 140 cell generations (Fig. 3) but did not significantly affect growth rate (the slope of the lines). Also, the growth rate declined very little on serial cultivation in the presence or absence of EGF until two transfers from the end of the life of the cultures. Thus the effect on culture lifetime does not depend on a change in growth rate.

When colony formation was examined at each transfer, however, large differences were apparent (Fig. 4). In the absence of EGF, the colony forming efficiency during the early transfers was in the range of 2–10%. At each transfer colony formation declined, and when it dropped below 0.1% (by about 50 generations), it was not possible to obtain growth at the next transfer. Colony formation by cells grown in the presence of EGF was higher from the very beginning, and although it declined with serial transfer, the rate of decline was much less than in the absence of EGF. The efficiency was still about 1% after 16 transfers, when both strains had reached 130 cell generations and were close to the end of their culture lifetime. An orcein stained chromosome preparation of strain HFE at 140 generations revealed a diploid chromosome number and no obvious abnormalities.

The number of keratinocytes which can be generated in culture through serial transfer depends not only on the number of cell generations the population can be grown but also on the plating efficiency at each transfer. In the absence of EGF, the possible expansion in culture of the keratinocyte population of newborns does not exceed a factor of 10^6. Since EGF increases both lifetime and plating efficiency, the corresponding value exceeds 10^{16}. Clearly, if large numbers of culture grown keratinocytes have any practical use such as for grafting, EGF would be valuable for the cultivation.

Fig. 4 The effect of EGF on colony formation during the culture lifetime of human epidermal keratinocytes. – – – –, Cultures grown in the presence of EGF; ——, cultures grown in the absence of EGF. ●, Strain HFE; ○, strain E. Roman numerals give transfer numbers. Each value for colony forming efficiency was derived by inoculating cells at 2 or 3 dilutions, so as to obtain at least two dishes containing 50–300 colonies.



Significance of the restricted lifetime of cultured mammalian cells

The existence of a reproducible lifetime of cultured human diploid fibroblasts[20] has suggested an analogy to the process of ageing and has led to many studies on the phenomenon, as well as to theories of its basis[4,21]. Although a reproducible lifetime can be obtained for fibroblasts under standard conditions, the lifetime can be increased by improving the culture conditions[22,23,24]. This would not be expected if the lifetime were limited by a fixed rate of mutational errors or errors in DNA replication. The dependence of the culture lifetime of diploid cells on the culture conditions is shown more clearly by keratinocytes, for we have succeeded in tripling the culture lifetime of this cell type by simply including EGF in the medium.

Although the culture lifetime of human keratinocytes in the presence of EGF exceeds considerably that of human fibroblasts under the best conditions, it is still far below what should be expected from the doubling time of the basal cell population *in vivo*[2]. Our method of calculating culture lifetime does not consider that some cells terminally differentiate in growing colonies and are therefore removed from the proliferating pool. Cells remaining in the pool therefore undergo more divisions than are calculated from the total cell yield per colony. Although we cannot correct for this factor, it seems likely that at least a small part of the discrepancy between culture lifetime and *in vivo* lifetime of the keratinocytes may be explained in this way.

It has been suggested[25] that restriction of the culture lifetime of fibroblasts and the depletion of colony forming smooth muscle cells of older animals are due to terminal differentiation, but no suitable marker exists to define a terminally differentiated state in these cell types. Haematopoietic cell populations, whose proliferative behaviour is usually described in terms of stem cell kinetics[26], show a decline in the number of colony forming cells during serial transplantation *in vivo*[27], a process apparently related to the increasing differentiation of the progeny.

For the cultured keratinocyte, we have ample evidence of ultimate terminal differentiation. In addition to loss of ability to form colonies, the process includes a large increase in cell size, the formation of cornified cell envelopes resistant to detergents[3], and the later development of squames whose nuclei and cytoplasmic organelles are destroyed, resulting in a final state resembling cells of the stratum corneum. Details of this differentiation will be described elsewhere; of importance here is that when growth of cultured keratinocytes is arrested, they enter this state of terminal differentiation. This is true at any stage of their culture life.

We have shown that multiplying keratinocytes can exist in different states related to their distance from obligatory terminal differentiation. That these states are revealed by the colony forming ability of the cells but not always by their growth rate is shown by two types of experiments. First, under conditions in which EGF did not increase growth rate, it increased the ability of the cells to form new colonies. Second, there was little or no decline in growth rate on serial transfer and no difference in growth rate between cultures in the presence or absence of EGF until close to the end of their culture lifetime; in contrast, colony forming ability declined to one-tenth or one-twentieth of the initial values before evident changes in growth rate, and EGF reduced this rate of loss almost from the very beginning. Subculture evidently selects against those hitherto dividing cells too close to terminal differentiation to re-enter the division cycle after transfer. We suggest that EGF extends the culture life of keratinocytes by increasing the distance of the multiplying cells from obligatory terminal differentiation.

These investigations were aided by grants from NCI.

Cosmic-ray electrons and galactic radio emission—a conflict?

MANY attempts have been made in the past to deduce information of astrophysical importance from a study of the galactic non-thermal radio continuum in relation to cosmic-ray electrons observed in the neighbourhood of the Earth (refs 1 and 2 and references therein). These investigations were carried out using the cosmic ray electron data obtained from a single experiment or by making use of an average spectrum derived from the world data, although it is known that the flux values observed by different experimenters in any energy band differ by as much as a factor of 4. This in turn has led to conflicting conclusions to be drawn from the analyses of different authors. In this paper, we present a different approach for analysing the observational data based on arguments of internal consistency between each measured electron spectrum and the magnetic field strength and the dimension of the radio-emitting region required to explain the radio observations. Such an analysis makes it possible to highlight the inconsistencies associated with some of the electron measurements and permits certain inferences of cosmic ray and astrophysical interest.

We will refer first to the spectral shape of the cosmic-ray electrons expected from radio observations. It is found from the latest compilation of the radio intensity, $I(\nu)$, by A. S. Webster (personal communication) between 10 and 8,000 MHz in the direction of the anticentre, that the spectrum above 300 MHz can be well represented by a simple power law of the type $I(\upsilon) \propto \upsilon^{-\alpha}$ with $\alpha = 0.79 \pm 0.08$. On the basis of the theory of synchrotron radiation, this implies that the energy spectrum of radio-emitting electrons in interstellar space is also a simple power law of the type $j(E) = AE^{-\gamma}$, where $\gamma = 2.58 \pm 0.16$ in the energy range of roughly 4–20 GeV for a typical magnetic field strength of 4 μG perpendicular to the line of sight; here $j(E)$ expressed in particles M^{-2} sr^{-1} s^{-1} GeV^{-1}) and A is a constant. Similarly, the radio spectrum in the direction of the halo minimum has the same spectral index between 200 MHz and 8,000 MHz. From an examination of the radio spectra from these two directions, it is inferred that the simple power law for the radio-emitting electrons should extend to at least 25 GeV and perhaps, far beyond. It is known from observations on cosmic-ray electrons above 5 GeV that they are not affected by solar modulation and, therefore, we expect that the energy spectrum of electrons observed in the neighbourhood of the Earth should also have a spectral index $\gamma = 2.58 \pm 0.16$ in the energy range between about 5 GeV and at least 25 GeV.

Table 1 summarises the experimental data on cosmic ray electron spectra determined by various experimental groups[3–15]. In this table, we have listed the experiments in ascending order of their departure in standard deviation from the expected spectral index of 2.58 ± 0.16. We have also examined the spectral index in the limited energy range between 5 GeV and 30 GeV, for those experiments which cover a wider energy range, and have found it to be the same within one standard deviation of the value given in the table. It is quite encouraging to notice that most of the experimental values of γ are consistent with the radio data within about 2σ. However, the measurements of Silverberg *et al.*[14] and Meegan and Earl[15] show departures by about 3σ and 4σ respectively and are thus in conflict with the radio data.

Table 1 Observed energy spectrum of cosmic-ray electrons above 5 GeV

Reference	Energy range (GeV)	A	γ	Departure (s.d.)
Marsden *et al.*[3]	5–15	287	2.77 ± 0.42*	0.4
Anand *et al.*[4]	12–750	113	2.69 ± 0.10	0.6
Scheepmaker and Tanaka[5]	5–290	127	2.70 ± 0.10	0.6
Zatsepin[6]	7–500	95	2.70 ± 0.05	0.7
Muller and Meyer[7]	30–900	51	2.75 ± 0.10	0.9
Agrinier *et al.*[8]	8–100	24	2.30 ± 0.20	1.1
Buffington *et al.*[9]	5–63	105	2.80 ± 0.10	1.2
Freier *et al.*[10]	8–100	105	3.00 ± 0.20	1.6
Webber and Rochstroh[11]	3–20	100	3.00 ± 0.20	1.6
Matsuo *et al.*[12]	40–800	377	3.20 ± 0.30	1.8
Hovestadt *et al.*[13]	5–22	204	2.97 ± 0.13*	1.9
Silverberg *et al.*[14]	10–220	430	3.10 ± 0.08	3.2
Meegan and Earl[15]	6–64	800	3.40 ± 0.10	4.3

*In these cases A and γ have been determined by us from the data.

We next examine the implications of the absolute intensity of cosmic ray electrons measured by various groups on the basis of the observed radio flux at 1,400 MHz toward the anticentre, which is found to be about 6.7×10^{-22} W (M^{-2} sr^{-1} Hz^{-1}), after normalising the spectrum given by Webster (personal communication) at 81.5 MHz using Purton's survey[16]. This value of the frequency was chosen in order to avoid sampling of electrons below 5 GeV, for the wide range of magnetic field strength used in the analysis. We then calculated for each electron spectrum given in Table 1 the extent of the radio-emitting volume for different mean field strengths perpendicular to the line of sight needed to account for the radio flux at 1,400 MHz, by assuming that the cosmic ray electrons and the magnetic field are homogeneously distributed throughout the emitting region. We also assumed that, for those measurements in which the minimum energy given in Table 1 is much larger than 5 GeV, the same electron spectra extend down to this energy. In Fig. 1, we have plotted the calculated magnetic field strength as a function of the extent of the radio-emitting region toward the anticentre for all the electron measurements listed in Table 1. We indicate in this figure the approximate position of various spiral arms, the longitudinal component of the magnetic field (line A) in the local arm from Faraday rotation measurements[17], and a reasonable upper limit to the field strength (line B) deduced by us on the basis of the marginal detection of 2.1 ± 2.0 μG for the ambient field in the local arm using the Zeeman splitting of 21-cm hydrogen line[18].

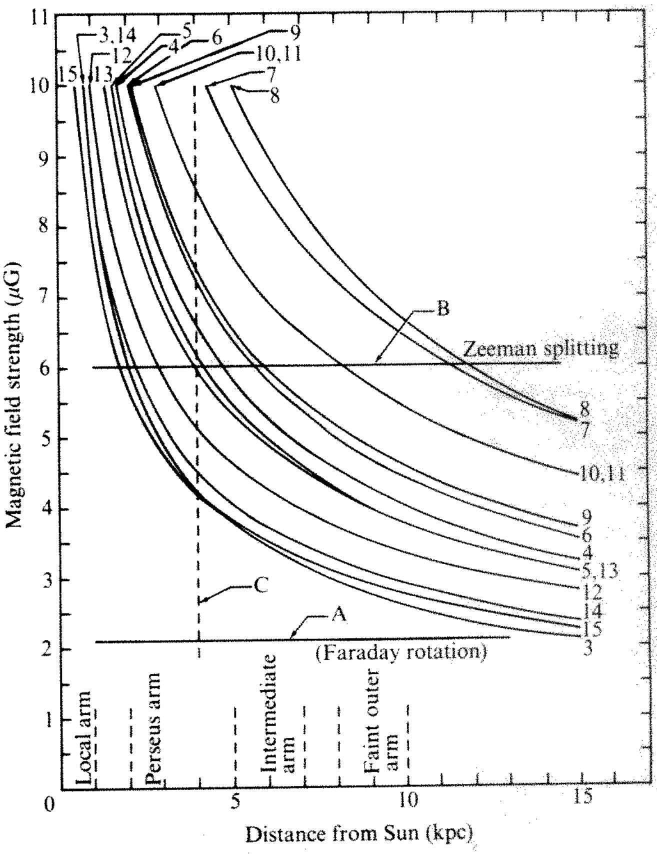

Fig. 1 The calculated mean magnetic field is plotted against the extent of the radio-emitting region toward the anticentre for various cosmic-ray electron measurements listed in Table 1 (details in text).

One observes from Fig. 1 that all the calculated curves fall above line A, thereby, demonstrating that either the magnetic field derived from Faraday rotation measurements is an underestimate or that the intensity of radio emitting electrons in the Galaxy is larger than that observed by any group listed in Table 1. However, gamma-ray observations in the energy region above 100 MeV[19] show that the interstellar intensity of nucleonic components of the cosmic rays in the few GeV region is not very different from that observed near the Earth. Therefore, we conclude from this argument that the cosmic ray electron measurements set a lower bound to the mean magnetic field of 2 μG for the interstellar space and that Faraday rotation measurements are indicative of a lower limit to the local magnetic field in the Galaxy.

It is generally recognised that the radio-emitting region toward the anticentre does not extend much beyond the Perseus arm, because the Intermediate arm itself is very faint in 21-cm observations having a gas density less than one-fifth of that of the Perseus arm[20]. We have, thus, drawn a line C in Fig. 1 at 4 kpc, as the most probable equivalent dimension of the radio-emitting region with a mean emissivity similar to that in the local arm. The intercepts of this line with the calculated curves indicate that the required field strength varies from about 4 μG to 11.5 μG, which is two to six times higher than that deduced from Faraday rotation measurements. In particular, the measurements of Freier *et al.*[10], Webber and Rochstroh[11], Müller and Meyer[7], and Agrinier *et* *al.*[8], give values ≥ 8.5 μG, which are much higher than even the upper limit set from the Zeeman splitting measurement (line B). In other words, these measurements would imply (from their intercepts with line B) an equivalent emitting region of at least 8 kpc toward the anticentre, which is difficult to accept regardless of the uncertainties associated with the positions of spiral arms in the outer parts of the Galaxy. Such large magnetic fields also require very high gas density in order to be contained in the galactic disk[21].

In conclusion, we have shown that (1) the observed spectral index of the radio continuum in the Galaxy is in conflict with some of the cosmic-ray electron measurements[14,15]; (2) the absolute intensities of cosmic-ray electrons measured by some of the experimenters[7,8,10,11] are so low that they cannot be reconciled either with the interstellar magnetic field limits or with the extent of the galactic disk toward the anticentre; and (3) it is likely that the field strength derived from Faraday rotation measurements give only a lower limit to the local magnetic field in the Galaxy.

We thank Dr A. S. Webster for communicating his latest compilation of the radio data up to 8,000 MHz and allowing us to utilise the same before publication.

Computation of periods of acoustical oscillations of the Sun

DISCOVERY of the regular pulsations of the Sun was reported in 1975–1976 by three groups of investigators[1-3]. It has been difficult to identify these oscillations, particularly the very stable 2 h 40 min one[1,2,4]. Having had experience in calculations of the free oscillations of gaseous–liquid Jupiter and Saturn[5], we decided to compute the periods of some acoustical modes for one of the complete solar models. We chose the Abraham and Ibem[6] Model I as a model of the interior, and a model of the convective zone from Spruit[7] which had a depth of 198,00 km; an empirical model HRSA[8] was taken as a model of the solar atmosphere.

The equations of small adiabatic oscillations and boundary conditions which we used are the same as those used for giant planets[5] and similar to those used since 1959 for the free oscillations of the Earth[9]. The equations are also similar to those usually used in stellar astrophysics[10,11], but boundary conditions have a slightly different form. Our method of computation[12] is similar to that used for the giant planets. The only difference is that here we have not used an analytical start from the centre when the equations were numerically integrated. We always started with orthogonal vectors at some distance from the centre. This technique, calling for special attention when applied, proved itself to be correct for Jupiter and Saturn as well as for the Earth. Such a technique permits the calculations of acoustical modes only, separately from gravity modes, because gravity modes are formed near the centre.

Table 1 Periods $_jT_{sn}$ of free oscillations of the Sun

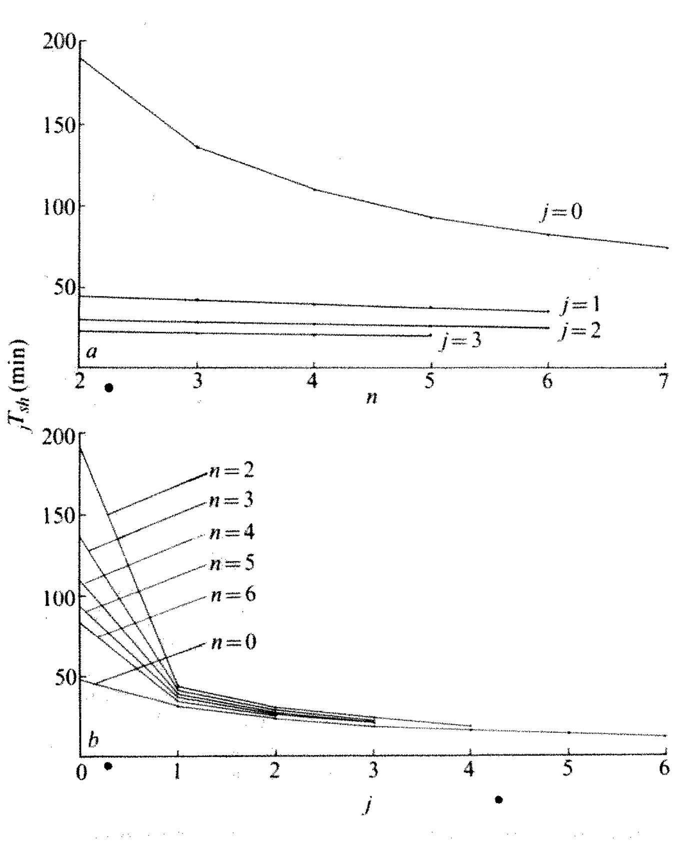
	Period (min)						
j/*n*	0	2	3	4	5	6	7
0	48	191	136	110	93.6	82.6	74.6
1	31	44	41	38.5	36.4	34.5	
2	23	30	28	27	25.5	24.5	
3	18	23	21.3	20.2	20.0		
4	—	18					
5	13						
6	11						

We report our results in Table 1 and Figs 1 and 2. The calculated periods of free oscillations are presented in Table 1. $_jT_{sn}$ denotes the period of the *j*th overtone of a spheroidal mode characterised by a spherical harmonic of degree *n*. The classification of radial modes ($n = 0$) on to overtones is that accepted for the oscillations of the Earth. The accuracy of computations is about 1 min for fundamental radial and quadrupole ($n = 2$) modes; the accuracy improves when either *n* or *j* increases.

Figure 1 shows the periods $_jT_{sn}$ as functions of both *n* and *j*.

The vector of displacements of a material point is characterised by its radial and tangential components. Figure 2 shows the tangential component *V* as a function of indimentional radius $\beta = r/R_\odot$ for the fundamental mode and the first overtones of quadrupole oscillations. The application of tangential component is more visible because of very strong attenuation of radial component with depth. For overtones V (β) has an oscillating character; index *j* determines the number of nodes.

Fig. 1 The periods $_jT_{sn}$: *a*, as functions of *n*, for the fundamental mode $j = 0$ and first overtones $j = 1$–3; *b*, as functions of *j*, for radial modes $n = 0$ and first spheroidal modes $n = 2$–6.



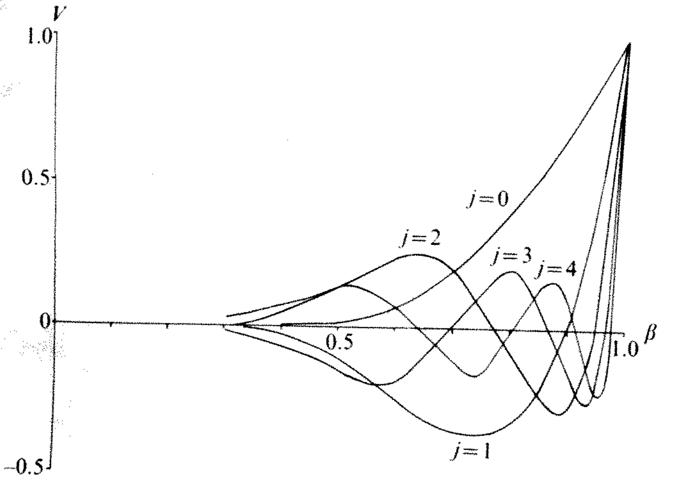


Fig. 2 The tangential component of displacements $V(\beta), \beta = r/R_\odot$, for the fundamental mode and first overtones of quadrupole oscillations.

In order to invert the procedure to improve the solar models, the first step is to identify precisely the observed oscillations. The comparison of the observed periods of oscillations of the Sun[1-3] with the computed periods in Table 1 makes it possible to assume that the mode with a period of 2 h 40 min (refs 1, 2) is the fundamental quadrupole mode, the mode with a period of 48 min (ref. 3) is the fundamental radial mode; the 40-min period[2] corresponds to the first quadrupole overtone, the 29-min period[2] corresponds either to the second quadrupole overtone or to the first radial overtone.

There are some discrepancies between our results and those of Christensen-Dalsgaard and Gough[5], and so there is another identification of the observed periods of the oscillations of the Sun. We think that the cause may be in the model. We could not examine the discrepancy in detail because we had not got the basic model for which the periods in ref. 5 were computed.

Recent calculations indicate that more accurate computations of the eigenfunctions in the inner regions may shift the periods slightly, without influencing the identification proposed.

We thank Dr V. M. Lubimov for discussion.

On presolar meteoritic sulphides

DISCOVERIES of isotopic anomalies in meteorites[1-4] inspired those same research groups to postulate nucleosynthetic inhomogeneities that were somehow carried into the early Solar System. Clayton [5,6] developed a picture treating most anomalies as extinct radioactivities trapped in mineral condensations in the expanding sites of explosive nucleosynthesis, presumably supernovae or novae[7]. As evidence for supernovae condensation grows, it becomes clear that one wants not only isotopic but also mineralogical evidence of presolar grains. What supernovae condensates bearing unique signature are likely to survive? We advance arguments here that one should search among the ubiquitous sulphides present in meteorites, searching especially for sulphides of titanium. Our reasoning is that many sulphides, especially of titanium, will not be expected in solar condensation sequences but are expected to dominate certain key zones of supernovae expansion.

The element sulphur seems to have resulted primarily from the nuclear explosions of oxygen and silicon. Woosley *et al.*[8] have analysed the arguments leading to that conclusion. The sulphur yield becomes more abundant than the oxygen fuel when about three-quarters of the oxygen has fused, and is more than 10^4 times more abundant when oxygen burning merges into silicon burning[9]. It is around this later time that the titanium abundance rises into equilibrium with those of Si, S and Ca. Therefore, if we concentrate on those supernova shells where Ti has been synthesised, we find $S/O > 10^4$. There is also no hydrogen. The elements Mg and Al are very deficient; roughly, $Mg/Si \approx 10^{-3}$ and $Al/Si \approx 10^{-3}$ while $S/Si \approx 1/2$. Shortly thereafter, the elements Cr, Fe and Ni rise to their natural abundance, without severely affecting key elemental abundances in the range $16 < A < 48$. Only Cl, K and the neutron-rich isotopes of S, Ar and Ca fall as the iron group rises. Here it is clear that following the few years required for that nuclear explosion to cool to 2000 K (refs 6, 10) the chemical condensation will proceed along unfamiliar lines. If this expanding supernova shell is not mixed by instabilities with oxygen-rich layers, the elements Si, Ca, Ti and, in sufficiently consumed Si burning, the iron group will condense in a sulphurous atmosphere. In those circumstances, on general chemical principles, sulphur is expected to play the rôle that oxygen normally plays in model solar condensation sequences[11]. It will be of enormous interest to compute analogous supernova condensation sequences, but, because many of the necessary thermodynamic data on sulphide minerals do not seem to be readily available, the plausibility of titanium sulphides is here argued for the purposes of advancing this type of argument and of calling attention to needed mineralogical research.

In conventional solar condensation sequences[11], Ti condenses completely and early as a sequence of oxides: perovskite $CaTiO_3$ at 1647 K, Ti_3O_5 at 1393 K, and rutile TiO_2 at 1139 K, all computed at a total pressure of 10^{-3} atm. Similar sequences with small temperature decreases characterise lower nebula pressures. The Ti is locked up as oxides through the falling temperatures, and free Ti and sulphides of Ti do not exist in the equilibrium calculations. In the expansion from the silicon-burning shells of supernovae, on the other hand, the abundances of key elements stand in the approximate ratio $Si:S:Ca:Ti \approx 10:5:0.7:0.03$, so that an analogous sequence of sulphides will be expected. Since a complete set of thermodynamic properties of sulphides is currently sketchy, at present it is not possible to predict exactly such a chemical condensation sequence. Hence we confine ourselves merely to pointing out that sulphides are expected to condense. Among them, titanium sulphides are especially interesting because their chemical properties, such as insolubility in H_2O, HCl, HF and solubility in concentrated HNO_3, closely resemble those of the puzzling mineral Q comprising less than 10^{-3} of the carbonaceous chondrite Allende[12]. Q is presumed to be a double sulphide of Fe and Cr, which can also easily condense in the silicon-burning ejecta. In fact, in late silicon burning, when Fe/S becomes greater than unity, most of the S may condense as FeS, so that some of the common meteoritic troilite may also have presolar origin. We concentrate instead on the titanium sulphides in the belief that they will not be synthesised in the solar condensation sequence.

Metallic sulphides grains, as postulated above, will not alone be diagnostic of condensation in a supernova-shell, as these can be formed in carbon star atmospheres too. While detailed chemical thermodynamic calculations are required to reveal the mineralogical differences between the two grains, an isotopic analysis may help distinguish between the two. For example, the most straightforward prediction from middle-to-late silicon burning is that presolar sulphides of Ti, Cr and Fe should be deficient in the two heaviest isotopes of S; that is, they should ideally be pure ^{32}S, although astrophysical instabilities may well mix the idealised layers. Early in silicon burning, however, when ^{33}S and ^{34}S are normal, a large fraction of Ti is concentrated into the light isotope ^{46}Ti; therefore, presolar titanium sulphides rich in ^{46}Ti are also to be expected when accompanied by normal S. Similarly, if presolar calcium sulphides survive, one finds that $^{34}S/^{32}S$ correlates with $^{42}Ca/^{40}Ca$, being normal early in the burning and falling to zero as the iron group rises. So our immediate suggestion is that the ubiquitous strange sulphides, especially containing Ti, are good candidates for isotopic analysis.

In suggesting that strange sulphide minerals may provide mineralogical evidence of presolar grains, we are assuming that solar condensation does not yield the same minerals. In the case of titanium, it seems likely that the refractory oxides made in the solar sequence will not be reduced later by H_2S, in which case it seems that no titanium sulphides are possible in the usual picture. Lord[13] has made this conclusion, but it may warrant a modern attack if the sulphides can be found. At present we offer this discussion in the belief that it could lead to important discoveries for the sciences of nucleosynthesis and the origin of the Solar System.

The first metamorphic sodic amphibole identified from the Newfoundland Appalachians—its occurrence, composition and possible tectonic implications

MODELS for the emplacement of the western Newfoundland ophiolite suites include obduction over an eastward-dipping subduction zone[1], but no blueschist facies assemblages, considered to form in response to the high P/T gradients associated with subduction, have yet been identified in this area. Magnesioriebeckite and crossite which occur in metavolcanics from the vicinity of Croque, northwestern Newfoundland, provide the first indication that these conditions may have been approached. This report deals with the petrographic relations, composition and probable conditions of formation of the Newfoundland sodic amphiboles, the latest in a series of occurrences described from Vermont[2,3], Quebec[4] and New Brunswick[5,6] (Fig. 1).

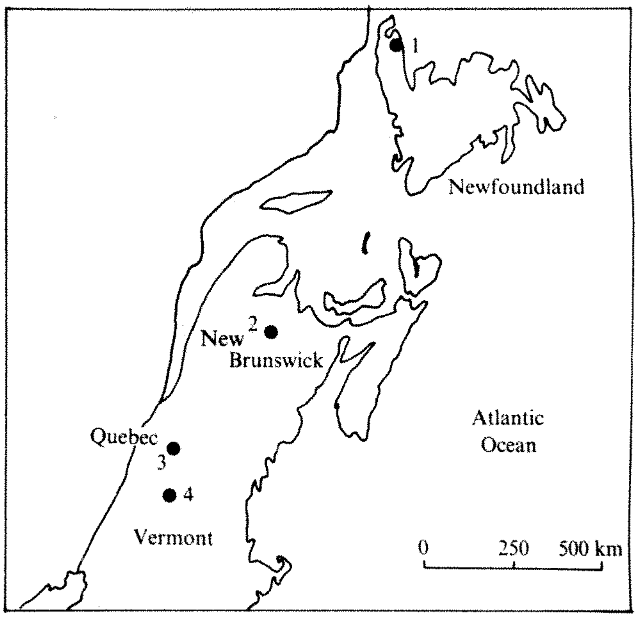

Fig. 1 A geographical location map showing the occurrence of sodic amphibole in the northern Appalachians. 1, Maiden Point Formation volcanics, Croque, Newfoundland (this paper); 2, Tetagouche Group Volcanics, New Brunswick[5,6]; 3, Tibbet Hill Volcanics, Quebec[4]; 4, Hazen's Notch Formation, Vermont[2,3].

The host rocks are undeformed metabasalts which occur at the structural base of the Maiden Point Formation, at the bottom of the Hare Bay Allochthon, a sequence of sedimentary, metamorphic and igneous rocks which includes a partial ophiolite at its top[7]. The greenschist facies mineral assemblage albite–epidote–actinolite–chlorite–sphene–stilpnomelane–magnetite–quartz–(white mica) replaces the original pyroxene and plagioclase. There is little or no preferred orientation of the minerals, and the outlines of the pre-existing plagioclase phenocrysts are often preserved. Actinolite and brown stilpnomelane appear to post-date all other phases, growing as well developed

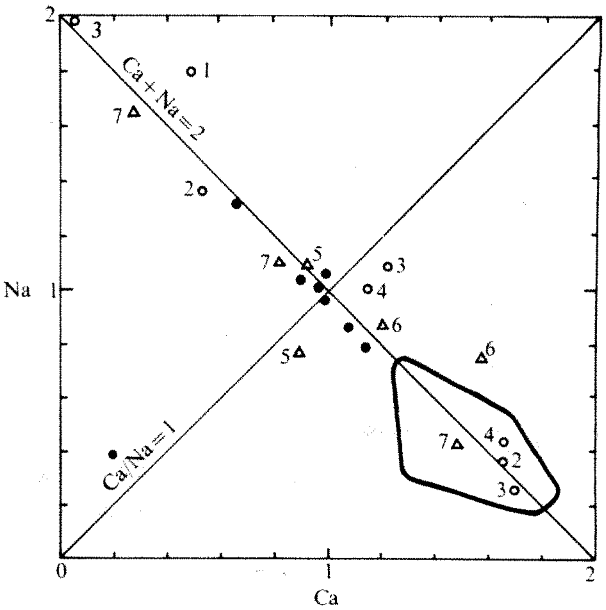

Fig. 2 The compositional range in terms of sodium and calcium content of amphiboles from the Croque metavolcanics (●). The outlined field includes all actinolite compositions from the area. Also plotted are amphibole compositions from elsewhere in the Appalachians (○) and other intermediate sodic–calcic compositions (△). 1, New Brunswick (H. Helmstaedt, private communication); 2, Quebec[4]; 3, Vermont (representative analyses of end members from the Tillotson Peak area, (J. Laird, private communication); 4, Vermont[3]; 5, Labrador[13]; 6, Switzerland[10]; 7, Washington[14].

acicular or sheaflike grains across a fine-grained mat of chlorite, epidote, albite and sphene. Actinolite and stilpnomelane do not appear in the matrix. Rare veinlets of albite, epidote and quartz transect the groundmass.

Amphibole with the pleochroic scheme X=yellow-green, Y=blue-violet, Z=indigo occurs in three samples from a suite originally collected by Smyth[7]. It rarely forms discrete grains, generally occurring as irregular zones or patches within actinolite crystals. Where a regular relationship can be defined, the blue amphibole tends to occur as cores rimmed by actinolite. No sharp boundaries between the actinolite and the sodic amphibole grains are visible. Where both amphiboles are present, actinolite is always the more abundant phase.

*Ferric iron was estimated according to the method of Papike *et al.*[20]

Microprobe analyses show that the amphiboles range continuously from sodic to calcic compositions (Table 1). The calcium-rich amphiboles have the low Al content and nearly ideal M4 site occupancy (Ca+Na=2.0) that identify them as actinolites[8] (Fig. 2). Approximately one-quarter of the analysed actinolites are unusually rich in sodium, with $1.2 < Ca < 1.5$ formula units, and are transitional into sodic compositions, with $Ca < 1.2$ units. The sodic amphiboles are best described as magnesioriebeckite (Fig. 3), with one analysed grain containing enough octahedral Al to be classified as crossite. Although the range of compositions between actinolite and magnesioriebeckite appears to be continuous when all the analyses are considered, each of the three samples studied displays a somewhat different set of compositions. RS 78–69 contains no analysed grains with $1.0 < Ca < 1.4$, RS 71–172 has a complete range between 1.0 and 1.8 Ca formula units, and RS 165–70 contains no amphibole with $Ca < 1.2$ units.

Studies of amphiboles from blueschist facies terrains have pointed to the existence of a miscibility gap between sodic and calcic compositions[9–13] and intermediate compositions, while rare, are not unknown (Fig. 2). Klein[10] cites one case of coexisting hornblende and sodic actinolite from a metamorphic ophiolite in the Swiss Alps. Because of lack of evidence for equilibrium coexistence and the associated epidote–amphibolite facies mineralogy, this pair was thought to have formed at pressures and temperatures above the proposed miscibility gap. Metamorphic conditions of $P > 6$–10 kbar and $T < 600$ °C were estimated for the formation of intermediate 'riebeckite–tremolite' from a metamorphosed iron formation in Labrador[13]. Amphiboles from the Shuksan region, Washington, show continuous zoning from crossite to actinolite[14]. In this case, Brown concluded that with increasing dT/dP the pair sodic amphibole—calcic amphibole is replaced by a single intermediate amphibole, which in turn is replaced by Na-rich actinolite and iron oxide. If this inferred relationship is correct and applicable to the Croque metavolcanics, sample RS 78–69 would have formed under conditions of relatively low dT/dP, since it is the only sample to show any gap between sodic and calcic compositions and also contains the most sodium-rich amphiboles. Samples RS 71–172, with its intermediate compositions, and RS 165–70, with its sodic actinolites, would have formed under progressively higher T/P gradients.

The presence of sodic amphibole alone is not sufficient to define a blueschist facies assemblage[15], particularly in this case where it is an uncommon phase and has a magnesioriebeckite–crossite composition rather than one close to glaucophane. The stability of magnesioriebeckite ranges from authigenic to magmatic conditions[8], and is probably very sensitive to bulk rock composition and f_{O_2} as well as pressure and temperature. The stability field of crossite has not been experimentally defined, but probably lies between those of glaucophane and magnesioriebeckite. The metamorphic conditions at Croque cannot be deduced from the presence of this phase alone, but must be related to the mineral assemblage as a whole.

Brown[16] has suggested that the reactions chlorite+K-feldspar=stilpnomelane+actinolite and chlorite+K-feldspar + magnetite = muscovite + stilpnomelane + actinolite occur within the chlorite zone of the greenschist facies, at relatively high pressures and over a wide range of temperatures. The reaction curves, with negative slopes, lie at lower pressures on a schematic diagram than the stability fields of glaucophane and lawsonite, although they may intersect the blueschist facies curves at high pressures

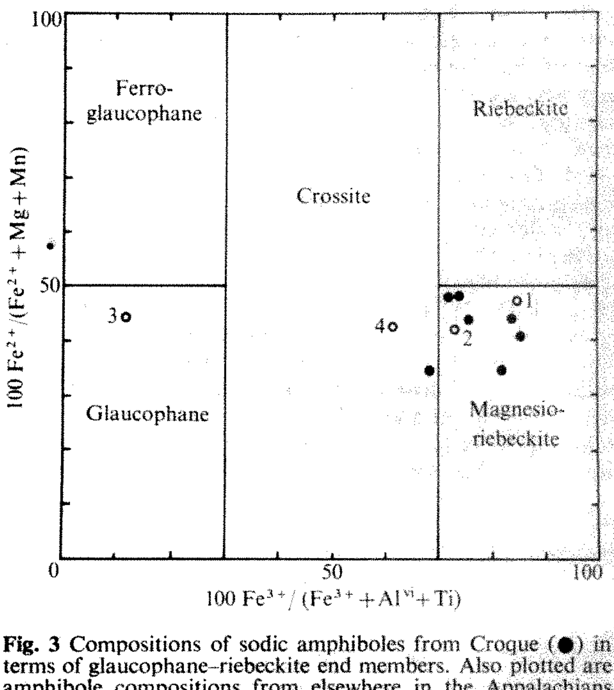

Fig. 3 Compositions of sodic amphiboles from Croque (●) in terms of glaucophane–riebeckite end members. Also plotted are amphibole compositions from elsewhere in the Appalachians (○). Ferric iron was estimated by the method of Papike *et al.*[20]. 1, New Brunswick (H. Helmstaedt, personal communication); 2, Quebec[4]; 3, Vermont (J. Laird, personal communication); 4, Vermont[3].

and very low temperatures. The mineral assemblages observed in the Croque metavolcanics seem to exemplify the proposed reaction relationships, with stilpnomelane+actinolite overgrowing the earlier chlorite-rich greenschist facies assemblage. White mica replaces feldspar in at least one example. On this basis it seems likely that the assemblages formed within the greenschist facies at rather high pressures, with one sample representing a possible transition to blueschist facies conditions.

Magnesioriebeckite occurs in comparable stratigraphic positions elsewhere in the Canadian Appalachians. Trzcienski[4] speculated, on the basis of 'crossite' in Tibbet Hill Volcanics of Quebec, that blueschist facies metamorphism had occurred in association with a subduction zone. However, Fig. 3 shows that the sodic amphibole in question is magnesioriebeckite, similar to the Croque amphiboles in composition. The presence of chlorite, stilpnomelane, actinolite and white mica in the assemblage, together with the similar stratigraphic position in volcanics which underlie a Cambro-Ordovician flysch sequence strongly suggest that the metamorphism occurred under conditions very similar to those in western Newfoundland. Magnesioriebeckite has also been observed in similar assemblages in Lower Palaeozoic volcanics in the New Brunswick Appalachians[5,6]. An amphibole with optical properties very similar to the sodic amphiboles in the Croque assemblage has been observed replacing chlorite in blocks of greywacke from the basal melange of the Humber Arm Allochthon in southwestern Newfoundland (R. K. Stevens, private communication). Glaucophane, barroisite and omphacite associated with Taconic metamorphism in Vermont[2,3] suggest that a higher P/T gradient was achieved in that region.

The structural position of the Croque metavolcanics and the lack of a tectonic fabric are consistent with metamorphism resulting from deep burial. However, only 3.4 km of overlying material can presently be accounted for in the structural sequence[17], although the mineral assemblages suggest that pressures of at least 3–4 kbar were involved. Current models for the onset of obduction in western Newfoundland would predict initial deep burial of the continental margin in response to loading by the overriding oceanic plate[18]. Later isostatic rebound and collapse of the continental margin sequence into the series of thrust sheets which is now observed would lead to the emplacement of the volcanics and associated greywackes into their present structural position. This model is supported by the presence of eclogitic dykes in the underlying, more deeply buried, Grenville basement to the east[19]. It would, however, represent conditions with lower P/T gradients than those reflected in the Franciscan 'subduction melange' of California and similar sequences where complete blueschist facies assemblages are common.

I thank Dr. W. R. Smyth for providing the thin sections and sample localities, and Dr R. K. Stevens, Dr K. D. Collerson, and Dr D. F. Strong for useful discussion and criticism. Dr J. Laird and Dr H. Helmstaedt provided additional information about the Vermont and New Brunswick occurrences, respectively, and Dr A. Thompson assisted with the microprobe analyses.

Global climate change during the 13,500-b.p. Gothenburg geomagnetic excursion

ROBERTS and Olsen[1] suggested that high latitude atmospheric ionisation has an important role in nucleating cirrus clouds. And Harrison and Prospero[2] deduce that, if this is correct, severe drops of the Earth's magnetic field strength, such as are believed to accompany reversals, would lead to increased upper atmospheric cloudiness at all latitudes and correspondingly to major climatic events. There is likely to be warming at high latitudes but considerable cooling in the middle latitudes, in a way analogous to the aerosols[3].

I decided to test this idea in connection with the Gothenburg Excursion, the youngest well-documented geomagnetic event in the geological record. Mörner and Lanser[4] have shown this episode to have been short-lived, only 13,750–12,350 yr b.p., and Creer *et al.*[5] on the cores from Lake Erie, but with less precise dating, identified the excursion only to within 14,000–11,000 yr b.p. The global nature of this magnetic disturbance is indicated by other dates from the Gulf of Mexico, Japan, France and Australia, and often correlated with the poorly dated 'Laschamp' Event.

What happened at that time to global climates? While no cause and effect relationship can be claimed at this stage, it is useful to point out that a number of dramatic events 'happened' at the same time, for example (Fig. 1):

North American glacial record. The great Laurentian ice sheet was in full retreat by 15,000 b.p. and was about one-third melted. But suddenly, according to Dreimanis and Goldthwait[6] the glaciers ceased their retreat and reoccupied approximately 500,000 km^2 of southern Canada and the American mid-west. This readvance over a distance of 550 km (Carey, Port Stanley Till) took place about 14,000 b.p. with a last oscillation at 13,000–12,700 b.p. (Port Huron). A corresponding but smaller readvance is indicated in the north-European record[7], and data from New Zealand and Patagonia also suggest a return of the glaciers.

Eustatic evidence of glacier volumes. Mörner[8] gave the amplitude of the negative eustatic oscillation in the interval 13,000–14,000 b.p. as 9–12 m. Inasmuch as 1 mm of glacio-eustatic change represents 360 km^3 of sea water, a 10 m oscillation would involve 3.6×10^6 km^3 of water or 4×10^6 km^3 of ice. If correct, these observations suggest that within a thousand-year interval a volume of ice was newly formed that was equivalent to 20 times all of the world's present mountain glaciers put together and a third more than all the ice in Greenland today.

Central African rainfall and Nile discharge. During the last glacial stage Lake Victoria (head of the White Nile) became a carbonate-rich evaporating lake and did not overflow. Precipitation was likewise very low in Ethiopia and the Blue Nile was severely impoverished. The middle valley of the Nile became the limit of flow and gradually became silted up with a vast wedge of sediments that built up to a height of 40 m above the present level of the Nile bed, according to my own surveys[9]. Comparable desiccations of other African rivers such as the Niger and Senegal are now established[10]. Even the Congo was locally overwhelmed by

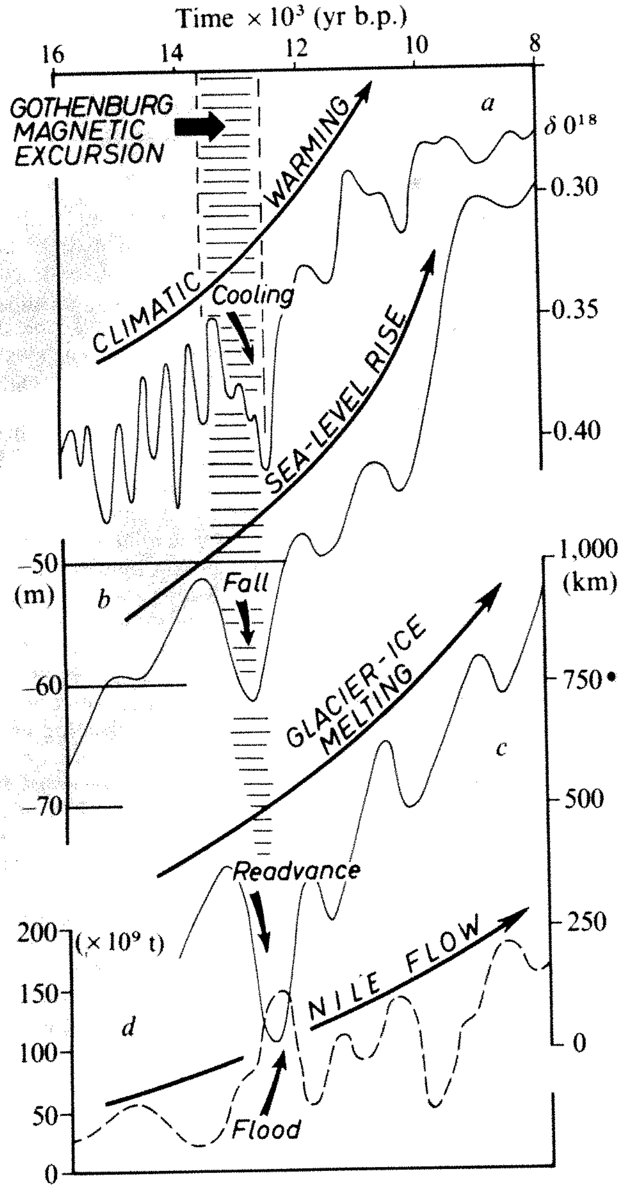

Fig. 1 Four climatic indicator curves for the period 16,000 to 8,000 b.p. The Gothenburg palaeomagnetic instability was approximately 13,750–12,350 b.p. according to Mörner and Lanser[4]. *a*, Climatic warming reflected by $^{18}O/^{16}O$ ice records from Camp Century, Greenland; *b*, sea-level rise, from data assembled by me; *c*, glacier-ice melting, measured as km of retreat in southern Canada[6]; *d*, Nile discharge, measured from the sedimentary cut and fill levels in Nubia[9].

dune sand[11]. The silt wedge of the Nile was dramatically cut through around 13,500 b.p. by an enormously augmented flow (at least four times the present discharge) and after a series of oscillations the talweg reached bedrock in many areas and the present regime was established. Sedimentation in the eastern Mediterranean seaward of the Nile delta up till around this time was a white, pelagic ooze, but then became abruptly followed by fine, terrigenous silts introduced by the Nile, which speaks for a sudden change in the fluvial regime.

It is clear from the discoveries of the last 15 yr (ref. 12) that the Milankovitch planetary insolation pattern shows a convincing correlation with gross planetary climate changes within a 92, 40, 26 × 10³ yr framework, and dynamic calculations seem to support the model[13]. Nevertheless, this theory offers us no hint of an explanation for brief climatic fluctuations or excursions on the scale of decades up to 5×10^3 yr.

The evidence of the Gothenburg fluctuation suggests that a major change in the normal global heat transfer was involved that seems to call for a non-steady state explanation. As recently recalculated by Berger[14], there was also a critical seasonality change affecting the 'sensitive' latitudes at about the same time as the Gothenburg excursion. This time was roughly about the mid-point in the gigantic melting that followed the last glacial maximum. It is difficult to relate it in any way to that warming trend. Quite the contrary, it correlates with a very brief but intense cooling. During the great melting, which lasted 10,000 yr, the sea level rose 135 m[15] and considerably changed the geography of land and water. Could a negative feedback have caused the Gothenburg cooling? In general the changes of albedo on a warming Earth combined with increasing dimensions of oceanic areas would lead to positive feedback, thus accelerating the melting. Indeed, the resultant exchange of mass loading on the Earth may very well be the cause of the magnetic instability itself[16]. The increased pluviosity of the equatorial regions at this time suggested by the Nile and other fluvial regimes might indicate a sudden drop in the continental evaporation rate.

Another curious coincidence seems to match the timing of the Gothenburg Excursion. Kopper[17] has demonstrated that in the evolution of man, each of the key subspecies introductions or cultural boundary horizons seems to correspond with an important magnetic reversal or excursion. The Gothenburg event appears to mark the end of the Neanderthals.

Most recently another report of this magnetic excursion was obtained from Blekinge, south-east Sweden, by Noel[18], but dated by uncorrected varve chronology as 12,077–12,103 ± 150 b.p. This controversial dating may be up to 300 years too young.

In summary, it should be emphasised that this proposed magnetic–climatic relationship is strictly limited to events on a scale of up to 10³ yr and is in no way a substitute for the Milankovitch modulation of ice-age climates, although in certain instances it may play a triggering role.

Dry years in south-east England since 1698

THE recent drought and water shortage in England has re-emphasized the need for a more detailed knowledge and better understanding of the climate of the past. Without such information it is impossible to make meaningful statistical

Table 1 Years of greatest soil moisture deficit for south-east England, 1871–1970

statements about the future occurrence of such extreme events. Many meteorological statements have been made about the severity and causes of the 1976 drought, mainly in the popular press, but also in the scientific literature[1]. These statements have generally concerned precipitation; but data on precipitation alone are not necessarily good indicators of drought. In this paper we distinguish between three different kinds of drought—meteorological, hydrological and agricultural drought—noting that agricultural and hydrological drought conditions are determined, not only by rainfall, but also by evaporation and by the timing of rainfall events. Using both precipitation and evaporation data for Kew we derive a time series of soil moisture deficits which we believe gives a more rational measure of agricultural drought severity than can be obtained from precipitation data alone.

Drought conditions are not determined solely by lack of rainfall. The precise evaluation of drought severity is difficult because different people perceive drought in different ways. To many people a 'drought' is a long period with little or no rainfall; indeed this is the basis of the definition introduced by Symons[2]. A more useful impression of drought severity is given by precipitation deficiency diagrams in which accumulated precipitation is compared with the long-term average for the station[3]. Accumulated departures from the average are a measure of drought severity. We may refer to a drought defined solely by deficiency of precipitation as a 'meteorological drought'. Though interesting in its own right, this is not a particularly useful definition of drought and Rodda[4] has stated unequivocally that "... a drought definition based solely on the absence of rain is hydrologically unrealistic". To quote Rodda further: "... though the causes of drought are meteorological its definition is best made in hydrological terms".

To industry and consumers of water, a drought occurs when water supplies become low. Thus a second type of drought, 'hydrological drought', is the result of a deficiency in 'excess' rainfall over some preceding period. 'Excess' precipitation is that which is neither evaporated nor used up in restoring soil moisture deficits and is therefore available to form surface run off and/or groundwater recharge. The length of a hydrological drought depends on the size of the region and the type of water resource affected[5].

To the farmer, drought conditions are those which lead to poor crop yields. An 'agricultural drought' will therefore be determined largely by conditions which lead to stunted growth or even wilting of crop plants. These are a combination of dry soil and a continuing high level of potential evapotranspiration, which the crop is unable to maintain by withdrawing water from the soil. This combination leads to a consistently high soil moisture deficit over the growing season. Thus the average soil moisture deficit over the 4-month period May to August can be used as an index of drought severity. (It is worth noting in passing the the opposite condition, of very wet soil during the growing season is equally adverse for crop yields.)

Definitions of drought have been exhaustively reviewed by Hounam *et al.*[6] who also point out the distinctions between different types of drought. Rodda *et al.*[5] in their discussion of drought indices conclude that soil moisture deficits provide the best practical drought index. Soil moisture deficits are the result of losses of soil moisture in periods when evapotranspiration exceeds rainfall. These losses depend on the type of vegetative cover; once the soil moisture is depleted below an effective root level, evapotranspiration can only proceed very slowly, at a rate much below the potential evapotranspiration rate which would occur from a fully wet soil. To account for the influence of vegetation type, and for the differences be-

tween actual and potential evapotranspiration, Penman[7] introduced the concept of a root constant. Penman's original work indicated that potential and actual evapotranspiration rates were effectively equal for soil moisture deficits less than $C+25$ mm (where C is the root constant (unit mm) a function of vegetation type). For greater soil moisture deficits actual evapotranspiration rates are considered to drop rapidly to about 10% of the potential rate at a soil moisture deficit of around $C+37.5$ mm. Beyond this the ratio of actual to potential evapotranspiration rate is assumed to remain at about 10%. Although there are differences due to soil type, this simple model gives remarkably good results in water balance calculations over a wide range of conditions[8].

Long homogeneous series of precipitation and evapotranspiration data for Kew going back to 1698 have been constructed and discussed by Wales-Smith[9–11]; these are the longest such series available anywhere in the world. From these data one can determine, month by month, the soil moisture deficit (D) for different types of vegetative cover. D values are generally calculated by using the method of Penman[7]. The Ministry of Agriculture and the Meteorological Office publish D values for different regions at regular intervals, and the Meteorological Office has calculated D values for Kew back to 1871 using the Penman approach as discussed by Grindley[8].

We have reconstructed monthly D values back to 1698 using using the same approach and the Kew data. For most of this period only monthly data are available so it has been necessary, in order to obtain a homogeneous series, to use monthly data throughout. It is, however, preferable to use daily precipitation and evaporation data. Grindley[8] has pointed out that, because precipitation is a sporadic process, the use of monthly data alone can produce significant errors in estimating month-end D. We have found that these errors can be reduced by dividing each month into ten segments, distributing monthly precipitation and potential evapotranspiration values evenly over these segments, and then calculating soil moisture deficits accumulated over successive segments. Using this procedure we have generated monthly values of D for both short ($C = 75$ mm) and long-rooted ($C = 200$ mm) vegetation for Kew from 1698 to 1976. (75 mm has commonly been used as a root constant for short-rooted vegetation although some authors have suggested that this value is too high[5].) The results are representative of south-east England: the Kew precipitation record correlates extremely well ($r = 0.89$) with the south-eastern England precipitation series constructed by Gray[12] for the period 1840–1970.

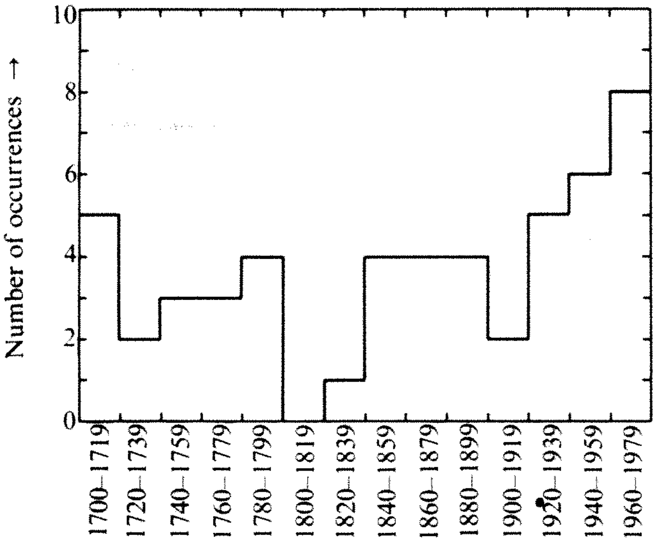

Fig. 1 Number of times the soil moisture deficit averaged over the growing season (average of month-end values for May, June, July and August) exceeded 100 mm in 20-yr intervals. The interval 1960–1979, which is still incomplete, has the highest number (8).

To test our method of soil moisture deficit calculation from monthly data we have compared our results with those calculated by the Meteorological Office using daily data. The Meteorological Office series gives the mean D over a standard catchment containing 50% short-rooted vegetation with a root constant of 75 mm, 30% long-rooted vegetation with a root constant of 200 mm, and 20% riparian land where a soil moisture deficit is never established. Using this standard catchment, the correlation between D values calculated from daily and from monthly data is extremely high; approximately 0.95 for both the 1200 month-end values and the 100 growing season (May to August) mean D values for the period 1871–1970. Furthermore, there is excellent agreement between the years with extreme D values (based on growing-season mean D) calculated using both methods. Table 1 shows the 11 'worst' years over the 100-yr test period ranked in order of decreasing mean D.

The similarity between these rankings is remarkably good when one considers that the 6th to 11th places cover a range of only 3.2 mm in mean D. The precise ranking is determined by very small differences in D. Furthermore, our results are in excellent agreement with those of Rodda[4]. His results for the period 1916–1964 show the most severe droughts as occurring in 1921, 1934, 1943 and 1944. Over the same period our data show 1921, 1934, 1938 and 1944 to be the most severe years. Rodda's results are based on data from Oxford while ours are based on data from Kew.

We have chosen to average D over the whole growing season, and to use a composite of short- and long-rooted vegetation results in order to provide a general agricultural drought index. Our index is thus a rather coarse one, and a high value will not always be an indicator of severe drought conditions for all plants. This makes a direct comparison with specific crop yields difficult, a problem which is accentuated by the influence that developments in agricultural technology have had on crop yields over the past century, which no purely environmental drought index can incorporate. Calculated growing season mean D (henceforth, D_m) values are given in Table 2.

Using this index, the 14 most severe agricultural droughts over the interval 1698–1976 are: 1705, 1731, 1762, 1781, 1844, 1893, 1901, 1921, 1934, 1938, 1944, 1965, 1974, 1976. The seven worst years are, in order, 1976, 1934, 1944, 1893, 1938, 1921 and 1974; all but one having occurred this century. 1976 shows up as the worst agricultural drought since at least 1698, although only fractionally more severe than 1934. Considering the method of constructing the series, however, it would be more realistic to say only that 1976 was among the three worst agricultural droughts during the 279-yr period of record. All three of these 'worst' droughts have occurred in the last 43 yr.

This is a strong indication that the series of D_m extremes is non-stationary. We tested this in the following manner. The series from 1707 to 1976 was divided into 27 10-yr periods and extreme D_m values for each decade were extracted and ranked. Recurrence intervals estimated by using the Gringorton[13] formula were then plotted against $(D_m)^n$ on a semi-logarithmic plot for various n. A linear fit was only possible for large n; $n = 12$ providing a good fit. From the linear fit the recurrence interval for the third highest value of D_m (1944) was estimated as 13.2 decades. In the last five decades (1927–1976) of the record, three events have occurred with equal or greater D_m (1934, 1944 and 1976). The probability of such a clustering occurring by chance, given a stationary series, is less than 0.4%. The null hypothesis that the series of decadal extremes is stationary must therefore be rejected.

An alternative estimate of the recurrence interval can be obtained by using the formula $(n+1)/m$ where n is the number of years in the record and m is the rank of a particular year[4].

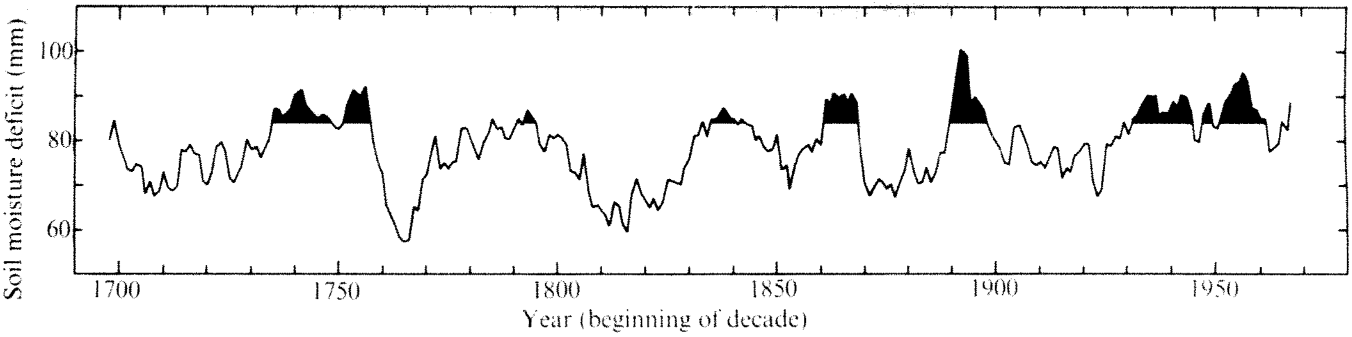

Fig. 2 Ten-yr running means of soil moisture deficit averaged over the growing season. The value of year n corresponds to the decade n to $n+9$ inclusive. An arbitrary datum level of 84 mm has been shown to accentuate the periods of higher deficits.

This gives a recurrence interval of 93.3 yr for the third highest D_m. Given a stationary series, the probability of three such events occurring in the past 50 yr is about 1.5%: a result essentially in accord with the previous analysis. The non-stationary of the extremes of the growing-season mean soil moisture deficit time series makes it extremely difficult to estimate the true return period for severe droughts.

Non-stationarity is further exemplified by the increased frequency of high D_m values this century: of the 14 worst years, 8 have occurred since 1900. This trend is illustrated in Fig. 1 which shows the number of times the growing-season mean D exceeded 100 mm in 20-yr intervals. The most noticeable features of Fig. 1 are the almost drought-free period from 1800 to 1839, and the fact that more high D_m years have occurred in the 17-yr period 1960–1976 than in any preceding 20-yr period. The drier soil conditions of this century are most probably associated with the warmer English climate which has prevailed since about 1880, although no effect of the cooling trend since 1940 is evident. This may indicate that urbanisation has had an effect on evaporation at Kew. Although we do not think such an effect can be large, it is a factor which warrants further investigation.

Another indication of the trend towards more frequent agricultural drought over the past 50 yr is given by Fig. 2 which shows 10-yr running means of average growing season D values. Figures 2 and 1 are not equivalent since the latter only isolates the extreme events. There are, however, some interesting comparisons. The recent trend to more frequent large D_m values does not show up in Fig. 2, although the period from 1930 to the present is the longest period of consistently high growing season soil moisture deficits since 1698, marginally 'worse' than that of the mid-eighteenth century.

We noted earlier that rainfall data alone do not provide a good indicator of agricultural drought. In support of this contention we found that D_m does not correlate particularly well with annual precipitation. The correlation with summer rainfall ($r = 0.80$) is somewhat better. However, in spite of this high correlation, the years of highest D_m do not in general correspond with the driest summers. This is because in addition to having low summer precipitation it is necessary to have established a high soil moisture deficit prior to the growing season, and to maintain high evapotranspiration rates during the growing season. Nevertheless, a good prediction of summer rainfall is a prerequisite for the prediction of agricultural drought: reliable rainfall estimates two to three months in advance appear to be essential.

Mr. B. G. Wales-Smith of the Meteorological Office provided an updated version of his Kew evapotranspiration series and an unpublished revised version of the Kew precipitation series. His help, that of the Meteorological Office, and that of a number of people who reviewed and commented on this manuscript, is gratefully acknowledged. This work was supported in part by a grant from the Rockefeller Foundation.

Structural relationships between corn yield and weather

REPORTS of crop–weather relationships are sparse in the literature and Fisher's classic paper in 1924 has not been improved upon[1]. We find this surprising in view of current concern regarding the ability of the world to feed its rapidly increasing population. This paper reports on progress in our research dealing with corn–weather relationships, a subject of general interest as corn is grown over large areas of the globe.

The data are taken from selected parts of the main corn growing region in South Africa (Fig. 1), namely, four spatially representative sub-regions in the Orange Free State. The data, for the period 1949/50 to 1964/5 consist of corn yields in 200 lb bags per morgen, monthly rainfall totals and mean temperatures at 0800 and 1400; the rainfall and temperature data apply to months over the growing season. By using the method of principal components, these data are shown to be uncorrelated[2]. Multiple regression analysis is applied to the data[3]. Yield is regressed in turn on rainfall, and temperature. The degrees of freedom dwindle, but this does not detract from the value of the strategy adopted. Time was also included in the regressions to account for any temporally varying yield stimuli not otherwise considered, such as fertiliser application. The importance of each month's rainfall and temperature in accounting for the total sum of squares in yield is shown in Figs 2 and 3. Temperature data are presented for the recording time that contributed most strongly to the sum of squares for yield; the order of inclusion of a month into the regression is indicated by the number at the top of each rectangle.

All four districts are in the summer rainfall region of the country. The yields for Bethlehem and Kroonstad show least dependence on individual monthly rainfall totals (Fig. 2). This is probably because the mean annual rainfall for these two is somewhat greater than for Bloemfontein and Hoopstad, therefore, rainfall is less inhibiting to yield at Bethlehem and Kroonstad than at the former two locations. Bloemfontein is situated furthest south and is the only region where yield is sensitive to mid-season rainfall. The yield for Bethlehem is related to both early and late rains. In the case of Hoopstad, and to a lesser extent Kroonstad, it is the late rains which are critical to yield variation.

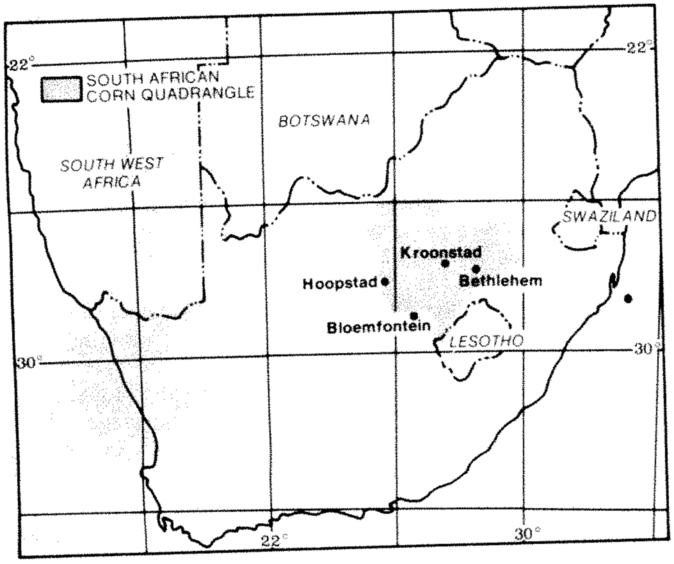

Fig. 1 The position of the South African main corn growing region (shaded), and the location of the sites considered in this paper.

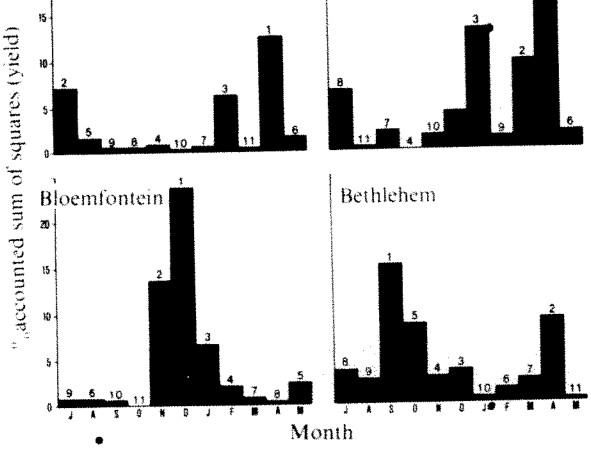
The partial correlation coefficients between yield and early rains are, significantly, negative. This applies to September for Bethlehem, as well as the early months for Kroonstad and Hoopstad. The late rains, and mid-season for Bloemfontein, have positive partial correlations with yield. The adverse effects of early rains result from intense rainfall coupled with instantaneous run-off wastage.

Fig. 2 The percentage of total sum of squares for corn yield accounted for by rain over the growing season.



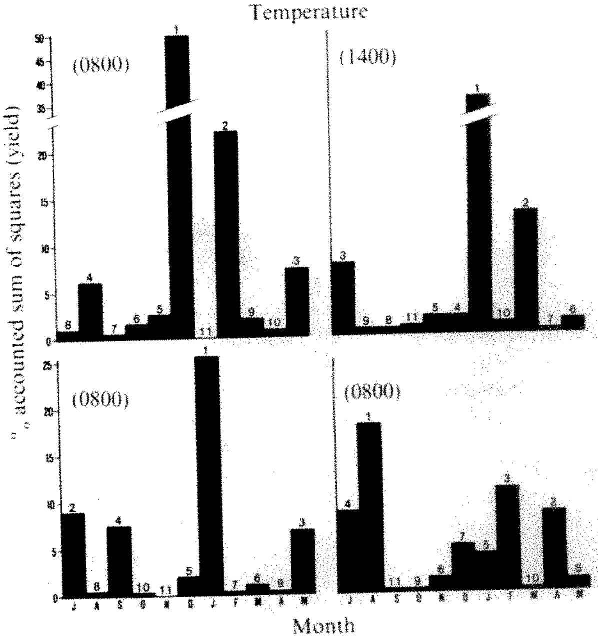


Fig. 3 The percentage of total sum of squares for corn yield accounted for by temperature over the growing season.

Yields at Bethlehem are least sensitive to temperature and when considered also in relation to rainfall, this is the most equitable region for corn. The yield has positive partial correlation with August's temperature. The mid-season temperature is important to yields in the other three regions. This applies particularly to Kroonstad which was little affected by rainfall. For this region the temperatures during December and February have negative partial correlations with corn yield while the converse is true for temperatures at the latter end of a season. This conformation is not unexpected; warm temperatures are required to assist germination, but warm temperatures concluding a season would result in loss of moisture from the crop, with consequent decreases in yield.

The most influential rainfall and temperature months were combined, and the regressions repeated. The structural relationships between yield, rainfall and temperature resulted in the following variables being drawn into the regressions. (1) Kroonstad: time, January, July, May, September and December temperatures. (2) Hoopstad: January temperature, time, March and July temperatures. (3) Bloemfontein: time, January, July, May, September and December temperatures. (4) Bethlehem: time, August temperature and September rainfall.

The percentage variance in yield accounted for by each regression is 85, 86, 95 and 70%, respectively, for factors 1, 2, 3 and 4 above. Note that, apart from time, temperature is the dominant limiting factor for yield. This emphasises the erroneous conclusions that may be drawn from an inspection of the simple correlation matrix. The advantages in using stepwise as an alternative to straightforward multiple regression become obvious. Arithmetic details relating to the analyses may be obtained from the authors.

We thank Mr P. Stickler for his help with diagrams.

Methylated arsenic from marine fauna

It has long been known that certain species of marine animals contain arsenic in their tissues at concentrations up to 100 p.p.m. (ref. 1), and there is little doubt that this arsenic is naturally acquired and does not reflect environmental pollution. The toxicity of arsenic is dependent on its chemical environment and valency state[2,3]. Since the demonstration of the rapid and complete excretion by the human kidney of arsenic consumed in fish and shellfish[1,4], it has been accepted that such arsenic is in an organic and nontoxic form[5]. Clearly full toxicological evaluation of the arsenic in marine animals awaits the elucidation of the precise chemical nature of that arsenic. We have found that mussels (*Mytilus edulis planulatus* Lamarck), western rock lobster (*Panulirus longipes cygnus* George), and stingray (*Dasyatis thetidis Waite*) contain dimethylated and trimethylated arsenic together with a small proportion of inorganic arsenic.

Lobsters were collected off the western shore of Garden Island and mussels and stingray were taken from Cockburn Sound, both in Western Australia. Total soft tissue from the mussels (containing 1 p.p.m. arsenic), tail muscle from the lobster (20 p.p.m. arsenic) and muscle from the disk of the stingray (20 p.p.m. arsenic) were used. Concentrations of arsenic were determined by vapour generation atomic absorption spectrophotometry[6] after digestion of the samples in a mixture of nitric and perchloric acids. Digestion of methanol extracts of the above tissues in aqueous sodium hydroxide led, after neutralisation, to a solution from which arsines were generated on addition of sodium borohydride. Fractional distillation of these arsines from a cold trap into an atomic absorption spectrophotometer[7] led to their identification and has provided information on the alkylation pattern of arsenic contained in fish and shellfish. Sodium borohydride treatment of the methanol extracts before sodium hydroxide digestion produced no volatile arsines.

Preliminary methanol extraction was carried out on macerated tissue of each species. Virtually all arsenic was removed from rock lobster and stingray tissues in this way; 60% of that in the mussel was recovered. The extracts were each treated as follows. Methanol was removed and the residue was digested in sodium hydroxide solution. A small portion of the digest was treated, after neutralisation and addition of buffer, *p*H 4–5, with aqueous sodium borohydride. The arsines generated were trapped in a tube packed with glass beads at the temperature of liquid nitrogen. The trap was linked to an atomic absorption spectrophotometer and allowed to warm, with periodic injection of the volatilised contents of the trap into the flame, as described before[7]. Comparison of the time taken for the arsines from lobster muscle digest to volatilise and enter the flame with those for the standards—arsine, methylarsine and dimethylarsine—revealed 5% unsubstituted arsine, 60% dimethylarsine and 35% of an arsine subsequently identified as trimethylarsine. The percentages represent the constituents of the neutralised base digest when the concentration of sodium hydroxide varied from 10 to 40%: the stronger the base, the greater the release of total arsenic susceptible to reduction. Sodium hydroxide in excess of 40% did not increase the total arsenic released. Digestion was always for 15 min.

Trimethylarsine was identified by use of rock lobster tissue only. The arsines produced by borohydride reduction of the sodium hydroxide digest were trapped by passing all effluent gases through toluene. After concentration, the toluene solution was subjected to gas chromatography and the peak corresponding to the unidentified arsine was located by smell at a sniffing port (strong garlic-like odour). Trimethylarsine was identified by gas chromatography–mass spectrometry[8].

In the sodium hydroxide digest inorganic arsenic is probably present as sodium arsenate or arsenite and dimethylated arsenic as sodium dimethylarsinate. The form of the trimethylated arsenic is more doubtful. Trimethylarsine oxide seems the most likely. The possibility that trimethylated arsenic was demethylating in the alkaline digestion conditions was discounted because the proportions of di- and trimethylated arsenic did not change within the range of sodium hydroxide concentrations that brought about their release. Also, the resistance of dimethyl (trifluoromethyl) arsine to hydrolysis[9] indicated that demethylation would not occur in even the strongest basic conditions used. The close similarities in proportions of the various arsenic compounds from the different species examined may indicate the partial breakdown, in the alkaline conditions used, of a single complex arsenical. That such dissimilar species should all contain arsenic in a single form may seem more likely than that all three should contain the same proportions of three arsenicals. There are, however, no observations on which to base such speculation. Work is in progress to elucidate the chemical structures associated with the methylated arsenicals in both the methanol extract and the sodium hydroxide digest. Preliminary work on the urine of subjects consuming fish containing arsenic suggests that the arsenic remains in a bound state in the body and is excreted in that form. Work is being continued on this aspect of the study.

Although we are still some way from the stage where detailed toxicological assessment of arsenic in marine fauna can be made, it is evident that most arsenic in such situations is organically bound and the general acceptance of the nontoxic nature of this arsenic on such grounds seems to be justified.

Jurassic labyrinthodont

The discovery of a member of the Labyrinthodontia in the Surat Basin of Queensland, Australia, brings the last known occurrence of this amphibian subclass firmly into the Jurassic.

The specimen was discovered on a property, Kolane, approximately 35 miles ENE of Taroom, within the oolitic member of the upper Evergreen Formation. As marine fossils are largely absent from Jurassic sediments of eastern Australia, the latter have been dated almost entirely by correlation of their microfloras with those of the Jurassic sequence in Western Australia the age of which has been determined by means of its marine faunas. Thus, the first appearance of *Tsugaepollenites segmentatus* and *T. dampieri* in the upper Evergreen clearly dates this formation as Upper Liassic[1,2]. In addition the possibility of an Upper Triassic age for the lower Evergreen Formation and the underlying precipice Sandstone is ruled out by the presence of *Classopollis classoides* which is not known from accurately dated pre-Jurassic sediments[1].

As far as can be ascertained before preparation, very little of the skeleton of the Kolane amphibian is missing so that, when prepared, this late survivor of the labyrinthodonts should also be one of the best known.

Many factors suggest that the specimen is a labyrinthodont amphibian. The teeth are labyrinthine in cross-section, the skull and dermal pectoral girdle are ornamented, and there are indications of sensory canal grooves on the skull. In addition, the shape of such limb or girdle bones which can be seen in cross-section is characteristic of Triassic members of the order Temnospondyli, as is the structure of the vertebrae with the neural arch detached from an enlarged intercentrum and a small unossified pleurocentrum.

The specimen is preserved in massive ironstone blocks, and preparation will present difficulties. But enough of the skull is exposed to allow determination down to familial level. The Kolane amphibian conforms to some of the most important criteria used by Welles and Estes[3] and Cosgriff[4] for inclusion of a skull in the family Brachyopidae. Its affinities within that group must remain uncertain pending its further preparation. The skull table is short and broad and on the right of the specimen the characteristic vertical plate of the pterygoid is exposed, while median to this the occipital condyle can be seen projecting well behind the level of the dorsal skull roof (Fig. 1). Orbits are well forward of the midline of the skull but are smaller than is usual in the brachyopids. The animal is big with its skull measuring more than twice the length and almost twice the breadth of the next biggest brachyopid, *Hadrokkosaurus bradyi* from the early Middle Trias[3]. A further link with that genus (which was also its closest relative in time) is that its vertebrae are of the rhachitomous type described by Welles and Estes[3] in *Hadrokkosaurus*.

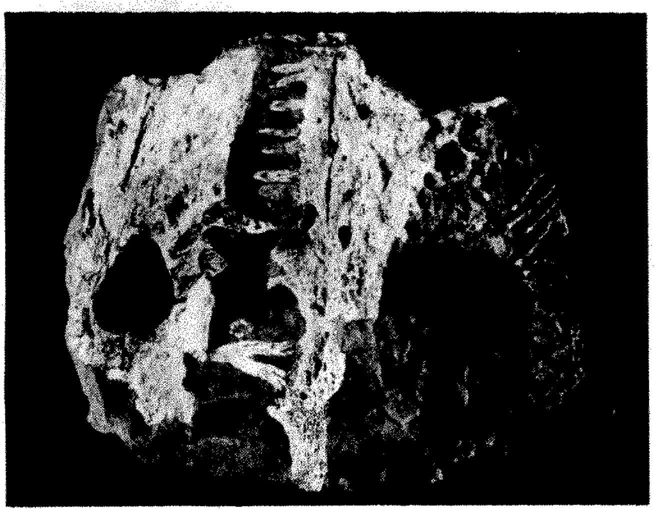

Fig. 1 Anterolateral view of part of the skull and lower jaw of the Jurassic labyrinthodont (Queensland Museum No. F7882). Part of the right orbit can be seen in the upper right hand section of the photograph. The scale measures 15 cm.

There has been one previous description of a Jurassic labyrinthodont. Longman in 1941[7] described *Austropelor wadleyi*, a jaw fragment from the Marburg Sandstone, also of Queensland, Australia. While the age of this sandstone is probably equivalent to that of the Evergreen Formation, the fact that labyrinthodonts elsewhere in the world apparently became extinct at the end of the Triassic led de Jersey[5] to postulate that this fragment must have been reworked from older sediments. Hence Colbert[6] in concluding his new interpretation of this supposed Jurassic labrinthodont states "there will have to be more definite evidence than is afforded by the single specimen of *Austropelor wadleyi* to justify the extension of the labyrinthodont amphibians into Jurassic sediments". The discovery of the Kolane amphibian has provided the evidence that Colbert sought.

Not only does this specimen extend the range of the Labyrinthodontia to the upper Lower Jurassic but it also extends the occurrence of the Brachyopidae through the Middle and Upper Triassic, and the Lower Jurassic.

I thank Dr Mary Wade of the Queensland Museum, Mr and Mrs Colin Kehl of Kolane, Queensland and the Australian Research Grants Committee.

Influence of temperature on cyanogenic polymorphisms

CYANOGENIC glucosides occur widely in the plant kingdom, and in species which are polymorphic for their presence or absence they probably have ecological significance. The cyanogenic morphs may be relatively unpalatable to grazing animals[1-3] and consequently have an advantage where grazing pressure is significant[4]. Cyanogenic morphs of *Trifolium repens* and *Lotus corniculatus* are relatively rare at high altitudes, and in Europe their distribution correlates with the January 5 °C isotherm[5]. It has been inferred that where low temperatures and frost are frequent, cyanogenesis confers a reduced physiological fitness, but this aspect of the polymorphism has received less attention and has not been established experimentally. A marked difference between the morphs in their response to artificial cold treatment is shown by the data reported here, together with evidence that this difference is significant in natural conditions.

Samples from the scarp slope of the Ochil fault line in the Forth Valley, Scotland, show the effect of altitude on the frequency of cyanogenic forms of *T. repens* and *L. corniculatus* (Table 1). At each site 100–150 plants were sampled, each a minimum of 1 m apart, and tested for the simultaneous presence of cyanogenic glucosides and β-glucosidase by the picrate paper test[6]. In both species the frequency of cyanogenics decreases as altitude increases; *L. corniculatus* is absent from the valley floor in this area. That it is selection which produces this distribution can be seen by comparing the seed and adult populations. *L. corniculatus* seed was collected at each site from 100 individuals, mixed and sown in garden plots. From each plot 250 individuals were selected randomly after 6 weeks growth and tested as before. Table 2 shows that in the highland site selection operates strongly against the cyanogenic morph and in the lowland site, to a lesser extent, against the acyanogenic morph. Selection probably operates through temperature, and so its effect was tested by placing individuals of both types at +5° C and then lowering the temperature, over 2 h, to −3 °C. After 1 h at −3 °C plants

were removed to 20 °C for 30 min and tissue was sampled at 12-h intervals. The rate of respiration of excised tissue was measured in Warburg manometers, in the dark, at 25 °C. Oxygen consumption, measured as μl of oxygen per h per g dry weight for each 12-h period was expressed as a percentage of the oxygen consumption of the same plant in the 12 h preceding treatment. Control plants received identical treatment but were maintained at 20 °C. Table 3 gives the mean values, with standard errors, of three experiments in each of which different plants were used—12 individuals altogether. Damage resulting from the cold treatment caused a marked increase in the oxygen consumption of both types, but after 48 h acyanogenics were respiring normally whereas the respiration of cyanogenics decreased below the control levels within 24 h and continued to decrease thereafter. In all individuals the treatment caused the plants to wilt, but death of all above-ground shoots occurred only in some cyanogenics; acyanogenics recovered.

Selection therefore is shown to operate against cyanogenic forms at increasing altitudes, and temperature is probably the specific factor. The interplay of temperature effects with differential grazing probably maintains the polymorphism and governs the ecology of the morphs in some areas.

Importance–value curves and diversity indices applied to a species-rich heathland in Western Australia

RANKING of species in a community from most to least important (abundant) to yield an 'importance-value' (*I–V*) curve is a device often used by ecologists to elucidate features of that community. Increasingly in the literature[1-5], an *I–V* curve which obeys the lognormal function is being accepted as describing the ultimate in plant species diversity. South-western Australia is renowned for its apparent floristic richness and high degree of endemism. An ecological study of sand heath, considered by botanists the major repository of this supposed 'incredible richness'[6,7], has revealed a type of *I–V* curve not previously noted for vegetation. The values for six of seven indices of species diversity examined were as high as, if not higher than, those for the most diverse communities previously recorded, including the richest of tropical rainforests[2,4,8-10]. All earlier indices of equitability (evenness of species' importance) are based on models of limited applicability and a new index, based on the actual slope of the *I–V* curve, is proposed here.

The study site, situated 15.5 km south of Eneabba (29°50′S, 115°15′E), was studied in mid-spring 1975. The vegetation was low open heath[11], consisting of nanophanerophytes (68%), hemicryptophytes (20.3%), chamaephytes (5.8%) and geophytes (5.8%)[12] and had been burnt about 7 yr before. According to Raunkiaer's leaf classes, 52.6% of the species were leptophylls, 26.3% nanophylls, 18.2% microphylls and 1% were mesophylls. The average growing season for agricultural plants in the area is 4 months. The soil was highly impoverished sand over yellow clay–loam at 50–60-cm depth in a shallow valley. A representative 1,500-m transect was run across the valley and 10 equi-spaced sectors, each consisting of an average of 50 contiguous 1-m² quadrats, were examined. The 13,066 individuals encountered were assigned to 172 species and their number and canopy cover class[13] in each quadrat were noted. The total of 500 quadrats contained more than 96% of the species present

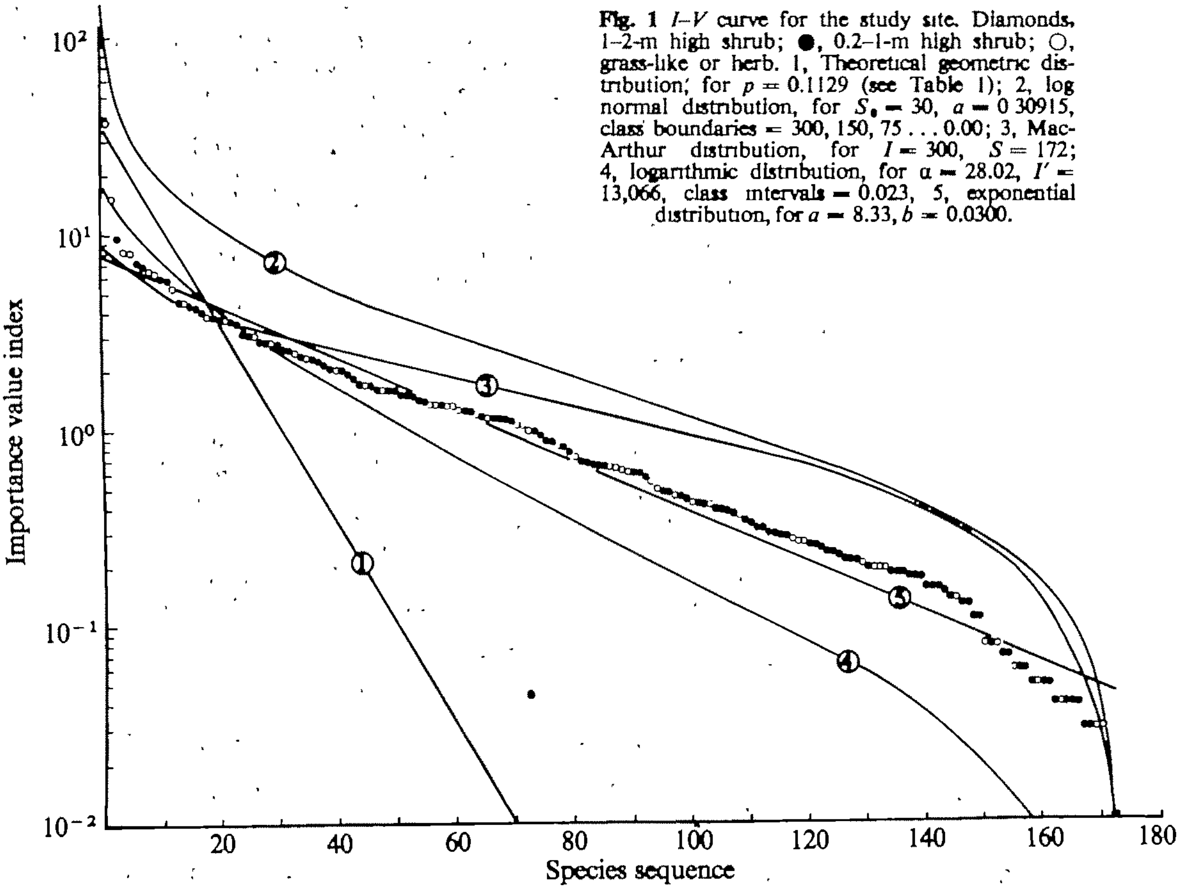

Fig. 1 *I–V* curve for the study site. Diamonds, 1–2-m high shrub; ●, 0.2–1-m high shrub; ○, grass-like or herb. 1, Theoretical geometric distribution; for $p = 0.1129$ (see Table 1); 2, log normal distribution, for $S_0 = 30$, $a = 0.30915$, class boundaries = 300, 150, 75 . . . 0.00; 3, MacArthur distribution, for $I = 300$, $S = 172$; 4, logarithmic distribution, for $\alpha = 28.02$, $I' = 13{,}066$, class intervals = 0.023, 5, exponential distribution, for $a = 8.33$, $b = 0.0300$.

in a 150-ha area about the transect, though this low heath extends, with some taxonomic changes, for hundreds of km².

Species' importance was based on the importance value index (IVI) of Curtish and McIntosh[14-16], as follows:

$$I_r = 0.1\sum_1^{10}\left(\frac{100f_r}{\Sigma_1^S f_i}+\frac{100d_r}{\Sigma_1^S d_i}+\frac{100c_r}{\Sigma_1^S c_i}\right)$$

where I_r is the mean IVI of the rth species for the ten sectors, f is the frequency of occurrence in the 50 quadrats, d is the number of individuals per sector, c is the total canopy cover per sector and S is the number of species in the sector. From this formula, the total importance value $(I) = \Sigma I_i = 300$. Though mathematically questionable, this measure was chosen to avoid bias in the exclusive use of any one index of abundance.

In Fig. 1, four mathematical distribution models often used to interpret empirical *I–V* curves have been superimposed on the data obtained for the study site. As expected from its low level of species' dominance, the vegetation had little in common with the geometric distribution[17] ($P<0.001$, Table 1). Though the lognormal curve[18] had a similar shape to the *I–V* curve, the importance of any species was always considerably less than predicted by this distribution ($P<0.001$) due to the leftward displacement of the modal interval. The presence of the complete untruncated curve using the lognormal model, however, confirms that the samples provided a good estimate of the number of species in the community[19]. The MacArthur

Table 1 Goodness of fit of various mathematical models to the *I-V* curve for the study site

Distribution	Formula	χ^2 value*	P	D_{max}†	P
Geometric	$\hat{I}_r = I_1(1-p_1)^{r-1}$	∞	<0.001	0.4134	<0.001

Exponential ($S_{10\%+1}-S_{90\%-1}$)	$\hat{I}_r = a\exp(-bS_r)$	0.57	>0.05	0.0100	>0.05

$\hat{I}_r$ = estimated IVI for the rth species, $p_1 = I_1/\Sigma I_i$, $\Delta\hat{S}_R$ = estimated number of species in an IVI interval R intervals from the modal interval with S_0 species, S = total number of species in the collection, a = constant (I_0), b = constant (slope), $S_r = r$, $\Delta\hat{S}'_R$ = estimated number of species in an IVI interval corresponding to R individuals, $\alpha = S/\log_e(1+I'/\alpha)$ where I' = total number of individuals.

*χ^2 test on 170 d.f., $\chi^2_{0.05} = 201.14$, $\chi^2_{0.001} = 233.80$.

†Kolmogorov–Smirnov test: $D_{0.05} = 0.0959$, $D_{0.01} = 0.1191$, $D_{0.001} = 0.1343$ on 172 d.f.

distribution[20] gave a very close fit, particularly when I_1 was omitted ($P > 0.05$), though its 'characteristic' slope was flatter. Features in common between expectations from the MacArthur model and trends in the heath vegetation are a homogeneous habitat, species related taxonomically (taxocenes) and structurally (synusiae), and populations stable and long-lived (no annuals were present)—all suggesting lack of dominance and strong competition for resources[5]. Points of disparity are the views that the model is only applicable to limited numbers of animal species in communities of limited extent[5].

By substituting number of individuals (I'_i) for I_i as the measure of importance it was possible to consider Fisher's logarithmic distribution[21]. This gave the closest fit of the four classical curves ($P > 0.05$), though its 'characteristic' slope was steeper. The model assumes that additional individuals encountered include previously uncollected (rare) species in preference to previously collected (common) species, highlighting, in this case, the large number of species of low relative importance. The model implies a spatially unlimited community, such that further sampling would have included progressively more species which, as already stated, would not have occurred in the present case. Even in the final category ($I'_i = 1$, $I_i = 0.00$–0.035) there were five rather than the 28 species predicted by the logarithmic function. Though lacking a theoretical basis at present, the best fit to the 'characteristic' slope of the I–V curve was provided by the truncated exponential distribution. Omission of the first and last 10% of species gave a near perfect fit (linear regression gives $r^2 = 0.992$), with implications for measures of diversity discussed below. The applicability of the total exponential curve was limited by its failure to change slope at the tails of the I–V curve, though the fit was still close ($r^2 = 0.971$).

The reason for the poor fit of the lognormal curve may be that the heath vegetation was not as rich as expected. But using Gleason's index, based on the species–area curve[22], the study site compared favourably with a tropical rain forest in Central Malaya (". . . the richest community ever recorded")[8] (Table 2). The figure for the rain forest was achieved with a much greater area (22.3 ha), far fewer individuals (2,629)—and hence a much higher Williams index[21], and almost at the opposite end of the life-form spectrum. The inverse of Simpson's index[23], based on the geometric function, and the Shannon–Wiener index[24], based on the severe restrictions of information theory and tending to 'downplay' differences in species-rich communities[5], had values in excess of a "species-rich" tropical forest in the Panama Canal Zone (". . . among the highest (H' values) ever reported for any community")[9]. The log-cycle equitability index[5], based on the geometric model, was more than twice that for a swamp-heath with "a remarkably high species richness" in south-eastern Queensland[10]. Whittaker's equitability index[4], based on the lognormal distribution, was more than four times that for the most diverse site along a 730–2,766 m gradient in south-eastern Arizona. Clearly, the present study site had 'surpassed' a lognormal relationship to reach a linear-sigmoid curve more related to the MacArthur or logarithmic models.

The restricted theoretical applicability of the usual measures of equitability described above, and the dissimilar slopes of the fitted theoretical distributions to that of the I–V curve under study, indicate the need for an index that more truly reflects the characteristic slope of the I–V curve and is not bound to particular community models. An inspection of 40 I–V curves in the literature[1,2,4,5,25,26] showed that, in addition to the present I–V curve, all sets of data would fit an exponential curve, especially if the first and last 10% of data were omitted. The remaining 80% have a slope (b) which can be determined from $I_r = a \exp(-b\ S_r)$. Then the characteristic slope equitability index (E_b) is given by

$$\Delta S/\Delta\log_{10}\hat{I} = (S_{90\%-1} - S_{10\%+1})/(\log_{10}\hat{p}_{10\%+1} - \log_{10}p_{90\%-1})$$

$$= 1/0.434b$$

(see Tables 1 and 2 for the meaning of the symbols).

The arguments for omitting the first and last 10% of the data are essentially that they describe slopes that may be quite different from the characteristic slope; their component species are unlikely to be characteristic of (restricted to) that community, and their slope generally shows little variation between communities fitting quite different I–V models. Indeed, a fuller description of the community might include the best fit lines of the three slopes, though this would seldom provide more information than E_b alone. Within the limits discussed here, the average concentration of importance for the first 10% of data ($\Sigma_1^{S_{10\%}} p_i^2/S_{10\%}$) may be informative for certain purposes. On the same basis, the last 10% of data should indicate the degree of rarity of the least common species in the community. But the presence/absence of species in the last 10% is very dependent on sample size, some ecologists even being reluctant to quantify at this level[26,27].

Table 2 Values of various indices of species diversity for the study site and other species-rich communities

Index	Formula	Study site	Previous highest	Reference
Gleason's	$\frac{S}{\log_{10}A}$	64.10 (Sector$_{10}$ = 69.2)	67.87	8
Williams	$\frac{S}{\log_e\left(1+\frac{I'}{\alpha}\right)}$	28.02 (Sector$_{10}$ = 37.4)	114.2	8
Simpson's (inverse)	$\frac{1}{\Sigma_1^S p_i^2}$	38.77	34.48	9
Shannon–Wiener	$-\Sigma_1^S p_i\log_2 p_i$	6.12	5.86	9
Log-cycle	$\frac{S}{\log_{10}p_1 - \log_{10}p_s}$	48.73	23.10	10
Whittaker's	$\frac{S}{4\sqrt{(\Sigma_1^S(\log_{10}p_i - \log_{10}\bar{p})^2/S)}}$	54.90	11.90	4
Characteristic slope	$\frac{S_{90\%-1} - S_{10\%+1}}{\log_{10}p_{10\%+1} - \log_{10}p_{90\%-1}}$	86.73	≃41.64	2

See Table 1 for meaning of symbols. In addition, A = area in m², $\log_{10}\bar{p} = \Sigma\log_{10}p_i/S$, $p_{10\%+1}$ = estimated p (or I) for the (10% + 1)th species from the truncated exponential curve fit in Table 1.

Using Whittaker's criteria of a good diversity index[5], E_b can be considered relatively independent of sample size—rare species do not influence the slope, and the effect of any overestimation of importance of dominants in small samples is minimised. Sampling error is low—80% of the species collected contribute to the index, standard regression analysis can be used to determine the level of sampling error and dispersion about the mean is minimised by removing the tails. E_b is conceptually meaningful—it is literally (the inverse of) the slope of the best fit line; the numerator is based on the total number of species and hence the formula also gives the relationship between richness and equitability. It is suitable for any taxocene or measure of importance, and its inverse-slope character enhances its sensitivity to changes in evenness.

E_b for the study site was more than twice that for a naturally regenerated deciduous forest in southern Illinois of "exceptionally high species diversity"[2]. Unlike the latter site, there was little evidence of vertical heterogeneity or creation of microhabitats in the heath vegetation that could explain its much greater diversity. Certainly the small life forms, open canopies and similar resource requirements would encourage close packing of these slow-growing perennials with minimal opportunity for dominance. This would be enhanced by proneness of the site to fire, drought and severe leaching. In addition, the site's location in a conjectured 'centre of diversification' of the south-western flora[28]—45% of the species belonged to a mere three families—would provide a large pool of coloniser species. Assuming that fluctuations about the present climate have occurred here in the past, this proposition is consistent with Stebbins' argument[29] that speciation is most favoured in transition zones between xeric and mesic or tropical environments.

Reciprocal altruism in *Papio anubis*

ALTRUISM is behaviour that benefits another individual at some cost to the altruist, costs and benefits being measured in terms of individual fitness. 'Reciprocal altruism' (ref. 1) implies the exchange of altruistic acts between unrelated individuals as well as between relatives. If the benefits to the recipient of an altruistic act exceed the costs to the altruist, and if the recipient is likely to reciprocate at a later time, then the cumulative benefits for both individuals will have exceeded the cumulative costs of their altruism. Natural selection would favour individuals that engaged in reciprocal altruism if they distributed their altruism with respect to the altruistic tendencies of the recipient, preferring individuals that were most likely to reciprocate and excluding nonaltruists from the benefits of further altruism. This model has been difficult to test because it is usually impossible to be certain that an example of altruism is not the product of 'kin selection'[2]. The genetic relationships between individuals in animal populations are seldom known and reciprocal altruism can only be cited when it can be found to occur regularly between unrelated individuals. I report here that altruistic behaviour involving the formation of coalitions among male olive baboons (*Papio anubis*) fulfils the criteria for reciprocal altruism.

Eighteen adult male *P. anubis* in three troops at Gombe National Park, Tanzania were studied for more than 1,100 h, between May and December 1972 and from June 1974 to May 1975. All data were collected on a focal sample basis[3]. Focal individuals are referred to as 'targets'. Each animal was observed regularly for a fixed period. Observations were made on foot at 5–10 m from the animal. Baboon studies have been in progress since 1967 and data concerning blood relationships and dates of transfer between troops are available. All males leave their natal troop at Gombe, and the males who breed within a particular troop are those that have transferred into that troop from elsewhere[4]. Males known or thought to have transferred into their troop of residence are termed 'adult males'. Sexually mature males still residing in their natal troop are 'natal males'. During the study, there were three, six to eleven, and eight to eleven adult males in the respective study troops.

The effectiveness of temporary coalitions of adult male *Papio* spp. during aggressive interactions against a single opponent has been described in *P. anubis*[5] and in *P. ursinus*[6]. Encounters between coalitions and single opponents in *P. cynocephalus* did not seem to affect subsequent dyadic encounters between a coalition member and the opponent[7]. Ransom noted that coalitions of *P. anubis* at Gombe were generally formed by one male enlisting a partner to help fight against an opponent[8]. The partner had not been involved directly in the encounter with the opponent before his enlistment. Coalitions were sometimes formed in attempts to separate an opponent from an oestrous female. *P. anubis* form exclusive consort pairs lasting for up to several days. If the female became available after such an attempt, she could be taken by only one of the two coalition partners.

Attempts at enlisting a coalition partner are referred to as 'soliciting'—a triadic interaction in which one individual, the enlisting animal, repeatedly and rapidly turns his head from a second individual, the solicited animal, towards a third individual (opponent), while continuously threatening the third. The function of headturning by the enlisting animal is to incite the solicited animal into joining him in threatening the opponent. An 'occasion' of soliciting is a bout of the behaviour followed by a gap of more than 10 s. The distribution of the number of 'occasions' of soliciting to the same partner per observation period was tested against a cumulative binomial distribution and did not differ significantly from expected values. Therefore, 'occasions' of soliciting are considered to be statistically independent from each other. For every occasion that soliciting involved the target male during an observation period, the identity and actions (enlisting, solicited, or opponent) of each participant were recorded. 'Occasions' were not recorded consistently in 1972, so data from that period are not included in measures of frequency. Although coalitions occasionally formed spontaneously, only those that resulted from soliciting are considered.

There were 140 examples of one adult male soliciting another during the 1974–75 study period. Soliciting resulted in coalitions on 97 occasions. On 20 occasions the opponent was consorting with an oestrous female and adult males were more likely to join a coalition if the opponent was in consort (2 × 2 $\chi^2 = 5.91$, $P < 0.02$, $n = 140$). On six occasions during both study periods the formation of a coalition directed against a consorting male resulted in the loss of the female by the opponent. In all six cases the female ended up with the enlisting male of the coalition ($P = 0.032$, two-tailed, sign test); the solicited male generally continued to fight the opponent while the enlisting male took over the female. In each of those cases the solicited male risked injury from fighting the opponent while the enlisting male gained access to an oestrous female. In most other examples of soliciting, no resource appeared to be at stake. The greater willingness to join a coalition against a consorting male may be related to the greater benefits that the altruism bestows on the recipient in those cases.

Thirteen different pairs of males reciprocated in joining coalitions at each other's request on separate occasions. These pairs comprised 12 different males. In six of these pairs, both pair members successfully enlisted their partner against the same opponent. Individual males which most frequently gave aid were those which most frequently received aid. There was a strong correlation between the frequency with which adult males joined coalitions and the frequency with which they successfully enlisted coalition partners ($\hat{\rho} = 0.84$, $z = 2.87$, $P < 0.004$, Kraemer test[9] based on Spearman correlations).

Each male tended to request aid from an individual who in turn requested aid from him. Using only one occasion of soliciting per pair per observation period (since spatial patterns are relatively stable), the distribution of soliciting by each of the 18 target males was examined to find which other male each target solicited most often, that is, his 'favourite partner'. Only the ten targets who solicited other males on four or more occasions were included. After the favourite partner was found for each target male, the distribution of soliciting by each partner was similarly examined. For nine out of ten target males, the favourite partner in turn solicited the target male more often than the average number of occasions that the partner solicited all adult males in their troop ($P = 0.022$, two-tailed, sign test) (Table 1). These results suggest that preferences for particular partners may be partly based on reciprocation.

It is difficult to test whether a non-altruist is excluded from further altruistic exchanges; a refusal to join a coalition in any given instance may occur because the costs to the potential altruist on that occasion are particularly high. There is evidence, however, that adult males are more likely to join coalitions with individuals which in turn would be able to help them. Females and juveniles ('non-males') solicited adult males 12 times, but adult males never solicited 'non-males' ($P < 0.001$, two-tailed, sign test). Adult males were less likely to respond to the solicitings of 'non-males' than they were to other adult males (2 × 2 $\chi^2 = 7.76$, $P < 0.01$, $n = 152$), even though 'non-males' solicited adult males against other 'non-males' far more often than adult males solicited other adult males against 'non-males' (2 × 2 $\chi^2 = 43.76$, $P < 0.001$, $n = 110$). Adult male baboons are very much larger than either adult females or juveniles, so that even though the aid of an adult male to a 'non-male' would generally incur small costs to the adult male, the benefits to the male from having a 'non-male' partner would be trivial, since a 'non-male' could not provide effective help in an encounter against another adult male and an adult male would not need help in fighting a 'non-male'.

The adult males in the troops studied transferred into their troop of residence singly[10]. The origins of many males entering a study troop were not definitely known, so it was impossible to determine the precise degree of relatedness between most adult males. The previous troop and dates of transfer of each male were known, however. In 4 of the 13 reciprocating pairs, both partners were first observed as young adults in different troops when they probably had not yet transferred for the first time. They did not reside in the same troop for another 5 yr. One pair not included earlier comprised an adult male and a 'natal' male which were known to have been born in separate troops. Although there is no proof that any of these individuals are completely unrelated, it is unlikely that they are close relatives.

Table 1 Soliciting activity of favourite partners of target males

FP, favourite partners.

In contests between a coalition and an opponent a previously uninvolved partner may benefit the enlisting male by reducing the latter's risk of injury in fighting the opponent. (Although only one male has been known to die from wounds received in a fight since 1967, non-fatal wounds are common.) By participating in a fight in which he would not have been otherwise involved, his aid will have been at some cost to himself. Whether or not the benefits to the recipient exceed the costs to the altruist (as required by the model) is difficult to determine. But, for the opponent, the potential costs in facing two males simultaneously rather than only one might be so much greater that it would often be to his advantage to avoid the coalition without fighting. If so, then the actual costs to the altruist are less than the reduction in costs to the enlisting male since the enlisting male would then be less likely actually to fight the opponent. When the formation of a coalition involves gaining access to an oestrous female further benefits are involved. Coalitions are the most common way of aggressively taking over an oestrous female from a consorting male at Gombe (D. A. Collins, in preparation). During the reproductive life of a male, which extends over 10 yr, there may be a large number of situations where it would be advantageous to enlist a coalition partner in an encounter against a consorting male. The number of offspring that a male sired as a result of participating in reciprocating coalitions would be greater than if he did not, while his lifespan would probably not be appreciably shortened by aiding coalition partners.

There are probably occasions when altruism is not involved. For example, the solicited male may sometimes join a coalition when there is a prospect of immediate benefit to himself. In such cases, explanations of the animal's behaviour are not necessary; the behaviour is not detrimental to his own fitness. The occurrence of genuine altruism, however, seems to be common enough to demand an alternative explanation.

I thank J. Goodall and the government of Tanzania for making this research possible, and T. H. Clutton-Brock, D. A. Collins, P. H. Harvey, H. C. Kraemer, J. Maynard Smith, A. E. Pusey, and R. W. Wrangham for advice. Field work was supported by grants from the Ford Foundation and the W.T. Grant Foundation.

Sound as a host-detection cue for the soft tick *Ornithodoros concanensis*

Two parasitic flies are attracted to their invertebrate hosts by sound: a tachinid, *Euphasiopteryx ochracea*, is attracted to field crickets by their song[1] and a sarcophagid, *Colcondamyia auditrix*, orients acoustically to cicada song[2]. We now report that an acarine, the argasid tick *Ornithodoros concanensis*, makes use of the vocal sounds of a vertebrate host as a cue in its host-finding behaviour.

Recorded vocalisations of nestling cliff swallows and electronically generated sounds of specific frequencies were used to test responses of unfed and engorged nymphs of *Ornithodoros concanensis*. Specific frequencies and their pattern of modulation were selected for testing after sonographic analysis of the recorded nestling vocalisations. Dominant sounds produced in the calls were in the 3,000–8,000-Hz range. Three frequencies (3,000, 5,200 and 8,000 Hz) prevalent in the nestling vocalisations and additional sounds above (12,000 and 15,000 Hz) and below (500 and 1,000 Hz) these levels were selected for testing. During experiments the generated sounds were modulated to a pulse repetition rate of one per s and a duration of 140 ms to approximate the pattern of nestling vocal emissions. Sound intensities for all generated frequencies and the recorded nestling sounds graded down from 62–66 dB on the edge of the stage proximal to the speaker (8 cm from the speaker) to 61–64 dB at the centre (19 cm from the speaker) to 60–62 dB at the distal edge of the stage (30 cm from the speaker). Control experiments were done with the speaker turned on but without taped bird sounds or output from the oscillator. The stage consisted of a circular paper grid (22 cm diameter) on a piece of 2.5-cm thick styrofoam. The loud speaker was positioned 8 cm from the stage and its base rested on a 2-cm thick polyurethane foam pad. The stage and speaker were enclosed within a rectangular sound arena (69 cm long, 24 cm wide and 31 cm high) constructed of 10-cm thick porous polyurethane foam. A diffuse light centred 150 cm above the stage generated light of less than 0.22 mlm cm^{-2} on the stage surface. During trials the temperature on the stage was 26.6 ± 1 °C and the relative humidity ranged from 15 to 18%. Before use in an experiment, ticks in individual vials were maintained for at least 6 weeks after feeding at 85% relative humidity, 25 °C, and in a 24-h light cycle with 14 h of light. Trials were begun 2 h after the onset of darkness. To initiate a trial the vial containing a tick was inverted gently and the tick was allowed to fall on to the centre of the stage. Tick movements were observed and the point at which each tick left the circular stage was recorded on a data sheet. At the conclusion of a trial a data-set resembled one of the plots in Fig. 1. The mean number of ticks used in each trial was 22. The numbers tested at each frequency and in controls are shown in Table 1, together with a summary of statistical analysis. Rayleigh's test[3] was used statistically to evaluate whether the circular dispersion of the ticks was non-random.

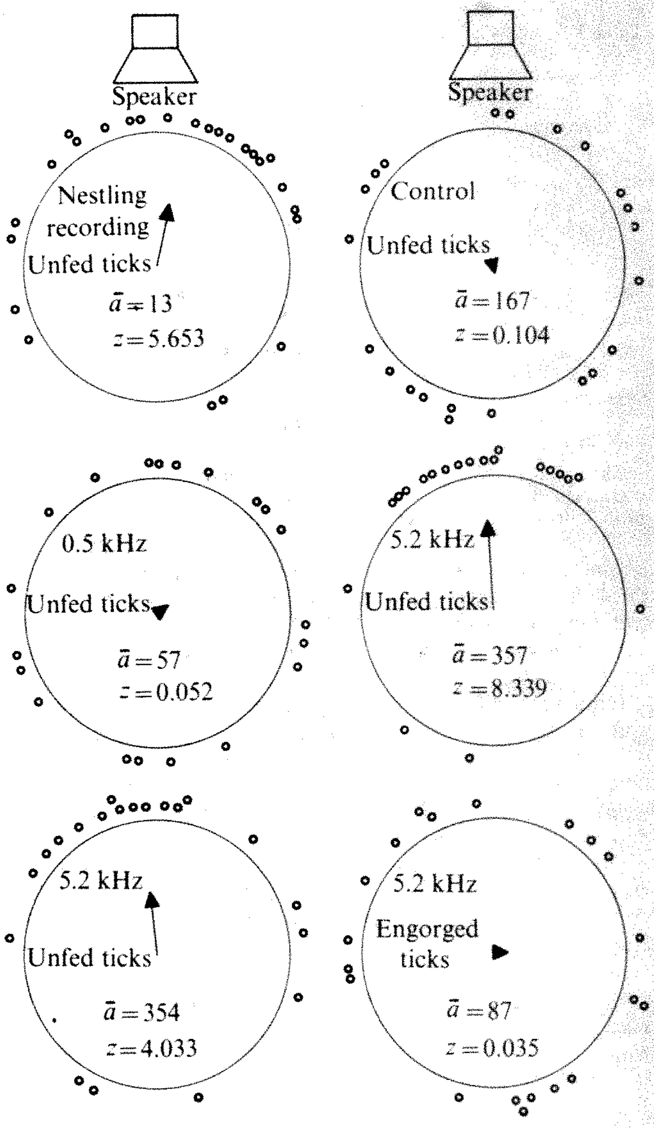

Fig. 1 Selected examples of the dispersal of ticks illustrate their tendency to move toward a speaker generating specific sounds. The small circles represent the positions to which ticks moved after being released in the centre of the circular stage. Symbols relating to the circular distribution analysis are: $\bar{a}$ = the mean angle vector; z = Rayleigh's critical value; and the length of the vector indicates the amount of relative circular dispersion of the group of ticks. Tape recordings of nestling cliff swallows were made with a Panasonic tape recorder (RQ-209-DAS) and a Panasonic dynamic microphone. The tape recordings were analysed with a Kay sonograph 6061A spectrum analyser. Specific sound frequencies were generated with a Hewlett–Packard Model 200 CDR wide range oscillator, a Grass S-5 stimulator, and a Grass AM-4 a.c. audio monitor. The Oxford loudspeaker (8.9-cm, 3.2 Ω) that was used has a frequency response of 50–15,000 Hz. Light intensity was measured by a Weston Model 76 illumination meter. Sound intensities were measured with a Type 2203 Brüel and Kjaer precision sound level meter.

In experimental trials unfed nymphs demonstrated a significantly pronounced movement toward the speaker when the recording of nestling sounds was played and when the frequencies within the nestling sound range (3,000, 5,200 and 8,000 Hz) were generated. Such movements were not seen with trials involving 500, 1,000, 12,000 and 15,000 Hz nor in control trials of unfed ticks (Table 1). After being released on the centre of the stage, unfed ticks characteristically would remain akinetic for 3–5 min. Positively responding ticks would then orient toward the sound source before proceeding forward with movements involving wavy or zigzag deviations from a straight line. From our results it was not possible to determine whether the pattern of orientation is a klinotaxis or a tropotaxis. A few ticks responded with pronounced turning suggestive of a klinokinesis. During trials involving the sounds to which ticks responded positively, it often seemed that the first pair of legs contracted in synchrony with each sound pulse from the speaker. By directing the modulated sounds of specific

Table 1 Analysis of tick responses to generated sound frequencies and recorded host vocalisations

Frequency (Hz)	Experimental trials No. of ticks	Experimental trials Probability	Controls No. of ticks	Controls Probability
Unfed				
500	21	NS	20	NS
1,000	19	NS	20	NS
3,000	23	$P < 0.001$	20	NS
5,200	20	$P < 0.001$	20	NS
8,000	30	$P < 0.05$	22	NS
12,000	21	NS	22	NS
15,000	20	NS	22	NS
Nestlings	25	$P < 0.005$	22	NS
Engorged				
5,200	20	NS	20	$P < 0.02$

The null hypothesis of a random distribution of ticks around the circle was accepted and the trial results were considered not significant (NS) if the probability was greater than the 0.05 level.

frequencies (for example, 3,000 Hz) at a tick being observed through a dissecting microscope, it was possible to confirm twitching or contracting of the first pair of legs with each sound pulse. This suggests a possible location of sound receptors in these appendages.

Immediately after observing a positive response of one group of unfed nymphs to 5,200 Hz, the ticks were fed on pigeons and individually retested at the same frequency. In contrast to the unfed ticks, engorged individuals were not temporarily akinetic when introduced to the stage, but immediately began to move. The pattern of dispersal of the engorged ticks was random.

Ornithodoros concanensis is a parasite of cliff swallows (*Petrochelidon pyrrhonota*), other birds and bats[4] associated with cliff and cave habitats in western North America. Concealed in the cracks and crevices during the day, the ticks move up the cliff face at night to obtain blood meals from cliff swallows roosting in their retort-shaped nests. Bird activity diminishes sharply at sunset but vocalisation in the nest continues during the night, particularly while young birds are present. Host-finding activity of unfed ticks begins 30 min to 1 h after sunset (approximately 2100 h), peaks 1–2 h later, and ebbs by 0100 or 0200 h. Experiments have indicated that nymphal *O. concanensis* are not stimulated by elevated concentrations of carbon dioxide that approximate normal (4–5%) or below normal levels of host-breath emission. Furthermore, host odour failed to elicit positive reactions and heat was important only at close range[5]. All indications are that sound is the principal cue used by *O. concanensis* for orientation to and location of host cliff swallows. After a blood meal is obtained the bird sounds are no longer attractive to the engorged tick and a combination of stimuli influences its movement out of the nest and back into a harbourage.

We thank H. B. Hartman, J. S. Mecham and L. M. O'Conner for aid and use of equipment and P. V. August for suggestions about biometric analysis. This investigation was supported by a grant from the US PHS.

Evidence for role of flagella as sensory transducers in mating of *Chlamydomonas reinhardi*

FLAGELLA and cilia are motility organelles of many cells. Modified cilia are present in most metazoan sensory cells[1], and mechanosensory transduction by cilia is found in many protozoans and some invertebrates[2]. The question arises as to whether flagella used primarily for motility also have sensory functions. In the unicellular alga *Chlamydomonas reinhardi*, flagella act as organs of motility. It has been observed, however, that flagellar contact initiates the mating process when gametes of opposite mating types are mixed[3–6]. We have been studying this phenomenon and report here observations on the role of flagella in initiating the mating reaction.

The mating process commences following the mixing of (+) and (−) gametes of *Chlamydomonas reinhardi*. Several physiological changes have been observed. These include cell wall lysis[4–6] and fertilisation tubule formation in the (+) gametes[5,6]. We have previously reported the accumulation of carbohydrates in a cell-free supernatant of mating cells, probably a result of cell wall lysis. The accumulation is specific and occurs only when live gametes of opposite mating types are mixed[7].

As shown in Fig. 1, there is a 45-min delay in carbohydrate accumulation if the gametes are deflagellated at the time of mixing. Flagellar regeneration in *Chlamydomonas reinhardi* has been well studied[8–11], but not in a mixture of

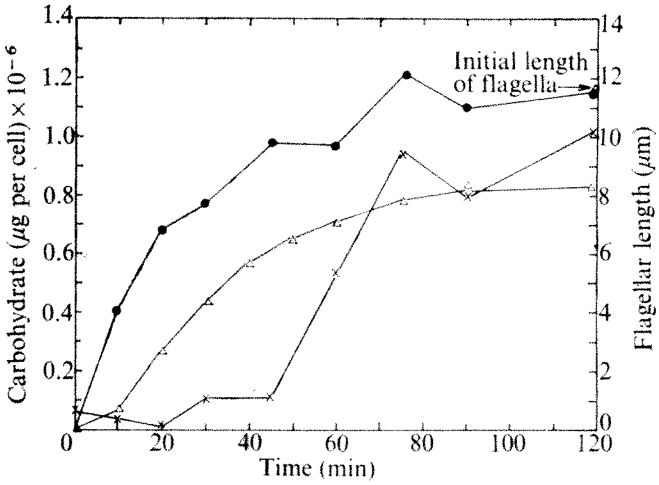

Fig. 1 Carbohydrate release and flagellar regeneration. *Chlamydomonas reinhardi* were grown as described before[7], except that they were on a 12-h light–12-h dark cycle. At time 0, active (+) and (−) gametes were mixed. The flagella of the experimental group were detached upon mixing using the *p*H method[12]. Deflagellation was accomplished by lowering the *p*H to 4.5 for 1 min with 10% acetic acid and neutralising with KOH. Detachment was followed with phase microscopy and more than 99% of the cells became deflagellated. Flagellar regeneration was observed in at least 90% of the cells which were deflagellated. The non-deflagellated control group had acetic acid and KOH added simultaneously. Samples of the cell suspension (1.6×10^7 cells) were taken at intervals and carbohydrate analysed in the cell-free supernatant as described before[7]. Flagellar regeneration was followed using the methods of Rosenbaum *et al.*[9]. It is interesting to note that after 2 h of regeneration, the flagella had reached only about 75% of their original length. For vegetative cells it has been reported that the flagella are 90% regenerated after 60 min[9]. We attribute the discrepancy to the fact that in our case, the cells are mating, and that during the actual cell fusion flagella grow slowly or not at all. ●——●, (+) and (−) gametes, non-deflagellated control; ×——×, (+) and (−) gametes, flagella detached upon mixing; △——△, flagella length in μm. Each point represents the average of two experiments.

mating gametes. To ascertain the relationship between flagellar length and initiation of mating, we monitored flagellar regeneration in a population of deflagellated mixed gametes. As indicated by the carbohydrate accumulation (Fig. 1), the mating reaction commences after the flagella have regenerated to more than 50% of their original length. Cells regain motility 25 min after deflagellation, and at this point the flagella are about 25% of their original length. There is, therefore, a delay of at least 20 min after the return of motility before carbohydrate accumulation can be detected. Thus, it seems that the limiting factor for mating is the length of the flagella, and that some sort of flagellar differentiation occurs when the organelles are about 50% regenerated. This maturation allows the organelle to act as a sensory transducer for the mating reaction.

An alternative explanation involves the lowered probabilities of gametic interaction when flagella are shorter than normal. This explanation is unlikely, however, for two reasons. First, the cells are at a very high concentration (2×10^7 cells ml^{-1}). Second, the 45-min delay in mating, as measured by carbohydrate accumulation, is present even if only one of the mating types is deflagellated and mixed with the opposite mating type. This implies that in spite of the increased likelihood of encounter resulting from the presence of full length flagella in one of the mating types, mating did not occur until the flagella from the deflagellated cells attained 50% of their normal length. The crucial finding is that the time delay in this situation was identical to the delay following deflagellation of both mating types.

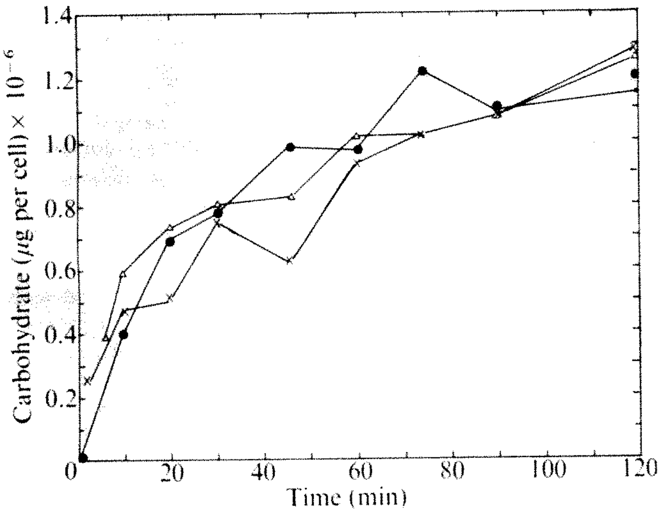

Fig. 2 Carbohydrate release and detachment of flagella. Conditions of cell growth, flagellum detachment and carbohydrate analysis are the same as in Fig. 1. At time 0, active (+) and (−) gametes of *Chlamydomonas reinhardi* were mixed. At 2 min and 4 min after mixing, aliquots were taken and deflagellated. At intervals thereafter, samples of the cellular suspension (1.6×10^7 cells) were taken and analysed for carbohydrate as previously described[7]. ●——●, (+) and (−) gametes, non-deflagellated control; ×——×, (+) and (−) gametes, flagella detached 2 min after mixing; △——△, (+) and (−) gametes, flagella detached 4 min after mixing. Each point represents the average of two experiments.

Figure 2 shows the effect of deflagellation at various times after mixing the gametes. It can be seen that cells deflagellated at either 2 min or 4 min after mixing continue in the normal time course of carbohydrates accumulation. Since the deflagellation procedure (a quick *p*H change—see Fig. 1) does not in itself induce the gametes, the lack of a delay in carbohydrate accumulation indicates that the flagella act as transducers within the first 2 min of mating.

From our data we can conclude that a signal responsible for initiating the mating process in the gametes of *Chlamydomonas reinhardi* is transmitted by means of the flagella. Without flagella that induction is delayed for 45 min, when the flagella have regenerated to more than one half their original length. This form of sensory transduction occurs within the first 2 min of mating, since the loss of flagella after that point does not inhibit the mating reaction as measured by carbohydrate accumulation. The reaction seems to be associated with the 'mature' tips of the flagella, and because of its specificity we assume it to be chemical. At this point, however, we cannot be specific as to the actual mechanism of the reception and transduction of the mating signal. The significance of this work lies in the fact that we have been able to demonstrate that the flagella of *Chlamydomonas reinhardi* are both organelles of motility and sensory transducers in the mating reaction.

Defective polymorphonuclear leukocyte function in a human periodontal disease

HUMAN periodontal diseases are the major cause of adult tooth loss. One such disease, localised idiopathic juvenile periodontitis (IJP) affects young people and is unusually severe, with a rapid progression. Previous studies have shed little light on the unusual susceptibility of some patients to this rare condition. Similarly, destructive periodontal syndromes have been described in patients with polymorphonuclear leukocyte (PMNL) dysfunction. We have measured two parameters of neutrophil function, chemotaxis and phagocytosis, and found that patients with IJP have significantly decreased PMNL function compared with healthy control subjects, but monocyte function remains unaffected in IJP. Reduced PMNL functions may contribute to the unusual susceptibility of patients to IJP.

Peridontal diseases are progressively destructive inflammatory processes affecting the supporting tissues of the teeth. By age 45 yr almost all individuals have periodontal disease; under age 45, a smaller but substantial part of the population is affected[1]. As periodontal diseases are accessible to study, they are excellent models for the investigation of host–parasite interactions in bacterial inflammatory disease.

Studies of IJP by many investigators have failed to establish any specific etiology[2] or account for the unusual susceptibility of certain individuals. A specific alteration in the host's protective response could explain the rapidly destructive character of this disease, but no major systemic involvement in such patients has been observed regularly. Therefore, any impairment in the host's protective response is likely to be subtle. Study of parameters of host resistance in patients with IJP, by sensitive procedures, may reveal mild alterations in protective response.

PMNL have been implicated in the inflammatory lesions of periodontal disease[3,4]. Patients with PMNL disorders such as cyclic neutropenia[5], agranulocytosis[6], and Chediak–

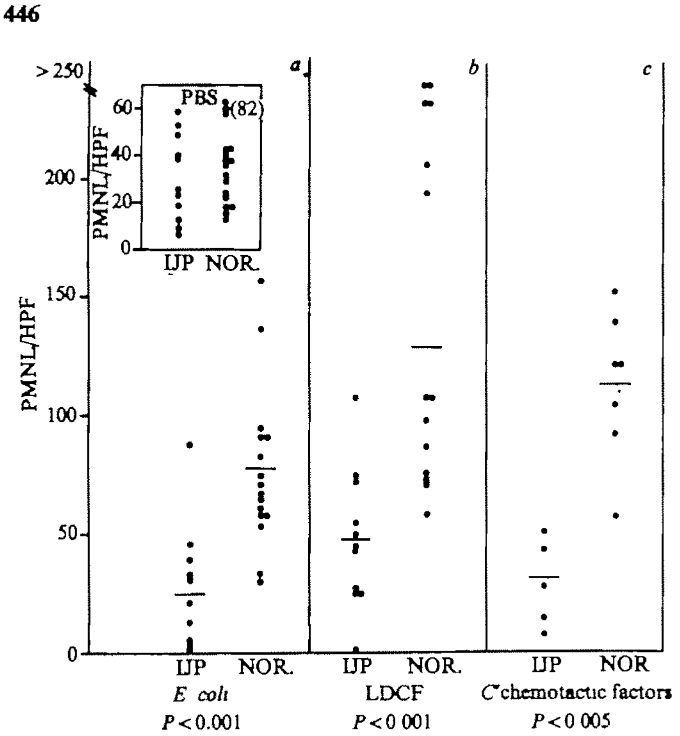

Fig. 1 Chemotactic response of PMN leukocytes (PMNL) from individuals with IJP compared to normal (NOR.) individuals. *a*, *E coli* 0127 was grown in trypticase soy broth for 18 h at 37 °C. The bacteria were removed from suspension by centrifugation and the culture filtrate was passed through a 0 20-µm filter. *b*, Leukocyte-derived chemotactic factor (LDCF) was prepared from a 48-h culture supernatant fluid of phytohemagglutinin-stimulated human peripheral blood mononuclear leukocytes. *c*, Chemotactic components of complement[18] were prepared by incubation (for 30 min at 37 °C) of 0 1 ml of fresh human serum with 0.9 ml of gelatin veronal buffer and 0.1 ml of a 1-mg-ml^{-1} suspension of lipopolysaccharide derived from *Salmonella typhimurium* (Difco). Each chemotactic preparation was divided into aliquots, used fresh or stored at −76 °C until used The chemotaxis assay was as described by Snyderman *et al*[12]. On any one day, responder cells prepared from peripheral blood of at least one individual with IJP were compared with responder cells prepared from one or more normal, age-matched subjects Leukocytes for each experiment were separated from erythrocytes by dextran sedimentation of whole blood Mononuclear cells and neutrophils were then purified from the leukocyte-rich plasma by Ficoll–Hypaque gradient centrifugation The neutrophils in the pellet were washed twice in 0.15 M NaCl buffered with 0.02 M sodium phosphate at *p*H 7 2 (PBS), and diluted with Gey's balanced salt solution (*p*H 7 2) to 2 5 × 10^6 cells per ml (personal communication from L. C. Altman). The neutrophils were placed in the top compartments and the chemotactic preparations or PBS (non-chemotactic negative control) were placed in the bottom compartments of modified Boyden chambers. The compartments were separated by a polycarbonate filter with 3-µm diameter pores (Nuclepore, Wallabs) The chambers were incubated for 30 min at 37 °C in an atmosphere of 5% CO_2 in humid air. The filters were then removed, stained, mounted on slides and viewed in a microscope. Cells migrating to the lower surface of the filter in 20 oil immersion fields were counted. Cell migration was expressed as the mean number of migrated cells per high-power field (HPF) for quadruplicate samples minus the mean background number of cells per field migrating towards a non-chemotactic (PBS) control. Data from IJP and normal subjects were grouped and compared by the Mann–Whitney U test Horizontal bars represent the arithmetic mean for each group

Higashi disease[7] show unusually severe loss of the supporting alveolar bone of the teeth. This may result from defective PMNL defence against oral bacteria. *In vitro* assays have shown leukocyte function to be reduced in many diseases. For example, Snyderman[8] has shown a defect in mononuclear leukocyte chemotaxis in patients with chronic mucocutaneous candidiasis. Defective PMNL chemotaxis is also associated with many disease conditions[9,10]. Gillman *et al.* reported a positive correlation between reduced neutrophil phagocytosis and susceptibility to middle ear infections in otherwise healthy individuals[11].

The subjects of our study were four males and five females in whom IJP was diagnosed as defined by the criteria of Kaslick[4]; three of the females were sisters. Diagnostic criteria, established by clinical and radiographic evaluation, included severe localised alveolar bone loss around the first molars and incisors of both maxillary and mandibular permanent teeth. Patients were 16–31 yr old (average 20.0 yr). Health status was established by a thorough medical history, a physical examination, and a battery of laboratory tests The results of the tests were always within established norms, and peripheral blood PMNL numbers were not different from those of a panel of normal subjects. Leukocyte differential counts were also within the normal range. All patients had a negative history of frequent or unusual illnesses and seemed in good general health.

Chemotaxis of PMNL and monocytes, and phagocytosis by PMNL were measured. Peripheral blood leukocytes were assayed simultaneously from patients with IJP and from normal subjects of similar age, sex and race. Samples from those with IJP were assayed on at least two separate occasions to demonstrate reproducibility of the observations. Chemotaxis was assayed using the modified Boyden chamber technique described by Snyderman[12], and phagocytosis was measured by the procedure of van Oss and Stinson[13].

When tested with *Escherichia coli* culture filtrate, leukocyte-derived chemotactic factor, and human complement-derived chemotactic factors[12], the polymorphonuclear leukocyte chemotactic response of patients with IJP was significantly less ($P<0.005$) than that of normal subjects (Fig. 1) By contrast, the chemotactic response of peripheral blood monocytes of IJP patients did not differ from that of the normal subjects No differences were seen between the groups in background PMN or monocyte cell migration against the non-chemotactant saline control.

Phagocytosis of opsonised *Staphylococcus aureus* by PMNL from patients with IJP and normal subjects was then compared (Table 1) All the subjects with IJP had depressed PMN phagocytosis as compared with normal controls. The contact angles formed by sessile drops of saline water on monolayers of PMNL (see refs 14 and 15) of patients and normal controls are also compared in Table 1 A higher contact angle, and thus a less hydrophilic surface of phagocytic cells is invariably accompanied by a decrease in phagocytic activity[15]. The differences in phagocytosis as well as in contact angles are significant at the 95% confidence level or greater with one exception. Leukocytes of two young patients with generalised periodontitis, clinically distinct from IJP, showed normal responses in assays for chemotaxis and phagocytosis

Thus there is a reduction in both chemotaxis and phagocytosis by PMN leukocytes in patients with IJP, although monocyte chemotaxis is normal In assays of the peripheral blood leukocyte blastogenic responses to phytohaemagglutinin and streptolysin 0 in these IJP patients, no obvious defects were found. More discriminating tests are in progress to assess cellular immunity more fully.

Lavine *et al.*[16] studied the response of PMNL from patients with early onset periodontitis to *E coli*-derived chemotactic factor, and concluded that PMNL from these patients are characterised by an intracellular defect in chemotaxis unrelated to serum inhibitory factors This disease entity was probably IJP, providing further evidence that such PMNL have defective chemotaxis.

Newman *et al.*[17] noted several distinct anaerobic Gram-negative rods, exhibiting surface translocation which seemed

*Average number of microorganisms (*Staphylococcus aureus*, opsonised with 1% human γ-globulin) phagocytised per granulocyte, ± s.e. All tests on patients and on normal controls that were done on the same day are displayed horizontally. The differences in phagocytic activities between patients and normal controls are all significant to $P < 0.05$, except for LB ($P = 0.11$). The differences between contact angles measured on patients' and normal controls' granulocytes are all significant to $P < 0.05$.

to be present in the lesions of IJP. Rats monoinfected with these organisms rapidly develop severe alveolar bone loss, so these bacteria may be potential pathogens. They may release factors that penetrate the ulcerated gingival epithelium and enter the systemic circulation. Such factors may affect PMNL, resulting in altered functions such as chemotaxis and phagocytosis. Studies are under way to test this hypothesis. Alternatively, pre-existing impairment in PMNL function may exist in persons with IJP, and proliferation of these unique organisms may result from this diminished host response.

We have demonstrated that a reduction in PMNL phagocytosis and chemotaxis is common to patients with IJP. Whether this reduction in host protective response is pre-existing or a result of the disease remains to be determined.

We thank Mrs Barbara Frank, Miss Susan Allen, Miss Constance Kowalski and Mrs Carol Wrzosek for technical assistance, and Miss Jane Brewer and Mrs Molly Carter for clinical assistance. Allotypes of mouse IgM immunoglobulin

GENETIC polymorphism of the structural genes encoding the class-specific (heavy) polypeptide chains of the immunoglobulin (Ig) molecules provides a useful set of markers for elucidating the arrangement and expression of these genes. On the basis of various antigenic, physiochemical and biological properties, the immunoglobulins of the mouse have been divided into eight distinct classes, IgM, IgD, IgA, IgG_1, IgG_{2a}, IgG_{2b}, IgG_3 and IgE, with a specific structural gene determining the heavy chain (H) for each class. Previous studies have documented the existence of a genetic polymorphism for five of these H-chain genes[1-3], with all the genes being closely linked constituting a heavy chain chromosome region. The most recent of these loci to be demonstrated (Ig-5, determining the δ chain)[3] was detected by the reaction of alloantisera prepared against spleen cells from mice differing in both *H–2* and allotype. These sera reacted with B lymphocytes of the appropriate allotype congenic strains, as assessed by either immunofluorescence, or cell surface iodination and polyacrylamide gel electrophoresis (PAGE). As most B lymphocytes express cell surface IgM as well as IgD (refs 4–6), we have further pursued these various approaches to identify Ig allotypes and have found a polymorphism of the heavy chain (μ) of murine IgM, a molecule found in pentameric form (19S) in serum, and in monomeric (8S) form on the surface of lymphocytes. This defines a locus, Ig-6, which encodes the μ chain of most mouse IgM immunoglobulin.

Alloantisera containing anti-IgM antibodies were raised in various strain combinations by two different methods. A small proportion of anti-allotype sera raised by repeated immunisation with pertussis anti-pertussis complexes[1], were found to contain antibodies to allotypic determinants on IgM molecules. However, the most effective antisera against IgM allotype have been raised by spleen cell immunisation (4–6 weekly injections of 10^7 spleen cells, with or without adjuvants) between strain combinations which differ in *H–2* type as well as allotype.

The binding capacities of these antisera against purified mouse immunoglobulins were assessed by radioimmunoassay[1] using purified ^{125}I-labelled mouse myeloma proteins[2]. Each labelled myeloma protein was more than 80% precipitable by the appropriate heterologous anti-mouse heavy-chain serum, while less than 10% was precipitated by all other anti-H-chain sera. The IgM proteins used were HPC-76 and MOPC104 (IG-6a) of BALB/c origin, and C.BPC112 (IG-6b) of C.B/20 (BALB/c Ig^b) origin (kindly provided by Dr M. Potter). The allelic designations for Ig-6

†Determined by radioimmunoassay as previously described[1].
‡Revealed by indirect immunofluorescence using a fluoresceinated goat anti-mouse IgG (refs 3 and 9).
§Analysis was by visual fluorescence microscopy and/or with a fluorescence-activated cell sorter (FACS).
Yes: almost all B cells were stained. No: few, if any, B cells were stained.
‖PAGE analysis of ^{125}I-labelled membrane protein precipitated by antisera[3].
Mouse strains used in these experiments are of the following allotypes: Ig^a-CBA, BALB/c, SJA, C57.Ig^a; Ig^b-C57BL/6, BAB/c.Ig^b (BAB/14 or C.B/20), SJL, CWB (C3H.SW.Ig^b).

are assigned as for other allotype loci according to the Ig-1 allele of the type strains in which they are found[2]. Thus, Ig-6a is from BALB/c and Ig-6b is from C57BL/6. The precipitating activity of such antisera against ^{125}I-labelled HPC-76 is shown in Fig. 1. Antisera GA20 and GA26 were both made in C57BL/6 (C57) against pertussis anti-pertussis (of CBA origin) complexes. Each contained anti-Ig-1a antibodies (Fig. 1*b*), but serum GA20 also contained anti-Ig-6a antibody (Fig. 1*a*). In contrast, the serum MA3 prepared in C57 mice against CBA spleen cells, contained no anti-Ig-1a antibody, but did contain anti-Ig-6a antibody (Fig. 1*a* and *b*).

The anti Ig-6a sera were specific since they did not precipitate an IgM myeloma of C.B/20 (Ig^b) origin, C.BPC112 (see Table 1). Their specificity was confirmed by inhibition studies in which no myeloma protein of other classes (IgA, IgG$_1$, IgG$_2$) inhibited precipitation of ^{125}I-labelled HPC-76. Furthermore, unlabelled HPC-76, MOPC104 and normal serum from BALB/c did inhibit this precipitation, although MOPC104 was considerably less effective in inhibiting than the other inhibitors.

Antisera to another IgM allotype, Ig-6a, were prepared in SJA (Ig^a) against spleen cells of Ig-1b positive strains BALB/c.Ig^b (BAB/14) or CWB (C3H.SW.Ig^b). These sera precipitated C.BPC112 but precipitated neither HPC-76 nor MOPC104 (Table 1). Inhibitions of precipitation were found with Ig-6b containing sera and not with Ig-6a containing sera or myelomas. Similarly, no non-IgM myeloma protein inhibited ^{125}I-C.BPC112 precipitation with these alloantisera (data not presented).

Close linkage of Ig-6 to the Ig heavy chain region is implied in the use of allotype congenic strains for antiserum testing. Anti-Ig-6a (for example, antiserum MA-3 in Fig. 1*c*) is inhibited in its precipitation of HPC-76 by serum from BALB/c (Ig^a) and not by serum from the congenic mice BALB/c.Ig^b (BAB/14) (Fig. 1*c*) nor from C.B/20 (data not shown) which have all the alleles of BALB/c except these closely linked to Ig-1. Since something more than 21 backcross generations are involved in the derivation of these strains (they are not completely independently derived), very close linkage is indicated for Ig-6 to Ig-1 and the other heavy-chain loci[2].

These results with radioimmunoassay analysis demonstrate that antisera prepared against either cell-surface 8S IgM or serum 19S IgM, are capable of binding to 19S IgM molecules. We have also shown by immunofluorescence, that these antisera can react with cell-surface 8S IgM. Spleen cells from 8-week-old BALB/c (Ig^a), BALB/c.Ig^b, SJL (Ig^b), or SJL.Ig^a (SJA) allotype congenic strains were treated with a 5–10% (v/v) concentration of the alloantisera, washed and then reacted with a fluorescein-conjugated goat anti-mouse γ_1 and γ_2 antiserum. The latter serum was

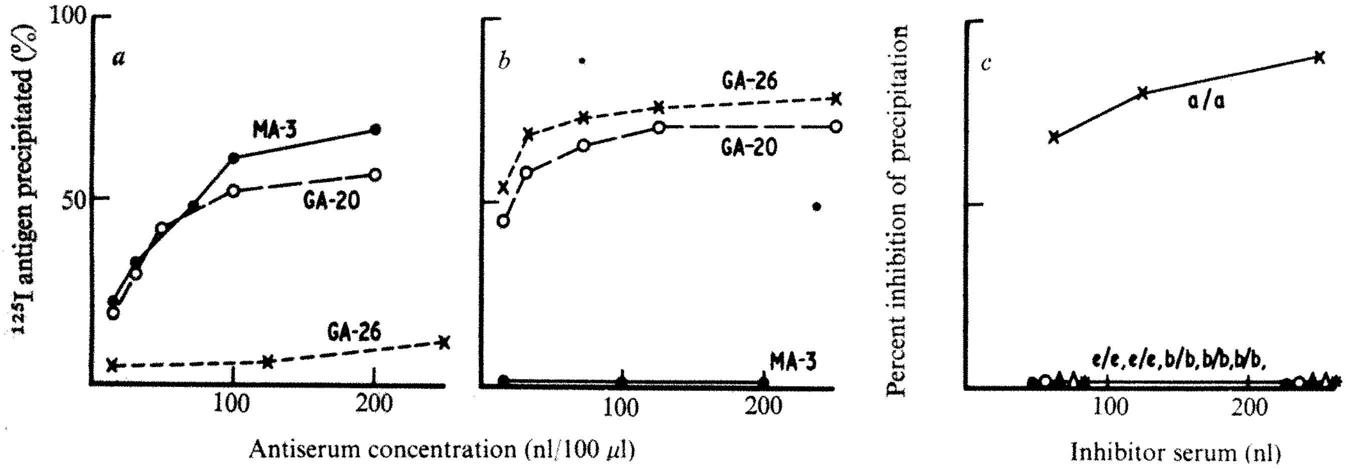

Fig. 1 Radioimmunoassay analysis of anti-Ig-6a antisera. The ability of alloantisera GA20, GA26 and MA3 to precipitate ^{125}I-labelled IgM (HPC-76 macroglobulin) or IgG$_{2a}$ (HPC-149) of BALB/c origin is shown in *a* and *b*, respectively, as the per cent precipitation of the labelled antigen against the amount of antiserum used. For panel *c* cell assays were performed in a volume of 100 μl with 5 ng of ^{125}I-labelled HPC-76 (Ig-6a). All inhibitor sera derived from 8-week-old mice of the following allotype congenic strains: BALB/c (Ig^a), BALB/c.Ig^b; C57BL(Ig^b), C57BL.Ig^e NZB (Ig^e), NZB.Ig^b. Note that the lack of inhibition by Ig^e sera indicates that Ig-6^a and Ig-6^e do not cross react with this antiserum. Further details of antigenic specificity will be published.

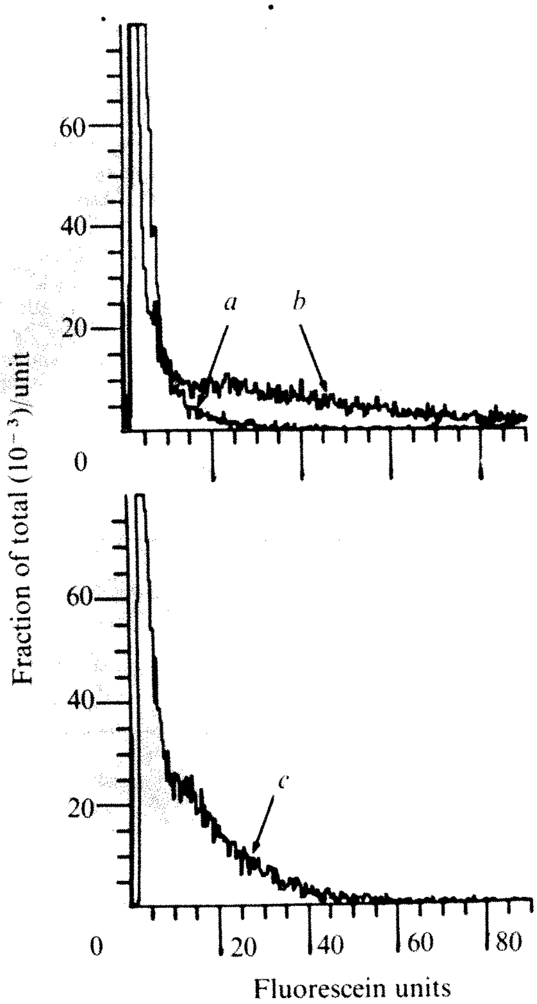

Fig. 2 FACS fluorescence analysis of anti-Ig.6^{b} serum. Fluorescence profile of SJA(Ig^{a}) anti-BALB/c.Ig^{b} serum on (*a*) SJA spleen cells (Ig^{a}), (*b*) SJL spleen cells (Ig^{b}), (*c*) SJL spleen cells after adsorption of serum with Sepharose-bound IgM myeloma C.BPC112 (Ig-6b). Cells (2×10^{6}) were reacted with 2 μl (diluted to 40 μl with buffered saline containing 0.2% sodium azide) SJA anti-BALB/c.Ig^{b} serum for 20 min at room temperature. These cells were washed and stained with fluoresceinated goat anti-mouse IgG for a further 20 min at room temperature and analysed on the FACS. Adsorption of this anti-Ig-6b serum by Sepharose-bound Ig-6a did not reduce its staining activity for SJL spleen cells.

completely non-reactive to IgM, as shown by immunofluorescence and radioimmunoassay. Fluorescence was detected by fluorescence microscopy as previously described[3], or by flow fluorometry with a fluorescence-activated cell sorter (FACS)[9]. These data are summarised in Table 1.

Table 1 shows that the same sera which precipitate secreted IgM also bind to cell surface IgM. Antisera made against pertussis–anti-pertussis complexes (that is, against secreted IgM) could be tested on spleen cells of any strain whereas antisera made against spleen cells could not because of the possible presence of antibodies to other cell surface alloantigens. With these latter antisera, spleen cells from mice congenic but for allotype with the antibody produced were used.

The antisera made in C57(Ig^{b}) against CBA(Ig^{a}) stained C57.Ig^{a} spleen cells and, of course, did not stain C57 cells (Table 1). Similarly, antisera made in SJA(Ig^{a}) against Ig^{b} cells stained SJL(Ig^{b}) but not SJA cells (Table 1 and Fig 2, *a* and *b*). Thus the surface molecules detected by these antisera are coded by genes in the Ig heavy-chain chromosome region.

The immunoglobulin class of the cell-surface molecules detected in these immunofluorescent reactions was determined by adsorption and blocking studies as well as by gel electrophoresis (PAGE). Serum MB1, SJA anti-BALB/c.Ig^{b} spleen, passed through a column of Sepharose-conjugated C.BPC112, an IgM of *b* allotype (Ig-6b), lost most of its staining activity for SJL (Fig. 2*c*). Therefore most of the reactivity is directed towards IgM. The antithetical serum against Ig-6a was similarly adsorbed by Sepharose MOPC104, an IgM myeloma from the Ig^{a} strain BALB/c (data not shown). Neither conjugate removed any staining activity from the opposite antisera. Heterologous anti-mouse μ chain blocked staining by both these antisera as well as by serum GA20. These same allotype antisera also precipitate cell surface IgM shown by PAGE of radioiodinated membrane proteins[3,7]. Thus, these alloantisera detect the allotypes Ig-6a and Ig-6b on cell-surface IgM.

Some antisera prepared by allogeneic spleen cell injections also have antibodies against IgD heavy-chain allotypes (Ig-5)[3,8]. Serum MB2 stained SJL spleen cells, although it contained no anti-Ig-6b reactivity as shown by radioimmune precipitation. This staining activity of SJL cells by serum MB2 was not removed by adsorption with insolubilised C.BPC112 nor was it blocked by pretreatment with heterologous anti-mouse μ. MB2 (Table 1) also precipitates radioiodinated cell surface IgD demonstrated by PAGE (ref. 3). Anti-Ig-5b activity also accounts for the small residual staining of IgM-adsorbed serum MB1 (Fig. 2*c*). The μ and δ precipitation activity of each of the sera detected by PAGE is given in the last column of Table 1. These data show that sera made against allogeneic spleen cells may have anti-allotype antibodies to δ chains (Ig-5), μ chains (Ig-6) or both in varying amounts. These new allotypes will serve as useful markers in following B-cell differentiation and gene expression. They may also aid in fine structure mapping of the Ig heavy-chain region which contains genes for both the constant and variable parts of the polypeptides. Some of these data has been presented[9]. A more detailed immunogenetic analysis of these loci will be published elsewhere.

Specific glucocorticoid inhibition of growth promoting effects of prostaglandin F$_{2\alpha}$ on 3T3 cells

GROWTH and differentiation of mammalian cells is considered to be controlled in part by the interaction of various hormones and other growth promoting factors[1]. Corticosteroids are hormones with a wide range of tissue specificity, intracellular receptor proteins having been described in various tissues[2] and cultured cells[3,4]. Glucocorticoids exert paradoxical effects on cell proliferation. Thus they promote cell growth of the mammary gland epithelium in mice and rats[5,6] and in mouse and rat organ[7–9] and rat tissue culture systems[10], and DNA synthesis in cultured parenchymal rat liver cells[11]. But they inhibit all stages of the inflammatory response, including the reparative growth of fibroblasts, loss of immune competence due to damage to lymphocytes, lipolysis and other anabolic (contra-insulin) effects in adipose tissue[12]. In cultured fibroblasts hydrocortisone can, in different conditions, either stimulate[13] or inhibit[14–16] DNA synthesis and cell devision. The growth promoting effects of the corticosteroids in fibroblasts and mammary epithelial cells may be related to their ability to synergise with the fibroblast growth factor (FGF) (refs 17 and 18) and prolactin[10] respectively. Growth inhibitory effects may be due to the predominantly catabolic action of the glucocorticoids[12]. Here we report that hydrocortisone can inhibit specifically the stimulation of DNA synthesis and cell division induced by prostaglandin F$_{2\alpha}$ (ref. 19) in Swiss mouse 3T3 and 3T6 cells. We suggest that the cell-growth-regulating properties of the corticosteroids are in part dependent on the identity of the co-inducing growth controlling factors, and that glucocorticoid inhibition of prostaglandin-stimulated cell growth may have a role in the anti-inflammatory response.

Prostaglandin F$_{2\alpha}$ added at 500 ng ml^{-1} to relatively quiescent 3T3 cells stimulated 20% of the cells to synthesise DNA in 26 h, whereas without any additions only 0.3% of the cells were synthesising DNA (Fig. 1). Addition of increasing concentrations of hydrocortisone with PGF$_{2\alpha}$ caused a reduction in the fraction of cells synthesising DNA, which reached a maximum of 85% inhibition at a concentration of 20 ng ml^{-1} (Fig. 1 insert). Addition of insulin (50 ng ml^{-1}) alone had little effect, but when added with PGF$_{2\alpha}$ it increased the fraction of cells synthesising DNA, thus showing a synergistic effect. The addition of hydrocortisone to PGF$_{2\alpha}$ and insulin, however, caused only partial suppression of the increase in DNA synthesis measured in the same period (40% inhibition with hydrocortisone at 40 ng ml^{-1}), even at high glucocorticoid concentrations (Fig. 1). Also the concentration of hydrocortisone required to produce half maximal inhibition of DNA synthesis was increased from 1 to 4 × 10^{-8} M in the presence of insulin (Fig. 1 insert). Addition of hydrocortisone alone or with insulin caused no stimulatory effect (Fig. 1). Preincubation of the quiescent cultures for 24 h with hydrocortisone (40 ng ml^{-1}) did not prevent the cells (95%) from synthesising DNA after addition of 10% serum.

The inhibitory effect of hydrocortisone on the stimulation of DNA synthesis produced by PGF$_{2\alpha}$ or PGF$_{2\alpha}$ and insulin was relatively specific for glucocorticoids. Thus increasing concentrations of dexamethasone as well as hydrocortisone inhibited the PGF$_{2\alpha}$-stimulation, whereas oestradiol, cortisone and testosterone were without effect (Fig. 2). Progesterone with or without insulin respectively caused only a marginal decrease or increase in the stimulatory effect of PGF$_{2\alpha}$. The concentration of dexamethasone required to cause 50% of the final reduction in DNA synthesis with PGF$_{2\alpha}$ was approximately ten times less than the corresponding hydrocortisone concentration. This correlates well with the difference in their relative glucocorticoid activities[20]. The failure of cortisone to inhibit PGF$_{2\alpha}$-stimulated DNA synthesis may be explained in part by the failure of 3T3 cells to convert cortisone into its active form, hydrocortisone[20]. Addition of hydrocortisone (400 ng ml^{-1}) to quiescent 3T6 cells plated in the absence of serum also caused a reduction in the fraction of cells synthesising DNA after a 24-h exposure to PGF$_{2\alpha}$ and insulin (Table 1). Thus the inhibitory effect of hydrocortisone was not due to the steroid interacting with other agents or hormones present in serum.

The capacity of hydrocortisone to inhibit DNA synthesis induced by PGF$_{2\alpha}$ was also reflected in its inhibition of cell multiplication. Hydrocortisone inhibited the increase in 3T3 cell numbers induced by PGF$_{2\alpha}$ or PGF$_{2\alpha}$ plus insulin after 48 h when added to quiescent cultures. Similar results were obtained when hydrocortisone was added to rapidly proliferating cells (not shown). Oestradiol at the same concentrations had no effect (Fig. 2*a*). That PGF$_{2\alpha}$ was acting directly on the cells and not through any intermediary metabolites and that hydrocortisone directly antagonised its action was suggested as follows. (1) Indomethacin (5 µM), which blocks the synthesis

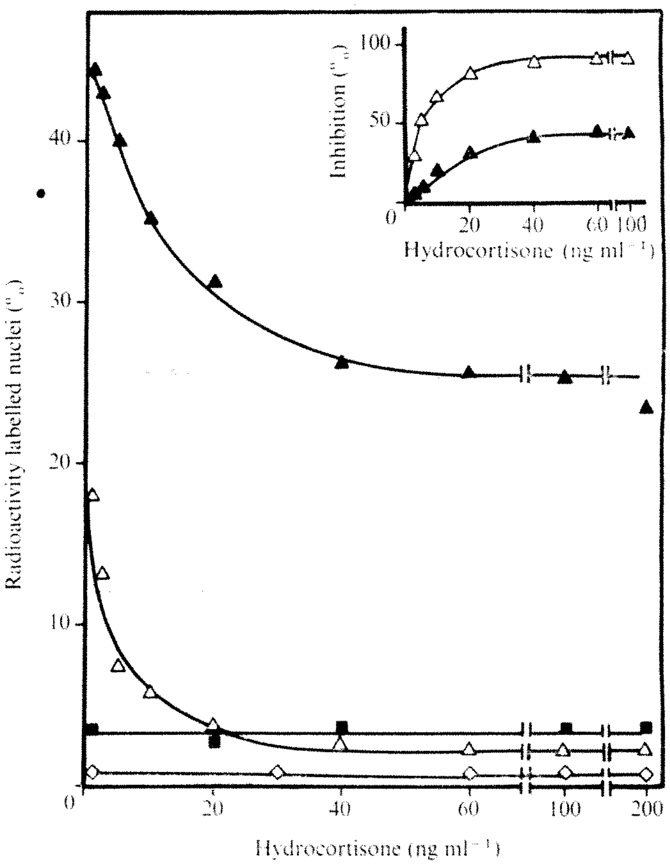

Fig. 1 Effect of various concentrations of hydrocortisone on the stimulation of DNA synthesis by PGF$_{2\alpha}$ and insulin. Additions to the cultures were as follows: PGF$_{2\alpha}$, 500 ng ml^{-1} (△); insulin, 50 ng ml^{-1} (■); PGF$_{2\alpha}$ and insulin (▲) and a control of no additions (◇) for increasing concentrations of hydrocortisone. The insert shows the percentage inhibition of the stimulation of DNA synthesis produced by hydrocortisone with either PGF$_{2\alpha}$ (△) or PGF$_{2\alpha}$ and insulin (▲). Swiss mouse 3T3 fibroblasts[31] were maintained in Dulbecco's modified Eagle's medium (DEM) containing penicillin (100 U ml^{-1}), streptomycin (100 µg ml^{-1}) and 10% foetal calf serum in 90-mm Nunc Petri dishes as described before[19]. For the determination of radioactively labelled cell nuclei, the cells were plated at 10^5 per 33-mm dish in 2 ml of DEM supplemented with 0.03 µM biotin, 0.05 µM vitamin B$_{12}$, 140 µM aspartic acid, 0.3 mM glutamic acid, 50 µM glutathione, 60 µM hypoxanthine and 5% foetal calf serum. The presence of the additional low molecular weight nutrients increased the fraction of cells synthesising DNA in the presence of PGE$_{2\alpha}$ alone with insulin when compared with those values reported[19] without supplementation[32] (M. K. O., D. C., P. S. R. and L. J. de A. in preparation). Methyl-^{3}H-thymidine was added to the medium at 3 µCi ml^{-1}, 1 µM from 0 until 26 h after the additions and the cells were continuously exposed to the extra additions until the cultures were processed for autoradiography as described before[18,19].

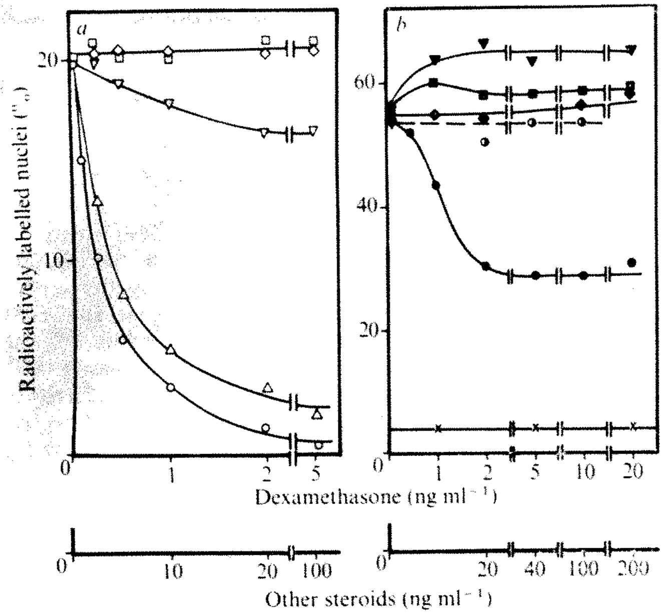

Fig. 2 Effect of various steroids on the stimulation of DNA synthesis induced by $PGF_{2\alpha}$ and insulin. *a*, Increasing concentrations of dexamethasone (○) (upper scale), hydrocortisone (△), cortisone (□), testosterone (◇) and progesterone (▽) (all on lower scale) were added to 3T3 cultures containing $PGF_{2\alpha}$ (500 ng ml^{-1}). *b*, Increasing concentrations of dexamethasone (●) (upper scale), cortisone (■), testesterone (◆), progesterone (▼), and oestradiol (◑) (all on lower scale) were added, together with $PGF_{2\alpha}$ and insulin (50 ng ml^{-1}). A control with insulin and dexamethasone alone is shown (×). The cells were radioactively labelled for autoradiography from 0 until 26 h after additions as described in Fig. 1.

Table 2 Effect of hydrocortisone on the stimulation of DNA synthesis by prostaglandin $F_{2\alpha}$ and insulin in 3T6 cells

Additions	DNA synthesis (% labelled nuclei)
None	1.3
$PGF_{2\alpha}$	14.0
Insulin	7.0
$PGF_{2\alpha}$ + insulin	31.0
$PGF_{2\alpha}$ + hydrocortisone	2.8
$PGF_{2\alpha}$ + insulin + hydrocortisone	12.4
Serum	100.0

Stock plates of Swiss mouse 3T6 cells[31] were grown in DEM with 10% foetal calf serum in 90-cm Petri dishes until the cultures were nearly confluent. The medium was removed, the cell monolayers were rinsed with 5 ml phosphate-buffered saline (0.17 M NaCl; 0.005 M KCl; 0.01 M sodium phosphate, *p*H 7.0), and the cultures were digested with 2 ml PBSA containing trypsin 100 μg ml^{-1}) for 1 min at 37 °C. The trypsin solution was then removed, and the cells were resuspended in 2.5 ml of DEM containing 0.1% serum and soybean trypsin inhibitor (200 μg ml^{-1}, Sigma, T 9003) and collected by centrifugation[32]. Cells were resuspended in 5 ml DEM and 0.1% serum, diluted 40-fold into DEM containing the extra nutrients described in Fig. 1, and then plated in 2 ml of medium at 1.5 × 10^5 cells per 33 mm dish. Final serum concentration was 0.0025%. Additions of PGF (500 ng ml^{-1}), insulin (50 ng ml^{-1}), hydrocortisone (40 ng ml^{-1}) and serum 10% were made 4 d later as indicated. The fraction of cells synthesising DNA 24 h later was recorded as described in Fig. 1.

of prostaglandins from their precursors in canine spleen[21], failed to inhibit the $PGF_{2\alpha}$-stimulated increase in DNA synthesis with or without insulin, while polyphloretin phosphate and SC 19220, inhibitors of the action of prostaglandins[22], also inhibited the mitogenic effect of $PGF_{2\alpha}$ in 3T3 cells (Table 1). (2) Stable analogues of the intermediary endoperoxides G_2 and H_2, which have similar physiological effects to $PGF_{2\alpha}$ in bronchoconstriction in animals[23] failed to stimulate cell proliferation with or without insulin present. (3) Possible antimitogenic prostaglandins which might have been synthesised or released after addition of hydrocortisone, such as PGE_1 and PGE_2 at low concentrations, failed to inhibit the mitogenic effect of $PGF_{2\alpha}$ or $PGF_{2\alpha}$ plus insulin in 3T3 cells (unpublished results).

The mechanism of action of the glucocorticoid-induced inhibition of DNA synthesis and its partial reversal by insulin is unknown, although glucocorticoid-induced reductions in glucose[24] rubidium and phosphate[25] uptakes have been reported in different cells and these transport systems are stimulated by $PGF_{2\alpha}$ or insulin in mouse fibroblasts[26]. Transport alterations probably do not mediate directly the inhibitory effect of glucocorticoids, since their reduction of the uptake of rubidium ions and phosphate is dependent on protein synthesis in rat thymocytes[25]. Furthermore, the growth of mouse L929 cells in medium containing high concentrations of fructose instead of glucose where the sugar enters the cell by passive diffusion rather than by carrier mediated transports[24] can also be inhibited by glucocorticoids. It is surprising that hydrocortisone, a predominantly catabolic hormone[12] can increase cell proliferation with FGF in fibroblastic cells[17,18], or with prolactin in mammary epithelial cultures[10]. Hydrocortisone, however, may

Table 1 Effect of inhibitors and analogues of $PGF_{2\alpha}$ on DNA synthesis and cell division

Additions	DNA synthesis (% ^{3}H-labelled nuclei)	Cell no. (× 10^{-5})
None (control)	0.2	6.03 ± 0.22
$PGF_{2\alpha}$	18.0	7.57 ± 0.03
$PGF_{2\alpha}$ + hydrocortisone	1.7	6.28 ± 0.22
$PGF_{2\alpha}$ + insulin	41.0	14.81 ± 1.1
$PGF_{2\alpha}$ + insulin + hydrocortisone	23.0	9.19 ± 0.4
$PGF_{2\alpha}$ + PPP	1.2	6.02 ± 0.0
$PGF_{2\alpha}$ + insulin + PPP	22.0	7.87 ± 0.6
$PGF_{2\alpha}$ + SC-19220	5.2	6.89 ± 0.6
$PGF_{2\alpha}$ + indomethacin (2.5 μM)	19.0	—
$PGF_{2\alpha}$ + indomethacin (5.0 μM)	17.7	8.85 ± 1.0
$PGF_{2\alpha}$ + insulin + indomethacin (2.5 μM)	42.0	—
$PGF_{2\alpha}$ + insulin + indomethacin (5.0 μM)	39.0	12.8 ± 0.3
Insulin	3.9	6.5 ± 0.6

U-46619	0.2	6.3 ± 0.1
Serum	97	24.50 ± 1.2
Serum + hydrocortisone	97	23.9 ± 0.2

3T3 cultures were plated at 10^5 cells per 33-mm Petri dish for the determination of DNA synthesis or 1.5 × 10^5 cells in 5 ml of medium per 5-cm Petri dish for determination of cell numbers as described in Fig. 1. After 4 d, when the cultures became stationary, $PGF_{2\alpha}$ (500 ng ml^{-1}); hydrocortisone (40 ng ml^{-1}), insulin (50 ng ml^{-1}); polyphloretin phosphate[22] (PPP, 5 μg ml^{-1}); 1-acetyl-2-(8-chloro-10,11-dihydrodibenz(*b,f*)(1,4)oxazepine-10-carbonyl)hydrazine[22] (SC 19220) (10 μg ml^{-1}); indomethacin 2.5 or 5 μM; (15S)-hydroxy-9α,11α(epoxymethano) prosta-5z,13-dienoic acid[23] (U-44069, 500 ng ml^{-1}); (15S)-hydroxy-11α,9α(epoxymethano) prosta-5z, 13-dienoic acid[23] (U-46619, 500 ng ml^{-1}), and 10% foetal calf serum were added as indicated. The fraction of cells synthesising DNA by 26 h or the numbers of cells ± s.e. observed by 48 h after additions is shown. In controls the amount (μg) of DNA isolated[33] per 10^6 cells 40 h after the addition of: nothing; $PGF_{2\alpha}$; $PGF_{2\alpha}$ + hydrocortisone; $PGF_{2\alpha}$ + insulin; $PGF_{2\alpha}$ + insulin + hydrocortisone; $PGF_{2\alpha}$ + insulin + indomethacin; serum was 11.6 ± 0.4; 15.0 ± 0.4; 12.2 ± 1.1; 19.3 ± 0.3; 14.1 ± 1.5; 19.2 ± 0.4 and 18.7 ± 2.1 respectively.

increase the efficiency of pituitary polypeptide interaction with the membrane in a manner similar to the way in which it specifically enhances lipolytic action of pituitary ACTH in fat cells[27].

In conclusion, both positive and negative effects of corticosteroids on the growth of cultured mouse fibroblasts have been reported. The same concentrations of hydrocortisone can either increase the rate of DNA synthesis induced by FGF (refs 17, 18) or decrease the rate induced by PGF$_{2\alpha}$ in the same Swiss mouse 3T3 cell cultures. Thus the cell growth regulatory properties of the glucocorticoids can be determined by the identity of the co-inducing growth controlling agents: this may in part explain their paradoxical effects in tissue culture. The exact physiological relevance of these observations is unknown. *In vivo* corticosteroids are potent anti-inflammatory agents[28], while prostaglandins may mediate some of the effects of the inflammatory process[21]. Hydrocortisone can inhibit both PGF$_{2\alpha}$-stimulated cell growth and collagen production in fibroblasts[28,29], so corticosteroid anti-inflammatory activity against prostaglandins may involve direct competition for control of various cellular processes including cell multiplication, and may not be solely due to inhibition of the production of prostaglandins[30].

We thank Dr R. Dulbecco for advice, Drs J. Pike and G. L. Bundy (Upjohn) for prostaglandins and synthetic analogues, Dr G. D. Clarje (Searle) for SC 19220, A. B. Leo (Helsinborg) for polyphloretin phosphate, Drs R. King, I. Mainwaring, and Julia Lever for criticism of the manuscript and Mrs Helga Durbin for technical assistance. L. J de A. is a Special Fellow of the Leukemia Society of America.

Altered cyclic AMP-binding and db cyclic AMP-unresponsiveness *in vivo*

CYCLIC AMP has been implicated in the regulation of cell growth. However, the molecular mechanism of cyclic AMP action, especially that involving the control of tumour growth *in vivo* is not clear. Our previous studies on two cell populations of Walker 256 mammary carcinoma (W256), one regressing (responsive), the other growing (unresponsive) under dibutyryl (db) cyclic AMP treatment, showed a correlation between altered cyclic AMP-binding of the tumour cytosol and db cyclic AMP-unresponsiveness[1]. Deficient cyclic AMP-binding in other malignant growth has also been reported[2–4]. It is suggested that the defective cyclic AMP-binding proteins may be the possible cause for

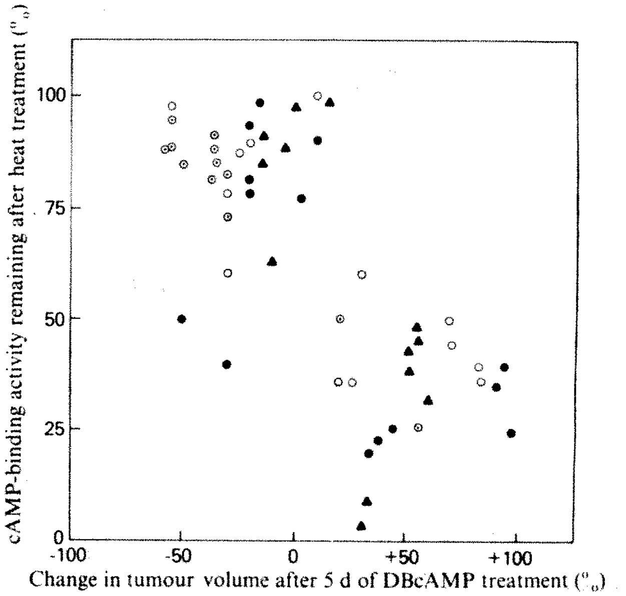

Fig. 1 Correlation between heat stability of cyclic AMP-binding and db cyclic AMP-induced tumour regression. ⊙, MTW9; ●, NMU; ○, R3230AC; ▲, hepatoma 5123. Growth of tumours was measured daily and expressed as the percentage change in volume[5]. Rats bearing 2–3-g tumours were injected[5] with db cyclic AMP for 5 d and killed 5 d later. Tumours were homogenised with 5 volumes of Tris-HCl buffer, 10 mM (*p*H 7.5). Protein concentrations of the cytosols (105,000*g*, 1 h) were adjusted to 2 mg ml^{-1} with the buffer. Aliquots of the cytosols were placed in glass tubes and heated (in duplicate) in a 50 °C water bath for 15 min stirring gently with a glass rod, then cooled to 0 °C. The unheated and heated cytosols were assayed for cyclic AMP-binding at 0 °C for 90 min by Gilman's competition protein binding assay[6] as previously described[1]. High affinity binding was determined at 10^{-8}M cyclic AMP (Y.S.C.-C. *et al.*, in preparation). Tumour cytosols were also heated as above after pre-incubation of cytosols with non-radioactive cyclic AMP (10^{-7} M) at 0 °C for 90 min. Both heated and unheated cytosols which were presaturated with cold cyclic AMP, were then treated with Dextran coated charcoal (DCC) to remove unbound cyclic AMP (Y.S.C.-C. and T.C., in preparation). One ml (2 mg protein) of each cytosol was added to a 400*g* DCC pellet derived from 4.0 ml of the DCC suspension (0.25% Norit A and 0.0025% Dextran, Grade C, in 0.01 M Tris-HCl, *p*H 8.0); the mixtures were incubated in a 23 °C water bath for 15 min with intermittent shaking every 5 min, then cooled to 0 °C, and centrifuged. The supernatants were assayed for cyclic AMP-binding at 2×10^{-8} M cyclic AMP by the modified method of Do Khac *et al.*[7] to enhance the cyclic AMP exchange. The reaction was carried out at 23 °C for 3 h. The specific binding activity[8] was expressed as the percent activity of the unheated control. Each symbol represents the average of duplicate determinations of a single tumour. Tumours frozen at −70 °C for up to 2 weeks gave results similar to those on unfrozen material. The heat stability test was also done with tumour biopsy specimens before db cyclic AMP treatment. The same correlation between the stability of the binding proteins and growth arrest was obtained. Protein concentrations were determined by the method of Lowry *et al.*[9]

the loss of growth control by cyclic AMP. To determine the relationship between the qualitative difference of cyclic AMP-binding proteins and db cyclic AMP-responsiveness *in vivo*, we have used various experimental tumour models, such as, transplantable mammary carcinoma (MTW9) in Wistar-Furth inbred female rats, a hormone-dependent tumour; primary, *N*-nitrosomethylurea-induced mammary carcinoma (NMU) and transplantable mammary adenocarcinoma (R3230AC) in Fischer female rats, hormone-responsive tumours; and hepatoma 5123 in Buffalo/N female rats.

Figure 1 shows a relationship between heat stability of cyclic AMP-binding proteins in tumour cytosol and db cyclic AMP-responsiveness *in vivo* with 4 types of rat tumours. The high-affinity binding activity (Y.S.C.-C., *et al.*, in preparation) of the cytosols from unresponsive tumours (growing under db cyclic AMP treatment) was reduced to 50% or less when the cytosol was pre-incubated at 50 °C for 15 min; under the same treatment, more than 75% of the binding activity of the cytosols from responsive tumours (regressing under db cyclic AMP treatment) was retained. Mixing of cytosols from both responsive and unresponsive tumors gave additivity in the heat stability, suggesting that the heat lability of unresponsive tumour binding was not due to enzymatic degradation of the binding proteins. Presaturation of free binding sites with unlabelled cyclic AMP did not alter the stability of the binding proteins; this suggests that the heat stability of the binding activity of the responsive tumours was not due to high cyclic AMP concentrations in the tumour cytosols which might protect against the inactivation of the binding protein. Moreover, 8 mM *β*-mercaptoethanol decreased the heat lability of the binding in the unresponsive tumours but had little or no effect on the stability of the binding in the responsive tumours. Thus, there seems to be a difference in the structure or conformation of the binding proteins between the responsive and the unresponsive tumours. For 44 of 52 tumours there was a striking parallel between stable cytoplasmic cyclic AMP-binding proteins and db cyclic AMP-induced tumour regression *in vivo* (Fig. 1). A correlation between heat stability of cyclic AMP-binding proteins and db cyclic AMP-responsiveness has also been found in cultured neuroblastoma cells by Simantov and Sachs[10] who reported that cells resistant to the cytotoxic effect of db cyclic AMP had cyclic AMP-binding proteins more sensitive to temperature than non-resistant cells.

The results in Fig. 2 show that the thermal lability of cyclic AMP-binding is associated with a reduced affinity of the binding proteins for cyclic AMP. The specific binding curves of db cyclic AMP-responsive and -unresponsive R3230AC tumours showed that the binding proteins in unresponsive tumour had a reduced apparent affinity for cyclic AMP, but the maximum binding sites in both tumours were similar. Scatchard analysis[11] of the binding curves gave K_d of 2.0×10^{-8} M and 1.2×10^{-7} M, for responsive and unresponsive tumours, respectively (Fig. 2, left, inset). It has been shown that cyclic AMP-binding proteins are a regulatory subunit of many mammalian protein kinases and the binding of cyclic AMP to the regulatory subunit stimulates the kinase activity[13-19]. Fig. 2 shows that cyclic AMP stimulation of protein kinase is apparently reduced in unresponsive tumour, whereas the K_m of the enzyme for ATP in the presence or absence of cyclic AMP is similar in responsive and unresponsive tumours (Fig. 2, right). These data are consistent with the difference in binding affinity for cyclic AMP observed between responsive and unresponsive tumours (Fig. 2, left).

The depression of cytosol binding activity of responsive W256 after db cyclic AMP treatment could be the result of an increase in endogenous binding of unlabelled cyclic AMP which decreases the exogenous ^{3}H-cyclic AMP-binding[2]. Alternatively, the decrease in the binding by the cytosol may reflect the change in intracellular compartmentalisation of binding protein and an actual loss of binding protein from the cytosol after db cyclic AMP treatment. These possibilities were examined by measuring cyclic AMP-binding and protein kinase actvites in cytosols and nuclei from db cyclic AMP-treated and control tumours using sucrose gradient centrifugation (Fig. 3). Cytosol from the db cyclic AMP-responsive R3230AC control (*a*) exhibited two major peaks of cyclic AMP-binding activity, sedimenting at 4.3S and 5.6S, respectively. The cytosol also contained cyclic AMP-independent and -dependent forms of protein kinase, sedimenting at 3.3S and 5.6S, respectively. The latter sedimentation constant is identical to that of the heavier cyclic AMP-binding peak. Cytosol from the db cyclic AMP-unresponsive control tumour (*e*) showed a different sedimentation pattern of cyclic AMP-binding and protein kinase activities: the binding component sedimenting at 4.3S and the cyclic AMP-independent protein kinase sedimenting at 3.3S decreased while the higher molecular weight species of these proteins which were not apparent in the responsive tumour cytosol increased

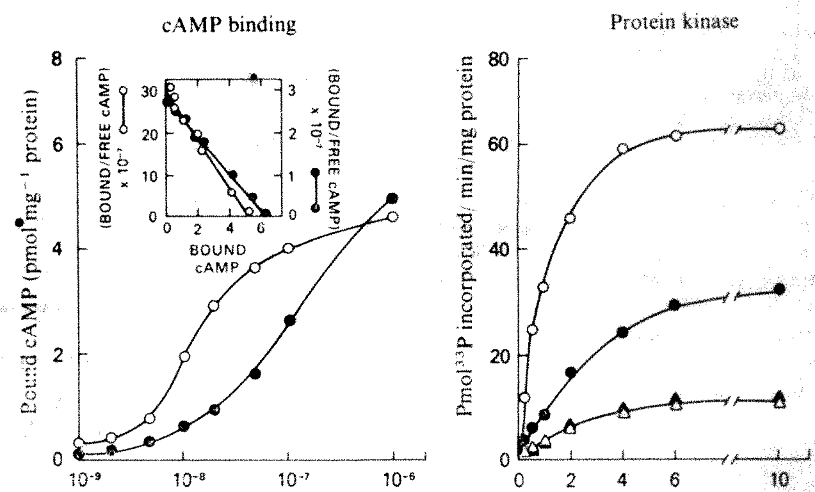

Fig. 2 Cyclic AMP-binding and protein kinase activities of db cyclic AMP-responsive (open symbols) and -unresponsive (closed symbols) R3230AC tumours. ○, ●, Cyclic AMP binding or protein kinase activity in the presence of cyclic AMP; △, ▲, Protein kinase activity in the absence of cyclic AMP. Db cyclic AMP-responsive and -unresponsive tumours were obtained from standard R3230AC transplants following a method previously described[12]. The preparation of tumour cytosol was the same as in legend to Fig. 1. Cyclic AMP binding was assayed at various concentrations of cyclic AMP as previously described[1]. Protein kinase activity was determined by the measurement of ^{33}P incorporation from γ-labelled ATP into histone. The reaction mixture (0.25 ml) contained: 100 mM potassium phosphate buffer (*p*H 7.5); 20 mM magnesium acetate; 1 mM theophylline; 0.6 mg calf thymus histone; 3×10^{-7} M (γ-^{33}P) ATP, 19 Ci mmol^{-1} (ICN Pharmaceuticals, Inc., Pikesville, Md.) with various concentrations of non-radioactive ATP; and cytosol (70 μg protein). Incubations were carried out at 30 °C for 5 min ± 1 μM cyclic AMP and the reactions were stopped by the addition of 0.5 ml of ice-cold 20% TCA. After standing for 30 min in an ice bath, the samples were filtered on to Millipore filters (0.45 μm). The filters were then washed 6 times with 5 ml of 5% TCA, dried and counted by liquid scintillation. Values represent one of the 2 similar experiments and 5 pooled tumours were used in each experiment.

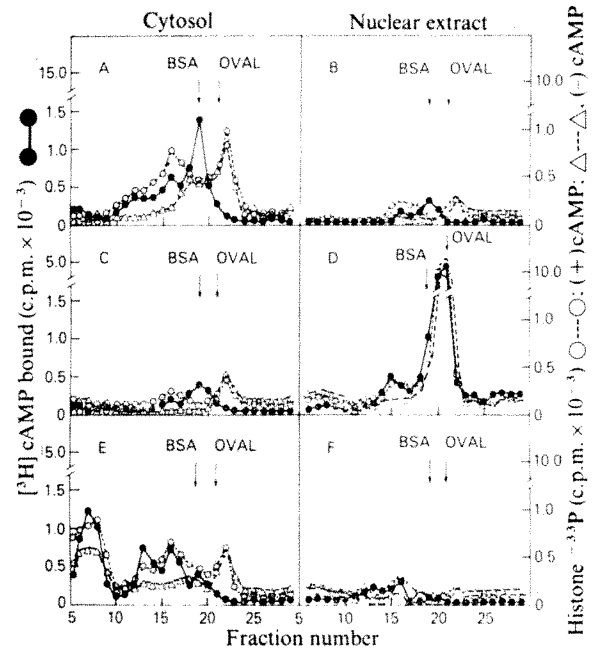

Fig. 3 Sucrose density gradient centrifugation of cytosols and nuclear extracts of db cyclic AMP-responsive and -unresponsive R3230AC mammary tumours before and after db cyclic AMP treatment. *a*, *b*, db cyclic AMP-responsive control; *c*, *d*, db cyclic AMP-responsive treated (db cyclic AMP treatment[5] for 5 days); *e*, *f*, db cyclic AMP-unresponsive control (db cyclic AMP-unresponsive-treated was similar to *e* and *f*). See description of Fig. 2 for db cyclic AMP-responsive and -unresponsive tumours. Tumours were homogenised in a Teflon–glass homogeniser with 2 volumes of 10 mM Tris-HCl buffer (*p*H 7.5). The supernatants (105,000*g* for 1 h) were used as cytosols. The pellets from 105,000*g* were rehomogenised in an original volume of 20 mM Tris-HCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, *p*H 7.5 (buffer A). These homogenates were passed through 3 layers of gauze and centrifuged at 770*g* for 10 min. The pellets were resuspended and homogenised in the same volume of buffer A, then centrifuged at 770*g* for 10 min. The nuclear pellets thus obtained were homogenised in one volume of 0.4 M KCl in 10mM Tris-HCl buffer (*p*H 7.5) and extracted at 0 °C for 90 min. The suspensions were centrifuged at 10,000*g* for 10 min and the clear supernatants used as nuclear extracts. Samples of cytosols and nuclear extracts containing 1.0 mg of protein were incubated at 23 °C for 3 h, with 10^{-6} M [³H]-cyclic AMP, 10 mM theophylline and 50 mM potassium phosphate buffer (*p*H 7.0) then layered on 5–20% sucrose gradient in 10 mM Tris-HCl buffer (*p*H 7.0) (nuclear gradient included 0.4 M KCl). Centrifugation was at 2 °C for 17 h at 45,000 r.p.m. in a Beckman SW 50.1 rotor. Thirty fractions were collected and assayed for cyclic AMP-binding (protein-bound ³H content) and for protein kinase activity. For the determination of cyclic AMP-binding, aliquots of each fraction were filtered onto Millipore filters (0.45 μm), washed and counted by liquid scintillation. Protein kinase activity was determined as in the legend to Fig. 2 at 0.5 mM ATP concentration. Sedimentation coefficients were determined by the method of Martin and Ames[20] using BSA (Bovine Serum Albumin, $S_{20,w} = 4.5$S) and OVAL (Ovalbumin, $S_{20,w} = 3.6$S) as internal standards. The values represent one of the 3 similar experiments.

markedly. The sedimentation profiles of cyclic AMP-binding and protein kinase of control nuclei from both responsive and unresponsive tumours (*b* and *f*) showed small broad peaks. In contrast, the nuclear extract from the db cyclic AMP-treated-responsive tumour (*d*) gave a sharp sedimentation profile composed mainly of a 3.6S species containing both cyclic AMP-binding and cyclic AMP-independent protein kinase activities. This increase in nuclear binding and kinase activities was accompanied by a decrease of these protein species in the cytoplasm (*c*).

The nuclear accumulation of cyclic AMP-binding and protein kinase components was not found in the db cyclic AMP-unresponsive tumour following the db cyclic AMP treatment; the sedimentation profiles of these macromolecular protein species in both the cytosol and nuclear extracts were the same as those in the untreated control tumour. The differences observed between db cyclic AMP-treated-responsive and -unresponsive tumour nuclei with respect to cyclic AMP-binding and protein kinase activities was not due to the presence of a modulator of the binding and kinase in the extracts since mixing of db cyclic AMP-treated-responsive and -unresponsive tumour nuclear extracts exhibited additivity of the binding and kinase activities. A similar correlation between the sedimentation characteristics of cyclic AMP-binding proteins and protein kinase and responsiveness to db cyclic AMP treatment was found with db cyclic AMP-responsive and -unresponsive 5123 hepatomas (data not shown).

Our studies have revealed a striking parallel between heat stability of cyclic AMP-binding and arrest of growth due to exogenous db cyclic AMP. Moreover, a close correlation was found between the heat stability of cyclic AMP-binding and affinity of the binding proteins for cyclic AMP: the binding proteins which are more stable to temperature possess a higher affinity for cyclic AMP than heat labile binding proteins. These qualitative differences of cyclic AMP-binding proteins between db cyclic AMP-responsive and -unresponsive tumours also reflect their capability for nuclear accumulation: only those binding proteins which are heat stable to temperature and exhibit a higher affinity for cyclic AMP accumulate into nuclei during db cyclic AMP treatment. These findings indicate that 'unresponsiveness' to db cyclic AMP treatment is closely associated with qualitative defects in cyclic AMP binding proteins. Thus the heat stability test of cytosol cyclic AMP-binding proteins could be used as a simple diagnostic method to assess the efficacy of cyclic AMP treatment of tumours.

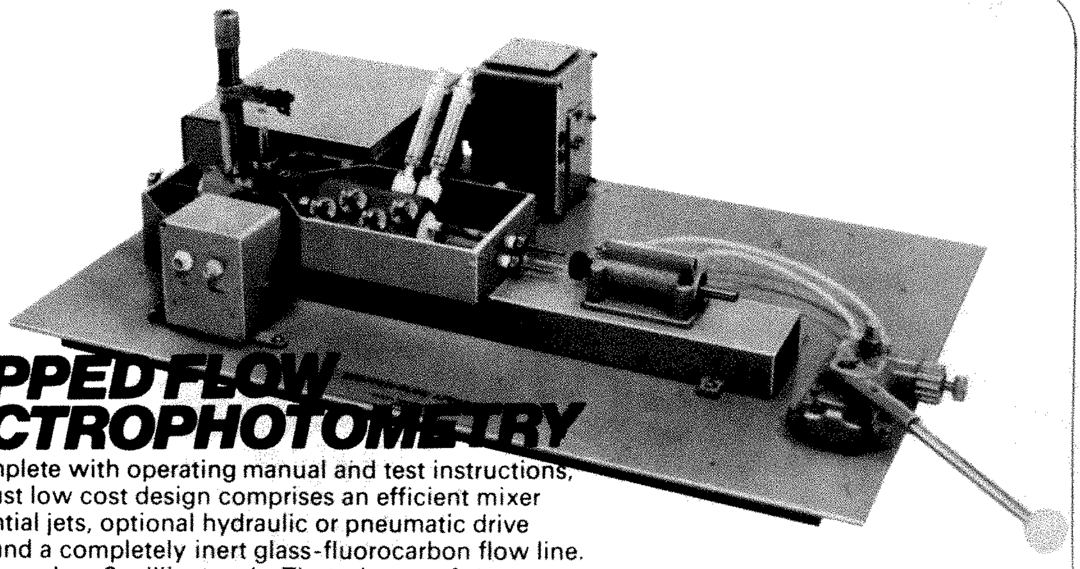
Prevention of senescence in the ascomycete *Podospora anserina* by the antibiotic tiamulin

THE syndrome of senescence or aging is common to all living material. In many fungi the peripheral hyphae become senescent after prolonged vegetative growth, that is, their growth rate decreases and they eventually die. In some fungi, senescence is caused by transmissible elements, of temporarily if their metabolism is drastically reduced[1,3], but

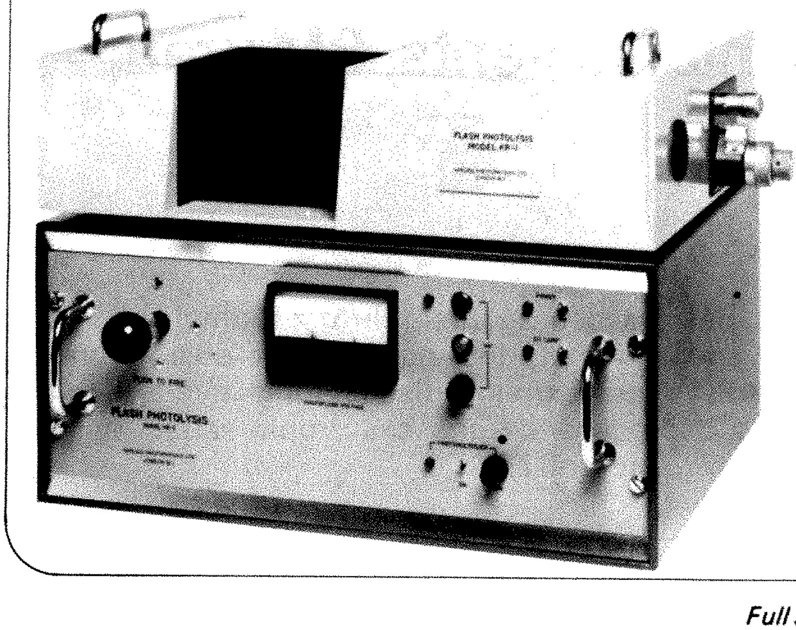


STOPPED FLOW SPECTROPHOTOMETRY

Supplied complete with operating manual and test instructions, this new robust low cost design comprises an efficient mixer with 8 tangential jets, optional hydraulic or pneumatic drive mechanism, and a completely inert glass-fluorocarbon flow line. Dead time is less than 2 milliseconds. The volumes of reagents needed to fill the flow line are very small (less than 3ml of each reagent is sufficient for more than 6 runs) and the apparatus is highly suitable for enzyme studies or work with limited amounts of material. There is provision for accurate temperature control (±0.1K) and additional provision for fluorescence work.

FAST REACTION APPARATUS

FLASH KINETIC SPECTROPHOTOMETRY



Model KR1 is a low cost flash kinetic spectrophotometer for measuring transient decay kinetics. It has a time resolution and sensitivity suitable for most research applications as well as for experiments in a teaching laboratory. The instrument uses two fast flash lamps dissipating a maximum of 200 joules and incorporating a wide range monochromator. Transient species which have moderate to strong absorptions in the region of 330–680mm and have lifetimes longer than 10 microseconds may be studied with this instrument.

Gel filtration and Affinity chromatography even in 6M GuHCl, organic solvents, 8M urea, 3M KSCN at pH3, pH12, 80°C

CROSS-LINKED SEPHAROSE is a new beaded agarose chromatographic medium with exceptional stability and extremely low non-specific adsorption. It can be used with confidence in the most extreme dissociating media including strong solutions of urea, guanidine hydrochloride, and chaotropic salts. Sepharose CL can also be used in organic solvents.

You can sterilize Sepharose CL repeatedly by autoclaving at 110°C - 120°C. Cross-linked Sepharose is available in three types: Sepharose® CL-2B, CL-4B and CL-6B.

Ask for the free booklet with data and details of new techniques, from your supplier of Sephadex®, Sepharose® and other separation media.

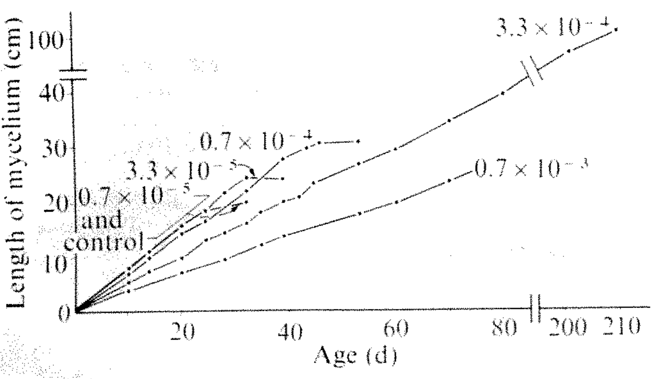

Fig. 1 Effect of the antibiotic tiamulin on the growth of *P. anserina.* Mycelia of the wild strain s$_1$ were grown at 25 °C in race tubes (length 50 cm) on cornmeal agar containing tiamulin as indicated. The growth curves were calculated from at least five parallel runs which were inoculated with mycelia 'freshly' regenerated by sexual propagation.

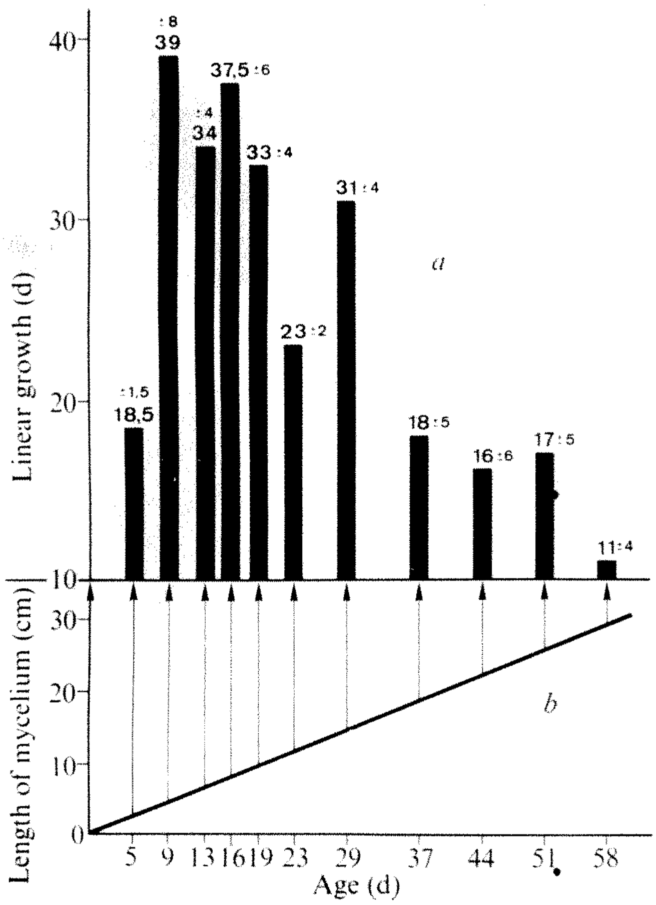
anastomosis. The onset of senescence is influenced by environmental as well as genetical factors[1–6]. In *Podospora anserina,* where senescence has been very thoroughly analysed, it was shown that senescent mycelia may recover temporarily if their metabolism is drastically reduced[1,5], the mycelia soon become senescent when grown in normal conditions. The nature of the senescent agent in *Podospora* is obscure. All efforts to demonstrate viruses or virus-like particles in aging hyphae of *Podospora* have failed (R. Bozarth, personal communication). Our endeavours to determine the nature and action of the senescent agent were encouraged by previous findings that the onset of senescence can be completely prevented by a synergistic action of specific genes[6]. In this paper we show that an antibiotic, tiamulin, can mimic the effect of these genes.

Fig. 2 Correlation between the length of time the mycelium has grown on tiamulin and the onset of senescence. *a*, Time of linear growth of samples taken at various intervals (arrows) and transferred to medium devoid of tiamulin. *b*, Growth curve of the mycelium kept on tiamulin (3.3 × 10^{-4} M). For experimental conditions see legend to Fig. 1.



Informative experiments showed that when some tetracyclines were incorporated into the agar medium they induced a 'stopper phenotype'[3], thus prolonging the life of the mycelium. In contrast, cholesterol reduced the life span by 30–50%. It is known that tetracyclines inhibit and cholesterol promotes the growth of mycoplasmas[7,8]. It is thus possible that these organisms could be involved in the senescence syndrome in *Podospora.*

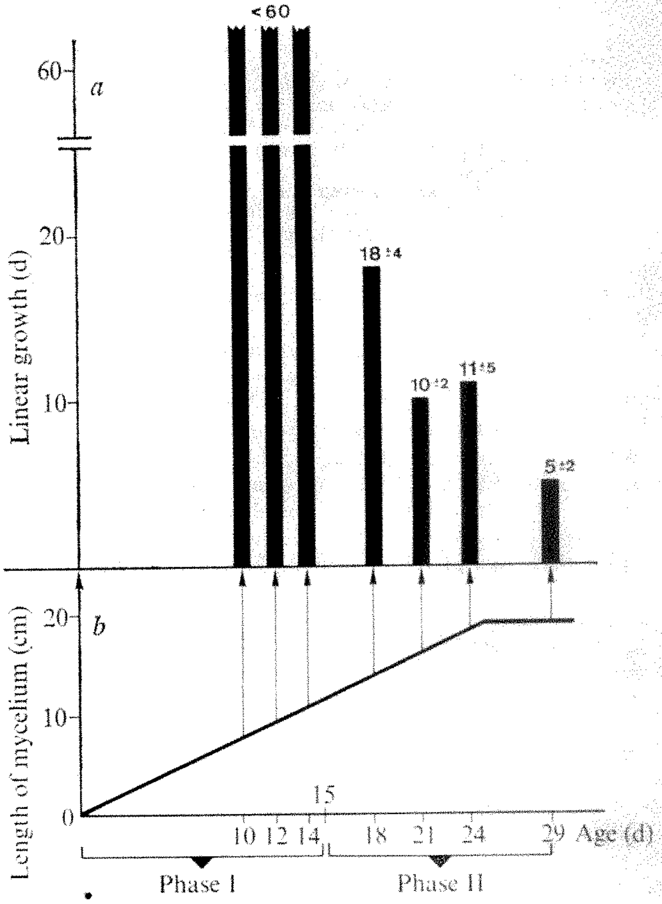


Fig. 3 Correlation between the age of mycelium and its sensitivity to tiamulin treatment. *a*, Time of linear growth of samples taken at various intervals (arrows) and transferred to medium containing 3.3 × 10^{-4} M tiamulin. *b*, Growth curve of mycelium grown on medium devoid of tiamulin. For experimental conditions see legend to Fig. 1.

This idea is substantiated by the results of infection experiments. When senescent and juvenile mycelia were mixed in a Waring blender and incubated at 25 °C for 24 h, a 100% infection was obtained only in media with a high osmotic value (20% sucrose); at low osmotic values (1–5% sucrose) few or no juvenile hyphae were infected. This osmotic sensitivity of the senescent agent is well in accordance with the properties of mycoplasma-like organisms (prokaryotic cells devoid of a cell wall).

In order to confirm this assumption we have looked at the effect of a new antibiotic, tiamulin, on the hyphal growth of *Podospora.* This antibiotic is supposed to be specific for mycoplasms (personal communication Biochemie Kundl, Österreich). As seen from Fig. 1, tiamulin can prevent senescence. The most effective concentration is around 10^{-4} M. Lower concentrations only postpone senescence whereas higher concentrations prevent senescence but have a toxic effect and reduce the linear growth rate. In order to obtain more information on the action of tiamulin we have performed two series of experiments

(Figs 2 and 3). As can be seen from the data in Fig. 2, the time at which the onset of senescence occurs is influenced by the period for which the mycelium is first grown on tiamulin medium. There is considerable delay up till 30 d after which the situation is reversed and the onset of senescence soon occurs. Possibly the mycelium becomes dependent on tiamulin at this time. It is evident that tiamulin does not cure senescence but can prevent it when present in the medium.

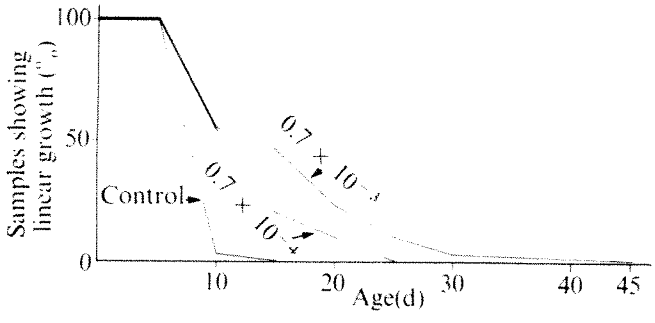

Fig. 4 Effect of various concentrations of tiamulin on senescent mycelium. Senescent mycelia grown in corn steep liquor in Fernbach flasks were homogenised in a Waring blender (60 s) in a solution of 20% sucrose containing tiamulin as indicated and incubated at 25 °C for 24 h. The life span of at least 30 samples at each concentration was followed after plating small inocula on corn meal agar. The curves are mean values showing the relative survival rates.

Figure 3 shows that the life span of *Podospora* can be roughly divided into two phases with respect to the life-prolonging effect of tiamulin. If given in phase I (0–15 d) senescence can be prevented. If given about 10 d before the onset of senescence (phase II, 15 d and later) there is no longer an effect; the mycelium continues to grow on the antibiotic for the rest of its normal life span.

These observations confirm earlier findings[1] that even before these symptoms of senescence become obvious, the senescent agent is present in the mycelium. These data allow us to conclude that tiamulin can only prevent the activity of the senescent agent up to a critical time (perhaps a particular stage of development of the agent or its concentration in the cell). After this time the agent spreads within the mycelium and after an appropriate 'incubation time' causes the senescent phenotype.

To show that the ineffectiveness of tiamulin in phase II is not a result of its reduced uptake by the aerial hyphae, a 'therapeutic' experiment was performed in liquid culture. From the data summarised in Fig. 4 it can be seen, that tiamulin is still effective to a certain extent on senescent mycelium and that this effect increases with the concentration of the antibiotic. Two interpretations are possible. First, tiamulin prevents the infection of the few juvenile hyphae still present in the senescent mycelium and allows them to grow despite the presence of neighbouring senescent hyphae. Second, tiamulin may cure infected but not severely damaged hyphae and give them a new chance to grow.

Our experiments have shown that tiamulin is effective in preventing the occurrence of senescence in *Podospora* in specific conditions. As yet we do not know whether tiamulin acts prophylactically or therapeutically, but the possibility that it is acting by killing mycoplasmas must be investigated, particularly since mycoplasma-like organisms have recently been found in a fungus[9]. The feasibility of using tiamulin and other derivatives of pleuromulin for preservation of strains and prolongation of fermentation time in the fermentation industry is under examination.

We wish to thank T. Itoh (Obihiro/Hokkaido, Japan) who contributed to the informative experiments with tetracycline and cholesterol during his stay in our laboratory as a fellow of the Heinrich-Hertz-Stiftung (Düsseldorf). Tiamulin (2-diethyl-aminoethyl)-thioacetoxy-mutilin-hydrogenfumerat) was kindly donated by Biochemie G.m.b.H. Kundl, Österreich. We thank the technical staff of our laboratory for their assistance, especially Frau U. Rojek and Frau H. Hüsemann.

Solubilised viral proteins produce fatal hepatitis in mice

PATHOGENICITY of viruses is commonly related to their ability to multiply within the host's cells. Although, in certain conditions, the inoculation of large doses of uninfectious virus can produce a fatal disease[1], the toxicity of viral components as such for laboratory animals has never been demonstrated. We have shown that although frog virus 3 (FV 3) is unable to multiply in mice, it produces an acute degenerative hepatitis leading to the death of the animals in less than 24 h (refs 2, 3). We report here that solubilised viral proteins also produce this hepatotoxic effect.

FV 3 structural proteins were solubilised in two steps. First, a purified virus suspension was incubated with Nonidet P-40 (final concentration 0.5%) for 5 h at room temperature. The detergent was then removed through extensive dialysis in 50 mM Tris-HCl, *p*H 8.5. Second, LiCl (20%, w/w) was added to the preparation and the mixture was left for 6 h at 0 °C then dialysed again and centrifuged at 100,000*g* for 1 h. The supernatant fluid containing the soluble viral extract (SVE) was used in experiments[4].

Intravenous (i.v.) inoculation of 0.2 mg of SVE proteins per mouse killed the animals within 24–48 h (Table 1); the

Table 1 Lethal effect of the solubilised viral extract in mice

SVE proteins (mg kg^{-1})	Treatment of SVE	Animals killed/animals inoculated
10	None	6/6
5	None	5/6
2.5	None	5/6
1.25	None	1/6
0.62	None	0/6
20	80 °C, 30 min	0/6
20	Trypsin*	0/6
20	Tris-HCl	6/6
20	FV$_3$ antibodies†	0/6
20	Normal rabbit serum	6/6

IC strain mice (18–20 g) were inoculated i.v. with 0.5 ml containing various amounts of viral proteins diluted in 50 mM Tris-HCl, *p*H 8.5, 15 mM NaCl.

*SVE (1.5 mg ml^{-1}) was incubated for 1 h at 37 °C with or without trypsin (0.5 mg ml^{-1}). Before the inoculation, 100 000 peptidase inhibitory units of iniprol (Choay) were added per ml of hydrolysed or unhydrolysed SVE.

†FV 3 antibodies were produced by inoculating rabbits with purified virus supplemented with complete Freund's adjuvent. SVE was mixed with anti FV 3 serum (final serum dilution 1/100) or normal rabbit serum for a 1-h incubation at 37 °C.

LD_{50} was about 2 mg per kg body weight. This lethal action was related to SVE proteins. Both heating the SVE for 30 min at 80 °C and trypsin digestion destroyed its toxicity. The toxicity could also be neutralised by specific FV 3 antibodies (Table 1).

Histological lesions were found only in the liver. The whole lobule was affected with the exception of one or two layers of cells around the centrolobular vein. These lesions were studied by electron microscopy at intervals after the inoculation of one LD_{100} of SVE. As early as 3 h afterwards, the nuclei of the hepatocytes were severely damaged; they showed an irregular shape, condensation of the chromatin, assembly of the interchromatin granules in dense clusters at the centre of the nucleus, and fibrillar inclusions (Fig. 1*a*).

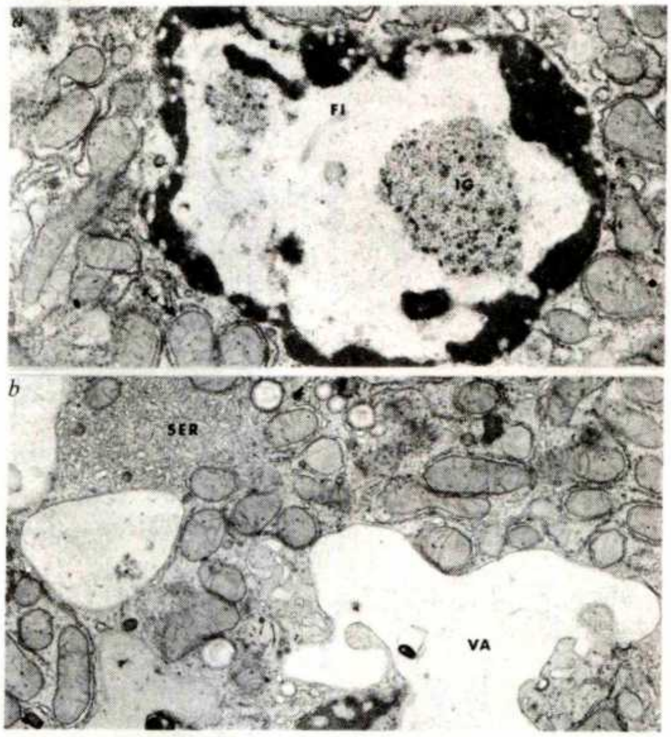

Fig. 1 Ultrastructural changes produced in hepatocytes of mice inoculated i.v. with SVE 10 mg per kg body weight. *a*, Hepatocyte nucleus observed 3 h after the inoculation. The condensation of the chromatin (CH) and the emptiness of the nucleoplasm appear clearly. The interchromatin granules (IG) are assembled into a dense cluster at the centre of the nucleus and some fibrillar inclusions (FI) are noticeable. 7,200. *b*, Part of the cytoplasm of a hepatocyte 9 h after inoculation. The cytoplasm shows numerous vacuoles (VA) as well as large areas of smooth endoplasmic reticulum (SER) (9,1120).

Cytoplasmic changes were only noticeable 9 h after the inoculation. They were characterised by alterations of both rough and smooth endoplasmic reticulum, accumulation of lipids and a final necrosis (Fig. 1*b*).

As with inoculation of virus particles, the macromolecular metabolism of the liver was markedly affected by SVE injection. Table 2 shows that both RNA and protein synthesis were depressed 3 h after inoculation, RNA synthesis being more severely affected.

Thus the inoculation of solubilised structural proteins from FV 3 produces the same morphological and biochemical alterations of the liver as the intact virions. Our results clearly demonstrate that viral proteins may be 'toxic' by themselves. Although it is unlikely that an organism would be naturally infected with an amount of virus sufficient to produce extensive lesions by this mechanism, most pathogenic viruses undergo several cycles of multiplication enabling toxic proteins to accumulate.

Table 2 Effect of SVE on RNA and protein syntheses in mouse livers

Time after inoculation (h)	c.p.m. incorporated	
	^{3}H-orotic acid	^{14}C-amino acid
0	147,680 (100)	269,520 (100)
3	81,200 (55)	180,560 (67)
6	59,040 (40)	161,680 (60)
9	51,680 (35)	134,760 (50)

Mice were inoculated i.v. with SVE at 10 mg per kg body weight. The mice received 50 μCi of ^{3}H-orotic acid (specific activity 22 Ci mmol^{-1}) and 10 μCi of ^{14}C-amino acids (specific activity 0.660 mCi mmol^{-1}) intraperitoneally 30 min before killing. The livers were removed rapidly and homogenised in 5 ml of 250 mM sucrose. RNA and protein synthesis were measured as incorporation of ^{3}H-orotic acid and ^{14}C amino acid respectively into the acid insoluble material of the liver homogenates. The results are expressed in c.p.m. per g of wet liver, each value representing the mean obtained with four animals. Figures in parentheses indicate the percentage of incorporation into the livers of the inoculated mice compared to the incorporation into the livers of the untreated animals.

The model described here should be of use in the study of the mechanisms responsible for the shutoff phenomenon and cell necrosis during lethal virus infection. Since non-replicative viral material can be highly toxic, the part played by the competition for essential metabolites as a factor in cytopathogenicity can in this case be ruled out.

Granulomatous hypersensitivity induced by sensory peripheral nerve

THE nature of granulomas remains uncertain. In sarcoidosis and Crohn's disease of the ileum, the aetiology is unknown. Even where a causative organism has been identified, as in tuberculosis and non-lepromatous leprosy, the role the mycobacteria play in the development of the granuloma is obscure[1]. There is no animal model available for the study of granulomatous hypersensitivity. But in susceptible human subjects it is possible to produce granulomas with tubercle formation by skin testing with zirconium[2] or beryllium[3]. Similarly, in sarcoidosis, granulomas with tubercles occur in patients skin-tested with Kveim antigen (sarcoid spleen or lymph node suspension). These reactions are specific for each antigen and independent of dose. Thus, chronic states of altered tissue reactivity or granulomatous hypersensitivity can be found in humans[4]. We have shown that rabbits develop skin lesions after injection with homogenates of peripheral sensory nerve[5]. Now we report that these lesions sometimes possess organised granulomas in tubercles, and that similar granulomas can be produced by skin-testing rabbits sensitised with sensory nerve, using cutaneous nerve as the challenging antigen. These results suggest that granulomas may sometimes be an autoimmune response to tissue antigens: in the case of non-lepromatous leprosy, to an antigen in peripheral nerve containing sensory fibres[5]. A specific diagnostic test for leprosy is therefore a possibility.

It is important to distinguish granulomas from foreign body and delayed-type hypersensitivity reactions, and we have used the following criteria. First, the granuloma should be organised in tubercles, with epithelioid cells located centrally, surrounded by lymphocytes. Second, the putative epithelioid cells should possess the histological features of the epithelioid cells found, for example, in zirconium-induced granulomas, that is they should be large pale staining clear cells, having prominent nucleoli, with the chromatin of large ovoid nuclei lying peripherally[1]. Third, it should be possible to produce the granuloma by challenge with antigen alone at sites remote from the original site of injection of antigen plus Freund's adjuvant, that is a state of granulomatous hypersensitivity should exist[4]. Fourth, electron microscopy of the cells should show evidence of secretory activity, with abundant rough endoplasmic reticulum in the cytoplasm, to distinguish between the secretory epithelioid cells and macrophages[6].

Skin patches developed systemically in 14 out of 20 Dutch bantam rabbits injected with sural nerve plus Freund's adjuvant as described previously[5]. It is important to stress that none of these patches developed at the site of the injections. In four of the responding rabbits histological features of granuloma were found in the patches which had formed on the dorsum of the foot, the footpad of which had been the site of the original injection. Tubercles and developing tubercles with centrally placed epithelioid cells surrounded by lymphocytes could be seen. Four rabbits given Freund's adjuvant alone and observed for 7 months did not develop these skin patches.

A second group of rabbits was used for the skin testing experiments. Initial sensitisation was by injection into one hind footpad of 0.2–0.4 ml of a homogenate of human peripheral nerve plus Freund's complete adjuvant, prepared as described previously[7]. Three different types of peripheral nerve were tried, sural (cutaneous), dorsal roots (sensory fibres) and ventral roots (mainly motor fibres). Subsequent skin testing in all cases was with 0.2 ml 10% human sural nerve homogenised in saline and injected intradermally into the back. The sensitisation and challenge regimen is summarised in Table 1.

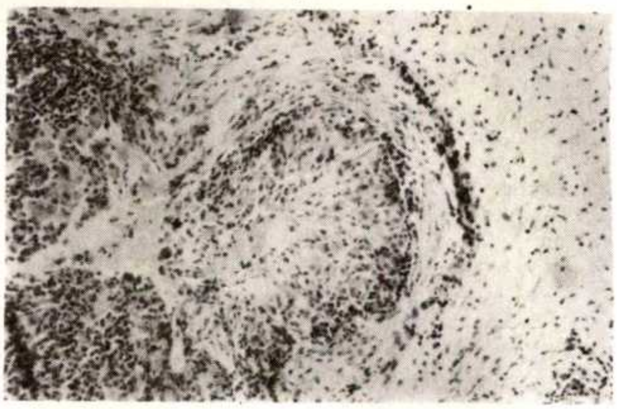

Fig. 1 Section of papule 5 weeks after intradermal injection of 0.2 ml 10% human sural nerve into back of rabbit, showing tubercule formation with epithelioid cells surrounded by lymphocytes. Stained with haemotoxylin and eosin, ×92. The rabbit had been injected with 0.2 ml sural nerve with Freund's adjuvant in the hind footpad 18 months before skin test.

Papules (5–10 mm in diameter) appeared in seven out of 18 rabbits skin-tested and these papules persisted until biopsy at 5 weeks. In the negative cases swellings were transient, not lasting beyond 2 weeks. In six out of the seven animals which developed papules, histological features of granulomas were found, that is tubercles and developing tubercles with centrally placed epithelioid cells surrounded by lymphocytes could be seen (Fig. 1). The epithelioid cells were large and pale staining with the chromatin lying peripherally in the large ovoid nuclei. Prominent nucleoli were frequently present. Langhan's-type giant cells with peripherally situated nuclei were present, the nuclei being similar in form to those of epithelioid cells[8] (Fig. 2).

In two rabbits part of the biopsy specimen was fixed for electron microscopy. In both specimens typical epithelioid cells were found, that is the cytoplasm contained abundant dilated rough endoplasmic reticulum with a moderately dense secretory product; an active Golgi apparatus was also present (Fig. 3). These observations confirm the secretory nature of the cells.

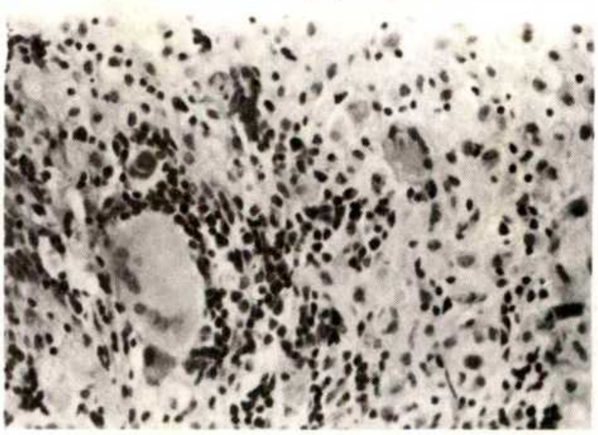

Fig. 2 Part of a developing tubercule with Langhan's-type giant cells and typical epithelioid cells, ×250. The rabbit had been injected with 0.2 ml dorsal roots with Freund's adjuvant 14 and 13 months before the skin test with sural nerve.

Rabbits which failed to develop papules showed histologically only diffuse collections of cells with no organisation into tubercles or distinguishing features of epithelioid

Table 1 Granuloma induction with various types of human peripheral nerve as sensitising antigen

No. of rabbits	Sensitising antigen	Sensitisation schedule before challenge with 10% sural antigen	Animals showing granuloma
7	Sural	A single injection (0.2 ml) 13 months to 2½ yr	4
5	Dorsal roots	14 months 0.2 ml* 13 months 0.2 ml 11 months 0.2 ml 3 months 0.4 ml	2 (1*)
4	Ventral roots	11 months 0.2 ml 10 months 0.4 ml 3 months 0.4 ml	0
2	None	—	0

*One positive had only two injections at 14 and 13 months before challenge.

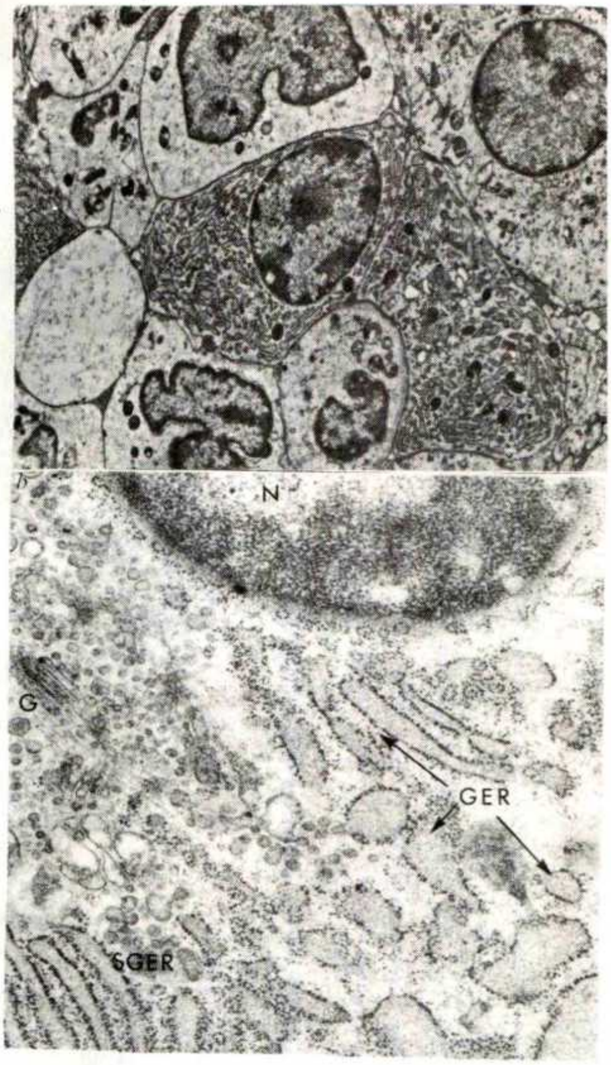

Fig. 3 *a*, Electron micrograph of part of a tubercule showing fully developed secretory epithelioid cells and undifferentiated mononuclear cells. The tubercule was taken from a skin papule 5 weeks after skin-testing with 0.2 ml 10% sural nerve in saline intradermally into the back of the rabbit previously injected with 0.2 ml sural nerve in Freund's adjuvant in footpad 2.5 yr before. Stain was lead uranyl acetate, ×3,440. *b*, Electron micrograph of part of a cell possessing the characteristic organelles of a secretory epithelioid cell. From the same tubercule as (*a*). GER, granular endoplasmic reticulum containing secretory product. SGER, stacks of granular endoplasmic reticulum. G, Golgi apparatus. N, nucleus. Stained with lead uranyl acetate, ×24,395.

cells. Injection of 0.2 ml 10% rat spleen or rat brain did not produce any papules in five out of six rabbits showing the positive granulomatous response to challenge with sural nerve; no histological features of granuloma were seen. A total of 32 skin tests, using rat spleen and rat brain as challenging antigen, produced no papules in these rabbits.

Central necrosis in tubercles was common in both spontaneously occurring and skin-test-induced granulomas which occasionally led to small abscess formation. Necrotic foci are common in beryllium granuloma[8,9] and in strongly reacting patients the Kveim test sometimes shows necrosis[10,11].

Thus we have induced granulomas and a state of granulomatous hypersensitivity in 10 rabbits and it seems that the antigen is located in peripheral nerves containing sensory fibres

A viable agent has been postulated as the cause of sarcoidosis and Crohn's disease, and samples of affected tissue have been inoculated into animals in an attempt to reproduce the disease[11-15]. Claims for successful attempts to reproduce Crohn's disease have not been confirmed[15]. Recently a virus has been isolated from ileal tissue affected by Crohn's disease, but this has not yet been shown to cause Crohn's granuloma. A viral agent, by modifying the cell surface antigen composition, could produce an autoimmune response.

In none of the experiments have the animals developed a state of granulomatous hypersensitivity, that is, skin testing at remote sites has not induced granuloma formation. Our results suggest that an autoimmune approach using tissue antigens from the ileum may be effective. The experimental model described here may be useful in testing drugs for use in sarcoidosis and Crohn's disease.

By inducing granulomas in rabbits we have reproduced the histological features of non-lepromatous leprosy; this supports previous work[5] suggesting that the skin lesions in the human disease are autoimmune responses to sensory peripheral nerve rather than being directly due to *Mycobacterium leprae*. It may also be possible to devise a skin test specific for leprosy, using sensory nerve as antigen. This test would be similar to the Kveim test for sarcoidosis, but would differ fundamentally from skin tests using the antigen *M. leprae* (lepromin) which are of no diagnostic value, giving foreign body reactions in both healthy people and those with non-lepromatous leprosy.

Motor neurone sprouting induced by prolonged tetrodotoxin block of nerve action potentials

PERIPHERAL axons retain into adult life the ability to grow, and do so either if they themselves are cut or if neighbouring tissues are denervated (collateral sprouting[1]). Collateral sprouting also occurs in botulinum toxin poisoning[2], motor end plate disease of mice[3] and myasthenia gravis of man[4]. Muscle inactivity is common to these otherwise different conditions. We have therefore investigated whether inactivity in a muscle, produced by a local nerve block, will give rise to collateral sprouting. By paralysing motor nerves for a few days with a local application of tetrodotoxin (TTX) we have found that motor nerve terminals in the affected muscles do grow collateral sprouts. We conclude that muscle inactivity results in a sprouting stimulus to nerves.

TTX was used because it is a specific blocker of Na^+ conductance in nerve[5] and does not interfere with axoplasmic transport[6,7]. This is important because Diamond *et al.*[8,9] believe that interference with axoplasmic flow can lead to sprouting. Adult mice, male and female (20–30 g), were anaesthetised with ether, the right sciatic nerve was exposed and a hollow cylindrical cuff of Silastoseal B (Midland Silicones) was placed carefully around the nerve. Cuffs were 1.5–3 mm long, 2 mm in diameter with a 1-mm diameter hollow core. They were made as described by Lavoie *et al.*[6], except that the quantities of TTX and NaCl were different. In the first experiments the cuffs contained approximately 1 μg of TTX and 3 mg of NaCl. These paralysed for 24–48 h and two or three had to be used to give sufficient paralysis. In later experiments the cuffs contained about 5 μg of TTX and 0.5 mg of NaCl, and before insertion they were sprayed inside and out with poly tetrafluoroethylene (PTFE, DMC Industrial Aerosols, No. 889RB). This delayed release of TTX and allowed larger doses to be given, thus prolonging paralysis, but often the paralysis was not as profound as with the other type of cuff. Control animals were mice with cuffs containing no TTX and mice with TTX-containing cuffs which paralysed for only 1 or 2 d; some of these were coated with PTFE, others were not. The ineffective cuffs were left *in situ* for a further 3 or 4 d to bring the period when the cuffs were present up to that for animals where paralysis lasted for 3.5–7 d. Paralysis was checked twice a day by observing the movement and stance of the mice and by picking them up by the tail to see if their toes spread normally. Paralysis was not always complete but provided it was marked it was counted as successful. Different cuffs of a given batch did not necessarily paralyse to the same extent. We attributed this to the difficulty of mixing the small quantities of TTX, NaCl and silicone rubber into a uniform paste, so that different amounts of TTX were probably present.

Animals were used for the acute experiment within 24 h of the disappearance or marked diminution of paralysis. The peroneus tertius and solar muscles together with their nerves were dissected out of the right and left leg and studied *in vitro* at room temperature (normally 20 °C), perfused continuously with well oxygenated fluid of the following composition: 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 5 mM $CaCl_2$, 1.24 mM HEPES, *p*H 7.4, 16.5 M glucose. Maximum isometric twitch and tetanic (50 per s) tension was recorded on stimulation of the nerve below the block. These tensions were compared with that evoked by direct stimulation of the muscle fibres (stimulus applied by two bright silver wires on either side of the muscle). The direct stimulus intensity was turned up gradually and usually maximum tension was produced by 10-V, 100-μs pulses. A 20-V, 300-μs pulse was then used to check that all the muscle fibres were being stimulated. If the direct and nerve-evoked tensions were not identical, the muscle was discarded as some axons had presumably been killed. This occurred on four out of 13 occasions in peroneus tertius, but not at all in 13 soleus muscles. When the two tensions were identical, a further check for absence of denervation was to grade the stimulus to the muscle nerve and, by sequentially bringing in motor units of different threshold, to count them. The number counted in this way in the experimental soleus and peroneus tertius was then compared with the figure for normal muscles from the opposite leg. When the direct tension equalled the nerve evoked tension, the unit numbers counted in this way were the same on the normal and experimental sides. The mean unit number for peroneus tertius was 11 and for soleus 21. The muscles were then curarised and end plate potentials were recorded with conventional 10 MΩ glass micropipettes. We sometimes had to use up to five times the normal dose $(5\times0.5\,\mu\mathrm{g\,ml}^{-1})$ of *d*-tubocurarine to block transmission in the experimental muscles. The recording of end plate potentials enabled us to check first that all fibres were innervated and second, by grading the stimulus to the nerve, whether as a result of sprouting any fibres had become polyneuronally innervated. Twenty to fifty fibres were examined in each muscle. Finally the preparations were stained for 5–6 h in a 4 : 1 solution of zinc iodide and osmium tetroxide[10], washed in water, teased with forceps and scissors into fine bundles, dehydrated, cleared in xylol and mounted in Permount.

Provided paralysis had lasted for 3.5 d or longer the histology showed fine ultraterminal sprouts extending from the motor nerve terminals. In some cases the fine branches were very short (Fig. 1*b*) and in others extensive outgrowths could be seen (Fig. 1*c*). The soleus endplates sprouted more vigorously than those in peroneus tertius which usually had only a single large sprout. This is in agreement with results from sprouting induced by botulinum toxin[11]. Five control animals with non-paralysing cuffs had normal endplates (Fig. 1*a*). To obtain an objective figure for the degree of sprouting, we measured for 50 endplates in each muscle, first the length, in the long axis of the muscle fibre, of the nerve

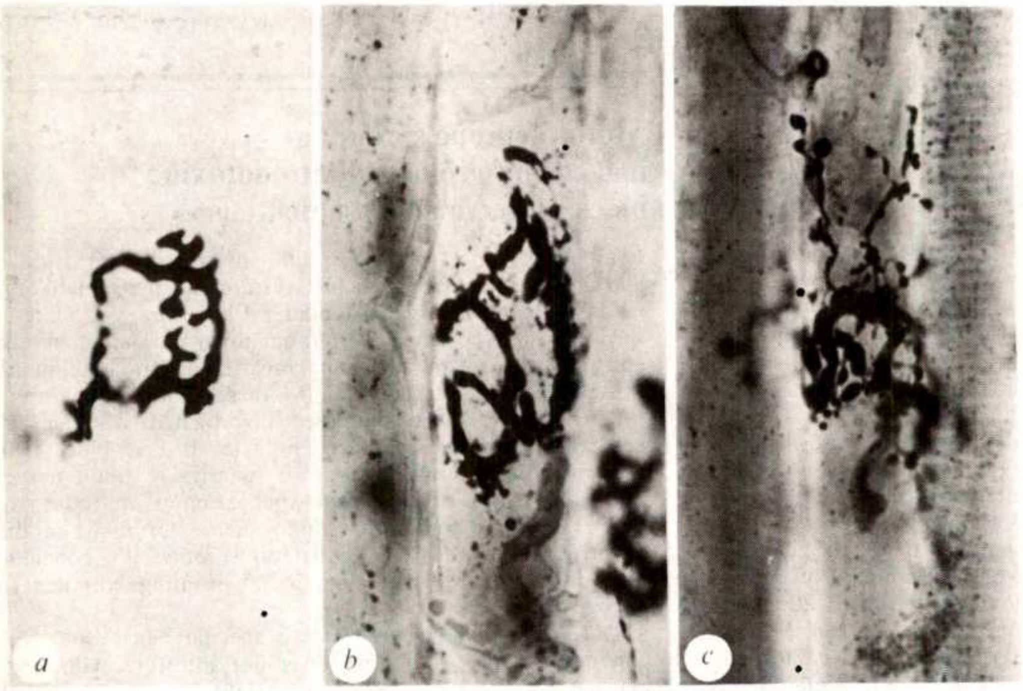

Fig. 1 Photomicrographs of mouse soleus endplates stained with zinc odide and osmium tetroxide[7] from: *a*, a control animal in which a nonparalysing cuff was present for 5 d; *b*, paralysis for 3.5d; *c*, paralysis for 5 d. The calibration bar on the right is 50 μm.

terminal which is densely stained by zinc iodide and osmium tetroxide, and second in those endplates with sprouts the length of endplate plus the furthest sprout extensions in both directions along the muscle fibre. Sprout length was taken as the difference between these two measurements. The percentage of endplates with sprouts in each experiment is shown in Fig. 2*a*, for paralysed, cuffed but not paralysed, and for normal muscles. Figure 2*b* shows, for each experimental muscle, the extent of sprouting (μm per endplate) obtained by dividing the total length of sprouts measured for that muscle by the number of endplates measured. For the control muscles the figure is near zero. As described by Barker and Ip[12], a small amount of sprouting is seen in normal muscles.

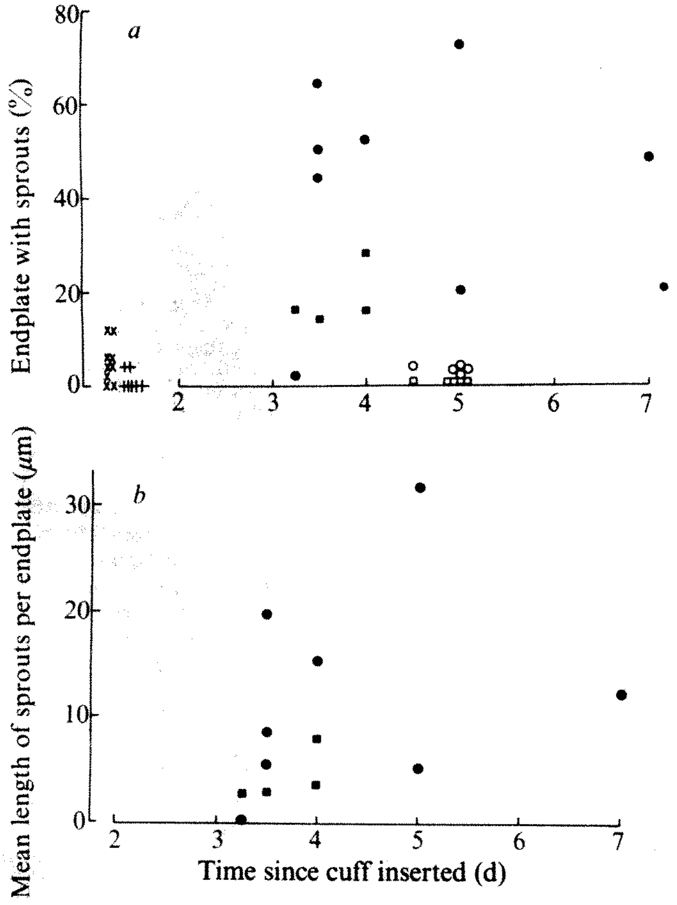

Fig. 2 *a*, Percentage of endplates with ultraterminal sprouts; *b*, mean length of sprouts per endplate (see text); ●, paralysed soleus; ■, paralysed peroneus tertius; ○, control soleus; □, control peroneus tertius; ×, normal soleus; +, normal peroneus tertius.

Even in muscles with much sprouting some endplates appeared quite normal. Our test for paralysis was not very sophisticated and it seems likely that not all the motor units were blocked for all the time, and it may also be that within one muscle the latent period before sprouting starts differs between motor units, as it does between units in different muscles[11]. Less than 2% of the fibres were found to be polyneuronally innervated by our physiological test. As a similarly very small proportion of normal mouse soleus fibres is polyneuronally innervated, it seems that the blocking times we have achieved are not long enough for sprouts to form functional endings on other fibres in significant numbers. If we can achieve longer blocks in future it will be interesting to see if they do and what their fate will be when paralysis wears off. In both normal and experimental muscles we failed to record endplate potentials in about 3% of fibres impaled.

These results show, in agreement with others[6,7] that TTX can be used to paralyse without killing nerves, and as control animals with cuffs showed no more than normal sprouting[12] any interference of the cuff *per se* with axoplasmic transport was not enough to cause sprouting. We therefore conclude that a few days inactivity of muscle gives rise to a sprouting stimulus. The work of Lomo[13,14] *et al.* has shown that inactivity induced by a local anaesthetic nerve block causes changes in the muscle membrane similar to those of denervation and this result has been confirmed by using TTX block[6,7]. The denervation changes can be prevented by direct stimulation of the muscle[13,14]. We have found (unpublished observations with G. M. Goodwin) that induction of sprouting by botulinum toxin can be prevented by direct stimulation of the muscle. Inflammation also causes muscle membrane hypersensitivity and can cause nerve sprouting[15]. It seems that sprouting is induced by a stimulus from the muscle which may be present normally to a small degree, but is greatly increased in various conditions; for example during prolonged inactivity or inflammation. Whether the stimulus is a diffusible chemical, or a change in the surface of tissues surrounding the nerve terminals is unknown.

Punishment learning and self-mutilation in Lesch–Nyhan disease

THE self-injurious behaviours (SIB) of Lesch–Nyhan children were studied during three learning paradigms: punishment, positive reinforcement and time-out from reinforcement following an attempt at self-injury. Punishment of self-injury by contingent electric finger shock failed to suppress these behaviours but positive reinforcement of non-self injury and time-out procedures were effective. The results stress the importance of environmental factors in the development and control of SIB and suggest the presence of an unusual learning defect which may be related to the specific enzyme deficiency in Lesch–Nyhan disease.

Lesch–Nyhan disease is an autosomal recessive disease in which the primary defect is in the synthesis of a catalytically ineffective enzyme, hypoxanthine phosphoribosyltransferase[1–3]. A most striking aspect of this disease is the bizarre pattern of self-mutilation that appears at about two years of age. Finger biting is characteristic. This may cause severe injury, even amputation. Elbow splints and hand bandages may have to be worn continuously to prevent damage. If the restraints are removed, the patient screams in apparent panic, 'compulsively' raises his hand to his mouth and will bite his fingers. Once securely restrained, the patient again becomes placid. Lip biting may also develop, requiring extraction of teeth. It should be noted that the children do not appear to be deficient in pain sensitivity, and are less retarded than originally thought[4]. Many biochemical approaches to treatment have been tried without success[5].

Five males, ages 3, 5, 11, 12 and 13 yr, with the characteristic clinical and biochemical findings of Lesch–Nyhan disease served as subjects. Before treatment all wore arm restraints and exhibited scars on fingers and lips. A standardised assessment procedure was devised to establish a baseline rate of SIB while avoiding extensive injury to the child. At the beginning of the baseline period the child is seated in a wheelchair and his arms are released from the restraints (a splint that prevents the elbows from bending). An assistant seated in front of the child intercepts the hand as it nears the mouth and places it back in the child's lap without speaking or otherwise interacting with the child (response prevention). Observers out of the child's line of vision record the behaviour. For a summary of the treatment procedure and results see Fig. 1.

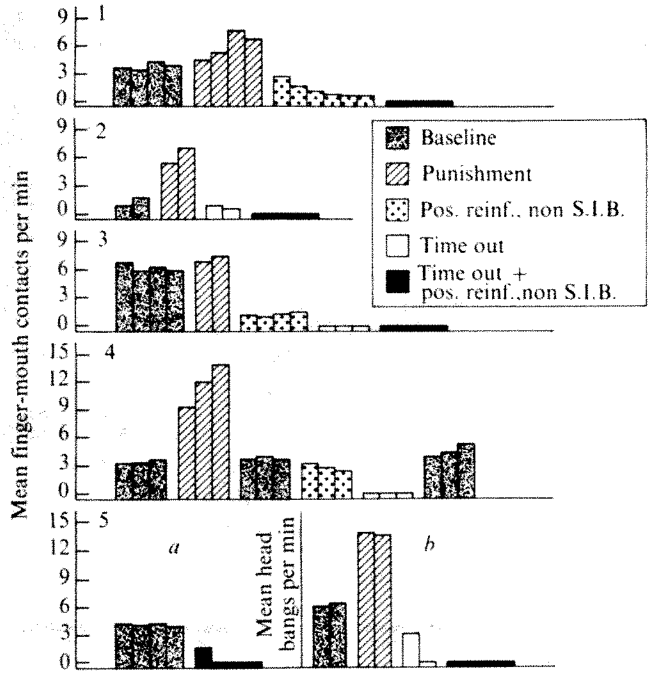

Fig. 1 Response of five Lesch–Nyhan children to treatment for SIB. Punishment does not decrease the frequency of undesirable incidents. Positive reinforcement of non-self injurious behaviour reduces the frequency; the best results are achieved with time-out and time-out plus positive reinforcement of non-SIB. Each bar represents the mean average SIB response rate per min during a session about 30 min long. Usually three sessions were conducted per day. The children's data are presented in the order of admission to the hospital.

'Aversive stimulation' has been the most widely used approach to the control of self-injury[6–12]. In the punishment paradigm, aversive stimulation is delivered immediately following the undesirable behaviour. Consent of the Human Research Committee was obtained and parents experienced the electric shock before agreeing to the treatment plan.

Subjects 1–4 were given electric finger shock contingent on each hand-to-mouth contact. The fifth child was given shock following each head bang. In all cases the shock intensity was 5 mA (a level generally described as quite painful). The results of the punishment procedure can be seen in Fig. 1. In all cases the procedure failed to suppress the frequency of SIB and, in fact, seemed to promote such behaviour.

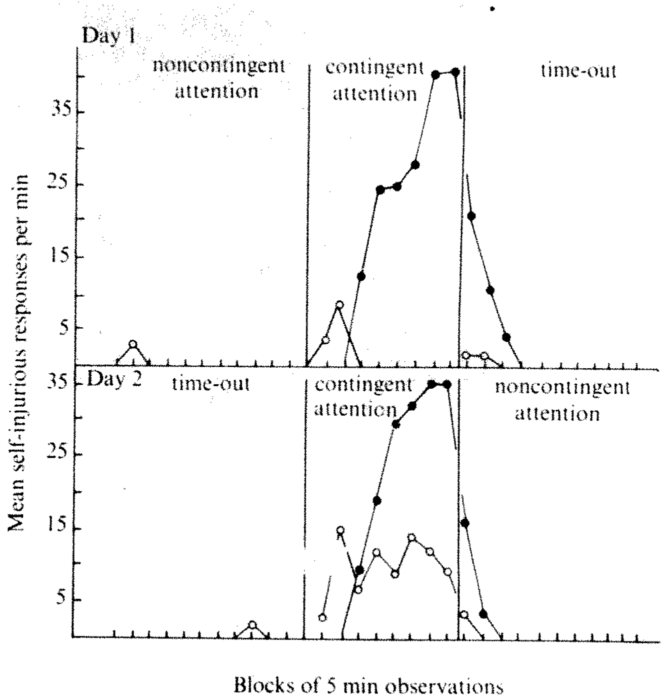

Fig. 2 SIB rate in response to non-contingent attention; contingent attention; and time-out. Each data point represents the mean number of finger biting (○) or lip biting (●) responses per min, for blocks of 5 min observations. For each of the two days the session was continuous (3 h) with no pause between manipulations.

Through naturalistic observation of parents and child it was determined that the frequency of SIB varies considerably and predictably with variations in the environment suggesting a learned behaviour that is under discriminatory control.

The facilitory influence of positive reinforcement of SIB can also be clearly demonstrated under controlled conditions. The therapist was instructed to give contingent attention by quickly interceding to prevent self-injury while making reassuring statements, and stroking the child. The frequency of SIB, in one child so treated, increased dramatically when compared to non-contingent attention or time-out (Fig. 2).

Positive reinforcement of non-SIB and time-out, either alone or in combination consistently produced rapid reductions and eliminations of SIB. When the child was not agitated or attempting to bite, the therapist would reinforce these behaviours by smiling, talking, playing or in other ways interacting with the child. Time-out consisted

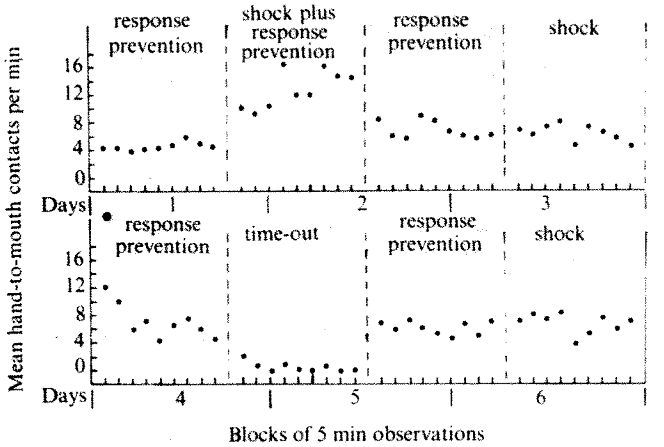

Fig. 3 Response of SIB to response interruption or baseline procedure; shock plus response interruption; shock alone; and time-out. Shock plus response interruption increases the SIB above baseline level. Shock alone produces no variation from baseline. Time-out reduces SIB to near zero. Each data point represents the mean number of hand-to-mouth contacts per min per 5 min observation period.

of the withdrawal of all attention to the child following each SIB attempt. The therapist simply turned away from the child for about 5 s. The response prevention procedure used during baseline of intercepting hand-to-mouth contacts was discontinued.

Because of the danger of self-injury, finger shock and the response prevention procedure always occurred together. This pairing of physical attention with finger shock could account for the increase in response rate during punishment. Before therapeutic training subject 5 was used to evaluate these two variable (Fig. 3). When shock is given without response interruption the SIB rate does not vary from baseline rates.

We have not shown in Fig. 1 the results of a programme for the maintenance of these effects. For all children, the rate of SIB remained at zero for approximately 3 months. At an 18-month follow-up the average SIB rate is 20% of initial baseline. Presently the behaviour is under a high degree of stimulus control with certain adults or specific settings producing complete absence of self-injury, while others produce SIB comparable to pretreatment rates.

An unexpected observation in these studies has been the inability to reduce or eliminate a particular behaviour by the administration of an aversive stimulus via the positive punishment paradigm[6]. This techniuqe is so regularly effective under experimental and natural conditions, and consistently effective in the elimination of SIB in other diagnoses, that its ineffectiveness in Lesch–Nyhan disease was particularly striking.

One explanation is that Lesch–Nyhan children are incapable of learning from aversive stimulation. In contrast, they learn quickly from positive reinforcement and time-out, suggesting a specific learning disability related to an identifiable gene. Such an explanation will depend on whether or not the inability to learn from aversive experience is specific to SIB or a general effect that extends to other aspects of learned behaviour.

Peri-ovulatory synchronisation of behaviour in male and female rhesus monkeys

RHESUS monkeys, like many other primates, do not restrict their sexual activity to the ovulatory period, and copulation may occur at any time during the menstrual cycle[1,2]. Thus, in the laboratory, the male's ejaculatory frequency is generally highest near mid-cycle (although different pairs show different patterns of mounting and ejaculation[3]) while, in the wild, sexual activity seems to be more or less restricted to the middle part of the cycle[4,5]. It is difficult to judge the stage of the cycle in troops of feral rhesus monkeys, but during the period of maximum sexual activity females actively approach males and form temporary consort bonds which involve mutual grooming and frequent copulations[6]. To obtain an independent and objective measure of female sexual motivation, we have used an operant conditioning technique in which the female was required to press a lever for access to her male partner. This has made it possible to relate changes in female motivation precisely to changes in the circulating levels of ovarian hormones. We have also demonstrated a synchronisation and maximisation of female sexual motivation with male ejaculatory performance during the peri-ovulatory (fertile) period of the menstrual cycle.

When pairs of rhesus monkeys are tested together in laboratory conditions, the close proximity and dominance of the male, nearly twice the size of the female in this species, strongly influences the female's behaviour, and it is difficult to obtain an independent measure of the female's sexual motivation uncontaminated by the threat of male aggression. Our operant conditioning technique was developed to avoid this problem by giving the females themselves control over their access to males[7]. The testing cages were divided by a movable partition, and pressing a lever 250 times on one side of the partition activated a servo-motor that raised it, facilitating access to the other side of the cage. Females were trained to perform this task, first for food reward and then, when they were familiar with the situation, for a male partner. The period from the introduction of the female into the cage to the moment the door opened (access time) was timed automatically. After the female obtained access to the male, a behaviour test of 1 h was conducted during which observers scored various aspects of the pair's behaviour from behind a one-way vision mirror[8]. If the female failed to obtain access in the 30 min allowed, animals were removed from the operant cage and, later the same day, were brought together in a different cage for a 1-h behaviour test; this preserved the continuity of the behavioural data.

Sixteen rhesus monkeys (nine females and seven males) were obtained directly from India. The Fallopian tubes of females were ligatured to prevent pregnancy. Results are based on 1,440 tests of 17 pairs conducted during 63 menstrual cycles (30.1±4.8 d, mean±s.d.). Data were combined by aligning the cycles on the first day of the next menstruation and calculating 3-d means. The frequency of ejaculation in these pairs followed a pattern similar to that found in earlier studies[2], and showed a maximum (1.63±0.05 ejaculations per test, mean±s.e.) at the end of the first half of the cycle (reverse days 18–16), and a minimum (0.80±0.07 ejaculations per test) in the middle of the second half of the cycle (reverse days 9–7) (Fig. 1). The shortest mean access time (342.3±23.3 s) also occurred during reverse cycle days 18–16, and the longest mean access times occurred near the beginning and end of the cycle. The highest ejaculation frequency and the fastest access time therefore occurred at, or just before, the expected time of ovulation[9]. These data confirmed the preliminary results obtained with this operant conditioning technique[7]. Although the nature of the stimulus that motivated females to lever-press for access to males remains unknown, and may well vary from pair to pair, access times for males were not correlated with access times for food rewards on the same day or with access times when a female instead of a male was the reinforcement. Thus, we can assume that the access time data reflected the female's motivation for the male and were not merely dependent on cyclic changes in the female's motor activity.

To obtain more precise information on the temporal relationship between behavioural parameters and hormonal status, blood samples were collected from five females on alternate days (daily near mid-cycle) during 33 menstrual cycles. These samples were analysed for progesterone, oestradiol, testosterone and dihydrotestosterone simultaneously using a radioimmunoassay that involved chromatography on Sephadex LH20. All these cycles appeared normal, with the characteristic pre-ovulatory oestradiol peak occurring 19–17 d before the next menstruation, and with rising progesterone titres signalling the development of corpora lutea. Hormonal and behavioural data from the periovulatory periods of these 33 cycles were then combined by aligning them on the days of the oestradiol peaks (Fig. 2). The highest mean ejaculation frequency and the fastest mean access time both occurred together 1 d after the oestradiol peak, and on that day all males always succeeded in ejaculating and all females always pressed for access to their partners. The statistical analysis of the behavioural data (for cyclicity and synchrony) is necessarily complex and involves the treatment of 18 separate indices for each of the 17 pairs; results will be fully reported elsewhere.

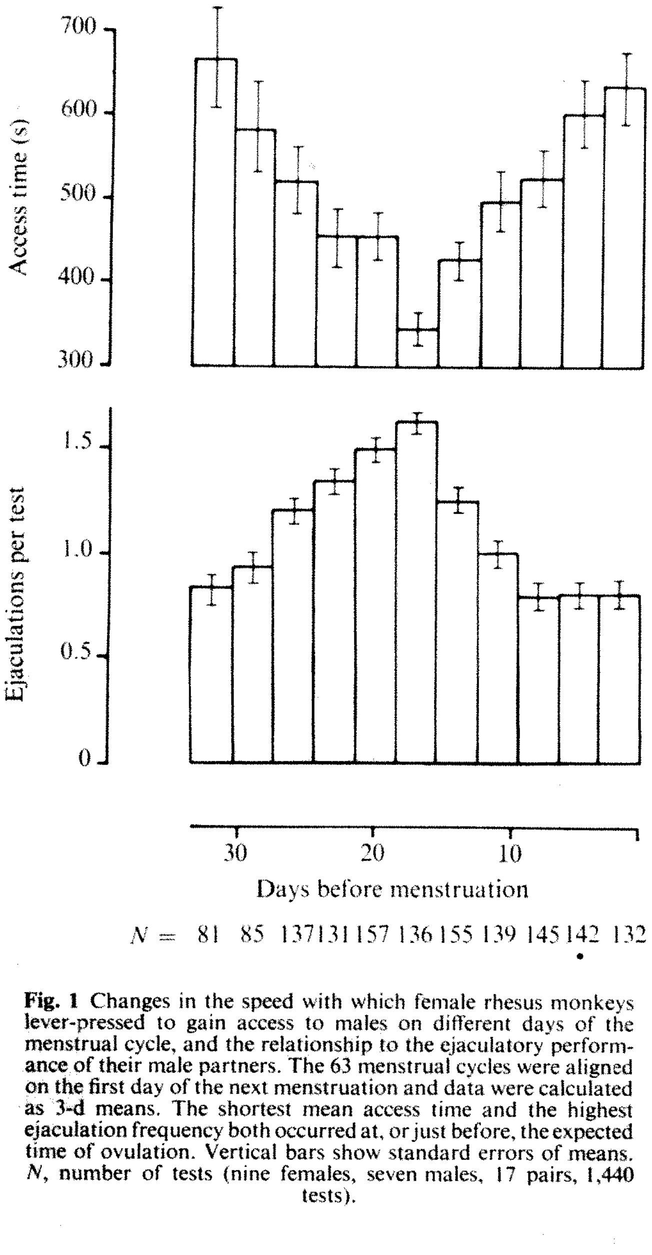

Fig. 1 Changes in the speed with which female rhesus monkeys lever-pressed to gain access to males on different days of the menstrual cycle, and the relationship to the ejaculatory performance of their male partners. The 63 menstrual cycles were aligned on the first day of the next menstruation and data were calculated as 3-d means. The shortest mean access time and the highest ejaculation frequency both occurred at, or just before, the expected time of ovulation. Vertical bars show standard errors of means. *N*, number of tests (nine females, seven males, 17 pairs, 1,440 tests).

Studies in which gonadal steroids were administered to ovariectomised rhesus monkeys showed that changes in the sexual behaviour of the pair can be induced by ovarian hormones[3]. Thus, the mid-cycle peak in plasma oestradiol, besides triggering the gonadotrophin surge responsible for ovulation 24–48 h later[10], may also synchronise and maximise the female's sexual motivation and the male's ejaculatory performance. The neuroendocrine mechanisms underlying the behavioural synchrony between the sexes and the timing of ovulation clearly have a selective advantage by optimising the chances for successful fertilisation and, thus, for survival in this highly evolved primate species in which sexual behaviour serves more than a purely reproductive function.

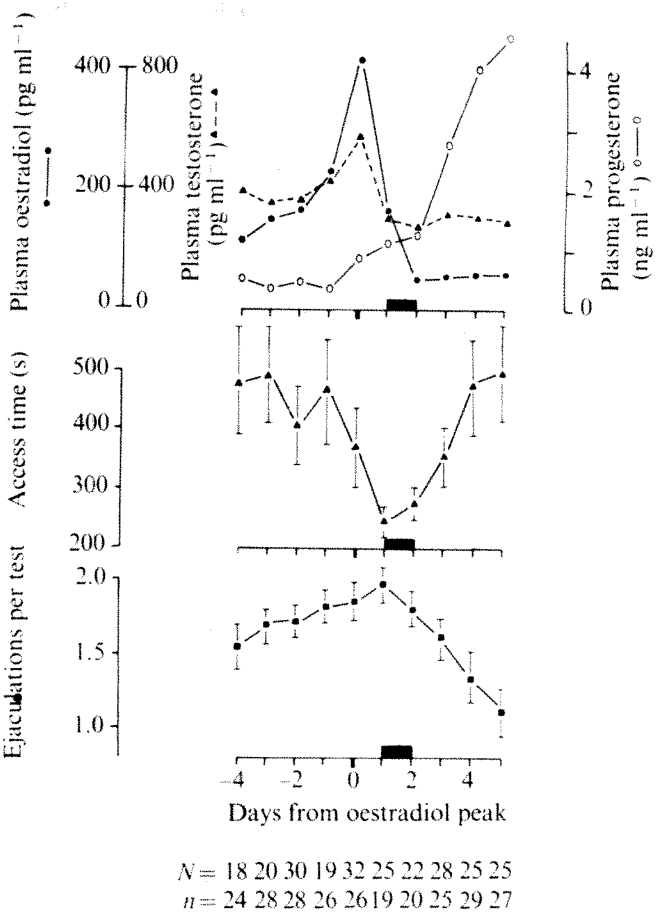

Fig. 2 Changes in the plasma steroids (oestradiol, progesterone and testosterone) of female rhesus monkeys in the peri-ovulatory period. Changes in the females' access times were synchronised with the expected time of ovulation (solid horizontal bars) when the males' ejaculations were at their maximum. The 33 cycles were aligned on the day of the oestradiol peak (day 0). Vertical bars show standard errors of means. *N*, number of plasma samples; *n*, number of behaviour tests (five females, five males, nine pairs, 252 tests).

Ca^{2+}-dependent ATPase activity of bovine receptor cell outer segment

THE bleaching of as little as one molecule of rhodopsin can trigger hyperpolarisation of the vertebrate visual receptor cell[1]. A light modulated Ca^{2+} flux may function in the receptor cell outer segments (OS) as an intracellular messenger amplifying and transducing the photochemical signal from its disk location to the external plasma membrane[2,3]. In support of this hypothesis, Ca^{2+} has been shown to be concentrated in dark adapted disks[4] and to be released on bleaching[5–7]. This suggests the presence of a Ca^{2+}-dependent ATPase, an enzyme often associated with cellular Ca^{2+} pumps. The report that either the bleaching of a few per cent of the rhodopsin molecules within a frog rod suspension or the intra-OS elevation of Ca^{2+} to 10^{-7} M or greater, by means of ionophore A23187, can induce a rapid and very large decrease in ATP content[8] provides indirect evidence for the presence of a Ca^{2+}-activated ATPase. Interpretation of this finding is difficult, however, due to other known light-activated, ATP-dependent OS functions[9]. We present here direct evidence that purified bovine OS exhibit significant Ca^{2+}-dependent ATPase activity, which seems to be independent of contributions from subcellular contamination.

Crude OS (OS_1) were prepared under dim red light from dark-adapted bovine retina (Hormel, Austin, Minnesota) by a sucrose floatation technique (modified from ref. 10), and highly purified OS (OS_2) were prepared by the method of Dratz[11]. Both preparations were lyophilised and stored at −78 °C.

A Ca^{2+}-dependent ATPase was present in the retinal homogenate and in OS_1. In contrast to the Mg^{2+}dependent and Na^+, K^+-enhanced Mg^2-dependent ATPases, each of which exhibit a threefold decrease in specific activity during OS_1 purification, the specific activity of the Ca^{2+}-dependent oligomycin-insensitive system increased (Tables 1 and 2) during purification.

A major difficulty in interpreting these results is that OS preparations are likely to contain mitochondria from the ellipsoid of the receptor cell[12], and mitochondria contain a Ca^{2+}-dependent ATPase system[13]. Mitochondrial Ca^{2+}-dependent ATPase, however, is completely inhibited by oligomycin[14,15]. Significantly, while oligomycin-sensitive, Ca^{2+}-dependent ATPase activity is observed in the retinal homogenate, its specific activity decreases to a negligible amount as OS_2 are purified (Table 2). This suggests that mitochondrial contaminants contribute little activity, if any, to the total OS_2 Ca^{2+}-dependent ATPase activity.

Table 2 Retinal Ca^{2+} dependent ATPase activity

Sample	10 μg oligomycin	No oligomycin
Retinal homogenate	5.9 ± 0.1(2)	8.8 ± 0.5(2)
Crude OS_1	6.8 ± 0.6(2)	7.5 ± 0.1(2)
Pure OS_2	8.0 ± 0.7(1)	7.9 ± 0.8(1)

Method of assay was as described in Table 1. Oligomycin was introduced in 25λ ethanol and samples were assayed in triplicate. Results are expressed in EU per mg protein as means ± s.e. with the number of assays in parentheses.

Maximal Ca^{2+} activation was observed at concentrations of 1 mM $CaCl_2$ or greater (Fig. 1), with no activity observed at concentrations less than 0.01 mM. Because the localisation of the ATPase and the availability of the added Ca^{2+} and ATP are unknown the Ca^{2+} concentrations could be considerably lower at the enzyme site. This might explain the high concentration required to activate the ATPase in these experiments compared with intracellular levels.

Localisation of the ATPase within the disk membrane would suggest a Ca^{2+} pump system which would account for the ability of the dark-adapted disk to accumulate Ca^{2+}.

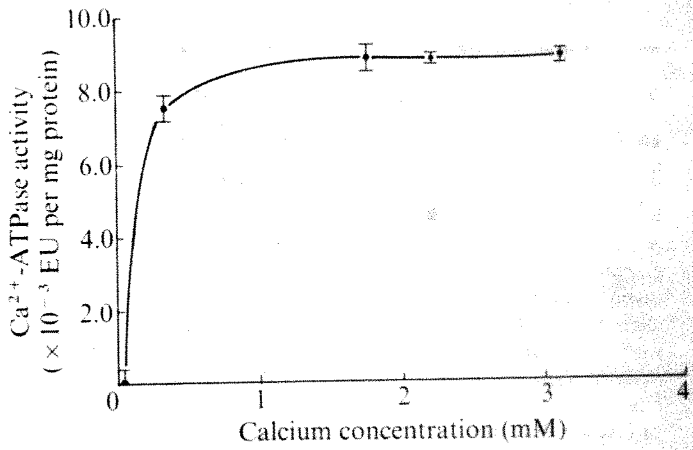

Fig. 1 ATPase activity as a function of free Ca^{2+}. Ca^{2+}-dependent ATPase was assayed as Table 1. $CaCl_2$ concentration varied. Free Ca^{2+} concentration was calculated using the association constant of the Ca $EDTA^{2-}$ salt[19].

Table 1 Retinal enzyme activities

Sample	Cyclic AMP diesterase	Mg^{2+} ATPase	Na^+ K^+ ATPase	Ca^{2+} ATPase
Retinal homogenate	7.4 ± 9(1)	29 ± 7(2)	8.8 ± 1.2(3)	5.9 ± 0.1(2)
Crude OS_1	30 ± 5(3)	9.9 ± 1.6(4)	3*	6.8 ± 0.6(2)

Cyclic nucleotide diesterase was assayed at V_{max}, using a modified two-step snake venom procedure[16]. Approximately 0.2 mg of protein was added to 1 ml containing 0.04 M Tris-HCl buffer *p*H 7.4, 0.09 M $MgCl_2$ and 0.02 M Tris cyclicAMP. The reaction was terminated after 4 min at 37 °C by a 1-min immersion in a boiling water bath. A second incubation at 37 °C with added *Crotalus atrox* venom yielded inorganic phosphate. In all assays phosphate was quantified colorimetrically by the method of Baginski *et al.*[17]. ATPase was assayed by the addition of 0.2–0.6 mg of protein to 1 ml solution containing one of the following solutions: 1, 0.1 mM EDTA, 3 mM $MgCl_2$, 0.05 M Tris-HCl buffer *p*H 7.4, 2 mM Tris-ATP, 1.35 mM Ouabain; 2, 0.1 mM EDTA, 0.15 M NaCl, 0.01 M KCl, 3 mM $MgCl_2$, 0.05 M Tris-HCL Buffer *p*H 7.4, 2 mM Tris-ATP; 3, 0.1 mM EDTA, 1 mM $CaCl_2$, 0.05 M Tris-HCl *p*H 7.4, 2 mM Tris-ATP, 10 μg oligomycin, 25λ ethanol. After a 20-min incubation at 37 °C the reaction was terminated by the addition of 4 ml of a solution containing 9% trichloroacetic acid, 1.8% ascorbic acid and 0.015% EDTA. The samples were centrifuged and an aliquot of the supernatant was removed for phosphate determination. To correct for the co-precipitation of phosphate with protein, a control containing a phosphate standard was used. The experimental details of this procedure, developed by Dr Herman Kauffman and R.A.S., will be published elsewhere. Mg^{2+}-dependent ATPase activity was obtained directly from the results of assay using mixture 1. Ouabain-sensitive (Na^+K^+-enhanced Mg^{2+}-dependent) ATPase activity was obtained by subtracting the Mg-dependent ATPase activity from that obtained with assay mixture 2. Assay mixture 3 yielded Ca^{2+}-dependent, oligomycin-insensitive ATPase activity. Protein was determined by method of Lowry *et al.*[18]. All assays were carried out in triplicate, the number of separate assays being given in parentheses. Results are expressed in EU (μmol min^{-1}) per mg protein as means ± s.e..

*The specific activity of Na^+K^+-enhanced, Mg^{2+}-dependent ATPase in purified OS was low and the enzyme assay was unstable. Assays were linear for only 5 min and the results are approximate.

Plasma membrane localisation, which cannot be excluded, would suggest a Ca^{2+}-modulated energy utilisation system, possibly involved in hyperpolarisation.

Ultraviolet light sensitivity and delayed DNA-chain maturation in Bloom's syndrome fibroblasts

BLOOM'S syndrome (BS) is a rare, autosomal recessive condition of pre-natal and post-natal growth retardation, sun-induced telangiectatic erythema, impaired immunological function and predisposition to cancer[1,2]. BS cells show a high incidence of chromosome breakage and rearrangement often with abnormal nuclear morphology. Chromosome exchanges appear mainly to involve homologous chromosomes, while sister chromatid exchanges are abnormally frequent[3]. These features suggest a defect of DNA replication or repair. In particular, the high incidence of sister chromatid exchanges may be explained if free ends in the DNA, resulting from abnormalities of DNA synthesis and/or repair, act as initiation points for exchange[4]. We report here that BS fibroblasts are abnormally sensitive to ultraviolet irradiation *in vitro* and show a rate of DNA synthesis and DNA chain maturation lower than controls. They do not, however, have defective bypass of ultraviolet light-induced lesions during DNA replication as xeroderma pigmentosum (XP) variants[5].

Skin fibroblasts from two patients with the typical clinical and cytogenetic features of BS (H.11325/PRU8638; H.12572/PRU10003), termed BS_1 and BS_2, respectively, and normal volunteers (H.9172; H.9527) were cultured from small skin biopsies in medium TC199, supplemented with 15% human serum and 2.5% chick embryo extract and then stored in liquid nitrogen. Cells usually at the sixth to eighth and occasionally at the ninth to twelfth passage were used.

Typically, BS fibroblasts grow poorly and ours showed plating efficiency of 7–18%, while that of controls was 23–51%. The labelling index of BS cells incubated in the presence of ^{3}H-thymidine (^{3}H-Tdr) was lower than that of control cells (Table 1) and usually reached a lower plateau during a 3-d incubation (Table 2). This indicated that a larger fraction of cells was not replicating in BS than in normal cultures.

BS cultures were more sensitive to ultraviolet radiation than controls. Survival curves (Fig. 1), standardised for plating efficiency, show that the two BS strains were similarly affected and that their curves lack a shoulder. If sensitivity is expressed in terms of the dose resulting in 37% survival, the BS strains were three times as sensitive as controls.

In spite of the ultraviolet sensitivity of BS cells, our autoradiographic data (Table 3) suggest that exposure to ultraviolet light depresses DNA synthesis in control and BS cells by similar amounts. The average grain count of BS nuclei, however, was lower than that of controls (Tables 1 and 3), suggesting that the rate of overall DNA synthesis in Bs nuclei is lower than in controls even in normal conditions.

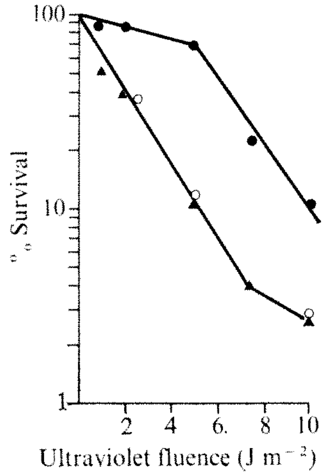

Fig. 1 Ultraviolet survival curves of normal (●) and BS (BS_1, ▲; BS_2, ○) fibroblasts. Inocula of 200 fibroblasts, plated in 60-mm plastic Petri dishes, were washed, after attachment, with phosphate-buffered saline and irradiated or sham-irradiated using a germicidal lamp emitting mainly ultraviolet light of 254 nm. When adequate colonies had grown in unirradiated cultures, all plates were collected and colonies of at least 50 cells were counted. The number of colonies scored at each ultraviolet dose is expressed as a percentage of the colonies in unirradiated cultures and shown on a logarithmic scale. The control curve was derived from eight experiments; that of BS_1 from four and that of BS_2 from one.

Pulse chase experiments showed that newly synthesised DNA from both BS cell strains consistently had lower molecular weights than DNA from control cells (Figs 2 and 3*a*). In time course experiments following a 1-h ^{3}H-Tdr pulse, this difference was maximal after a chase of 2.5 h, but persisted with diminishing magnitude when the chase was extended for up to 6 h. Ultraviolet

Table 1 Percentage of ^{3}H-Tdr-labelled cells and grain counts after 1-h pulse

	Experiment no.							
	1		2		3		4	5
Cell strain	%LC	GC	%LC	GC	%LC	GC	%LC	%LC
BS_1	5.8	40.5	5.4	41	3.2	57	16.7	2.6
Control	45	92.3	25	93	15	110	38.4	18.5

Coverslips from 60-mm Petri dishes, inoculated with 10^5 cells at the sixth to ninth passage, were collected a day later after a 1-h pulse in ^{3}H-Tr (12.5 Ci mmol^{-1}, 30 μCi ml^{-1}). They were then washed in phosphate-buffered saline (PBS), fixed in 3:1 methanol–acetic acid mixture and coated with AR 10 autoradiographic film. Autoradiographs were developed after 6-h exposure. Labelling indices (%LC) were estimated from samples of 2,000 cells and mean grain counts (GC) from 75 cells. BS cells show a 50% reduction in grain counts.

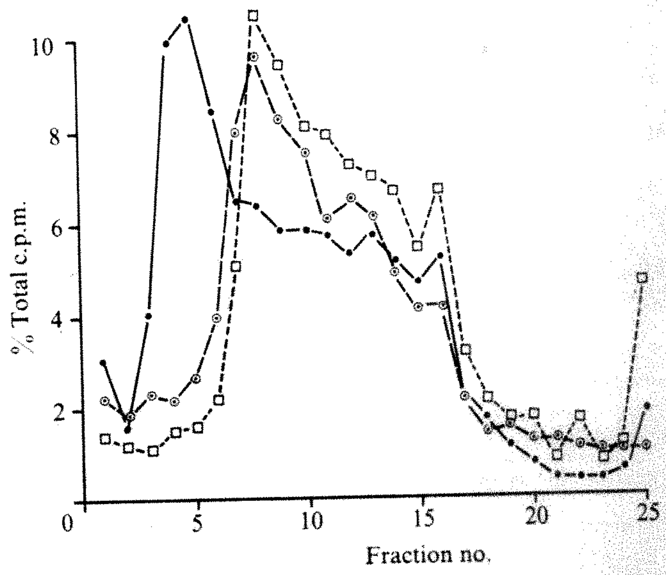

Fig. 2 Alkaline sucrose gradient profiles of newly-synthesised DNA in unirradiated control (●), BS$_1$ (□) and BS$_2$ (○) cells. 2.5 × 10^5 cells were cultured as described in the text in 60-mm Petri dishes and incubated for 2 d, washed in PBS (8 g of NaCl, 0.2 g lf KH_2PO_4, 0.2 g of KCl, 1 μg of Na_2HPO_4 per l of water) and incubated in 5 ml of warm medium for 1 h, pulse-labelled with ^{3}H-Tdr (33 μCi ml^{-1}; 25 C mmol^{-1}) for 1 h, washed with warm PBS and chased for 2.5 h with unlabelled medium containing thymidine and deoxyeytidine (both at 10μM). After incubation, cells were scraped off the Petri dishes with a piece of silicone rubber into 0.3 ml of PBS containing EDTA (0.2%), centrifuged (600g for 5 min at 18 °C) and resuspended in 0.15 ml of EDTA solution. The suspension was then exposed to δ irradiation (1.5–2.0 krad) from a ^{60}Co source to prevent entanglement of DNA strands[6]. Alkaline sucrose gradients (4.4 ml, 5–20%) containing 0.1 M NaOH and 0.1 M NaCl were overlain first with 0.2 ml of 2% sodium dodecyl sulphate containing 0.02 M EDTA; and then with 0.1 ml of the cell suspension. Centrifugation was for 75 min at 20 °C and 40,000. p.m. in an SW56 rotor in a Beckman L2-65B ultracentrifuge. After centrifugation, 10-drop fractions were collected from the bottom of the tubes and assayed for cold acid-insoluble radioactivity[7]. Sedimentation was towards the left.

irradiation before labelling (Fig. 3*b*) depressed the maturation of DNA chains to a similar extent in BS and control cells, while caffeine had no detectable effect in unirradiated control or BS cells (Fig 3*c*), but caused a moderate depression of DNA chain maturation in ultraviolet-irradiated control and BS cells (Fig. 3*d*). In contrast, and in agreement with Lehmann *et al.*[5], cells from a patient with XP-variant showed a much greater inhibition of DNA chain maturation after ultraviolet irradiation and this was accentuated by caffeine (Fig. 4). This effect of ultraviolet irradiation on XP-variant cells has been attributed to a defect in the bypass of induced lesions, probably due to a delay in the sealing of gaps left opposite pyrimidine dimers during the synthesis of new DNA strands (post-replication repair[5]). Ultraviolet irradiation with and without caffeine had no differential effect on the maturation of newly synthesised DNA of control and BS cells, suggesting that this form of repair is not inhibited in BS, as it is in XP-variants.

Our experiments show that BS fibroblasts *in vitro* have low viability and are abnormally sensitive to ultraviolet irradiation, their rate of DNA synthesis is low and maturation of new DNA chains is delayed. This is in keeping with the clinical features of BS,

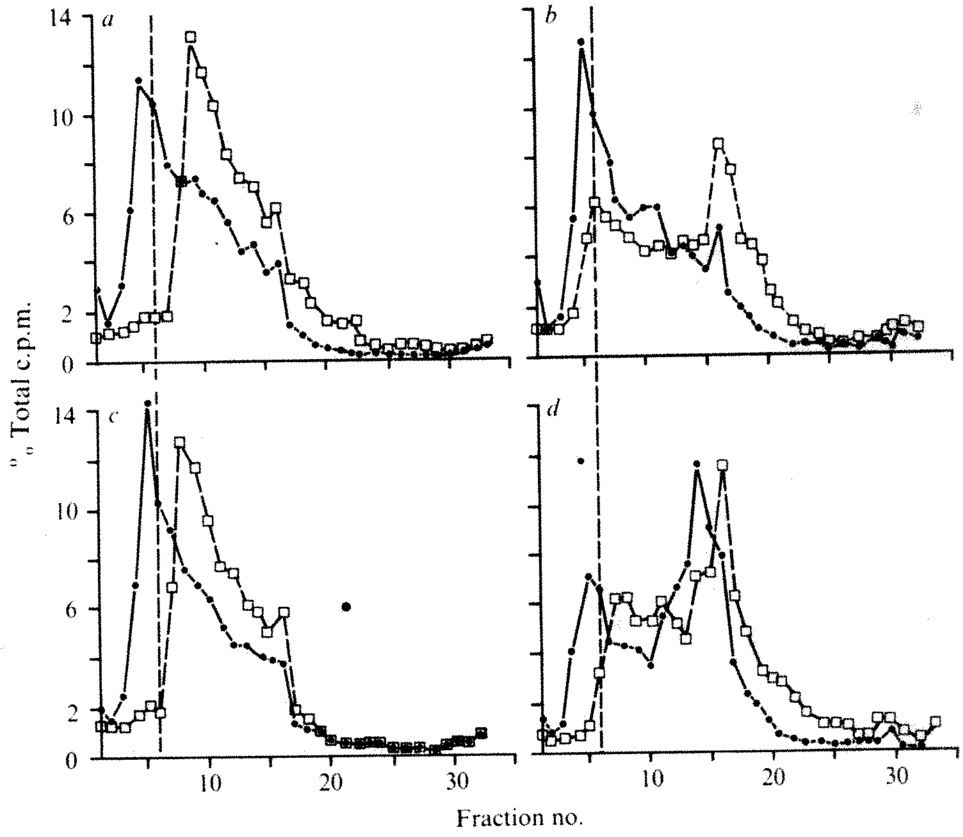

Fig. 3 Alkaline sucrose gradient profiles of DNA newly synthesised, either in the absence or presence of caffeine, by ultraviolet-irradiated and non-irradiated BS$_1$(   ) and control (   ) cells; methods were as described in Fig. 2, except for irradiated and/or caffeine-treated cells which were exposed, immediately after the initial washing with PBS, to germicidal light (mainly of 254 nm) at a fluence of 12.5 J m^{-2} and/or caffeine (0.3 mg ml^{-1}). The vertical line marks the sixth fraction of each gradient. *a*, Nonirradiated, no caffeine; *b*, Irradiated, no caffeine; *c*, non-irradiated caffeine; *d*, irradiated, caffeine. As in Fig. 2, the DNA of the BS cells sediments more slowly than the control and this difference is not influenced by the treatment, even where irradiation and caffeine result in a noticeable reduction in the sedimentation rate of both control and BS DNA (*d*).

Table 2 Percentage of ^{3}H-Tdr-labelled fibroblasts as a function of time

Cell strain	Experiment no.	Labelling period (h) 14	24	38	48	62	72
BS_1	1*	9.25	19.4	—	29.7	31.7	—
	2†	33.1	34.0	35.6	41.1	38.9	53.4

	3	30.4	76	—	72	78	83

*Cells at the eight passage.
†Cells at the fifth passage.
‡Cells at the ninth passage.

Cells at similar passages were plated in 35-mm Petri dishes containing coverslips (4×10^4 per dish) and labelled with ^{3}H-Tdr (1 μCi ml^{-1}, 1 Ci mmol^{-1}). The label was replenished daily. Collected coverslips were washed with PBS, fixed in 3:1 methanol–acetic mixture and coated with AR 10 autoradiographic film. Autoradiographs were developed after 10-d exposure. Samples of 2,000 cells were used to determine labelling indices.

Table 3 Mean grain counts per labelled nucleus after 1-h ^{3}H-Tdr pulse

Cell strain	Experimental treatment: No irradiation, no caffeine Mean	s.e.	No irradiation, plus caffeine Mean	s.e.	Irradiation, no caffeine Mean	s.e.	Irradiation, plus caffeine Mean	s.e.
BS_1	119	6.3	127	8.8	39.7	2.4	50.1	2.8
Control	131	8.1	182	8.4	71.0	4.0	76.9	3.9
BS_2	125	8.1	—	—	41.5	4.2	42.7	4.7
Control	186	7.6	227	23.4	58.3	2.6	62.6	3.6

Cells were plated in Petri dishes containing coverslips and treated as for those in Fig. 3. They were collected and autoradiographs were prepared as described in Table 1. Samples of 50 cells were used to calculate the mean grain counts. **BS** cells show a 30% reduction in grain counts. This is less than observed in Table 1; such discrepancy may be due to the different experimental procedures to which the cells have been exposed.

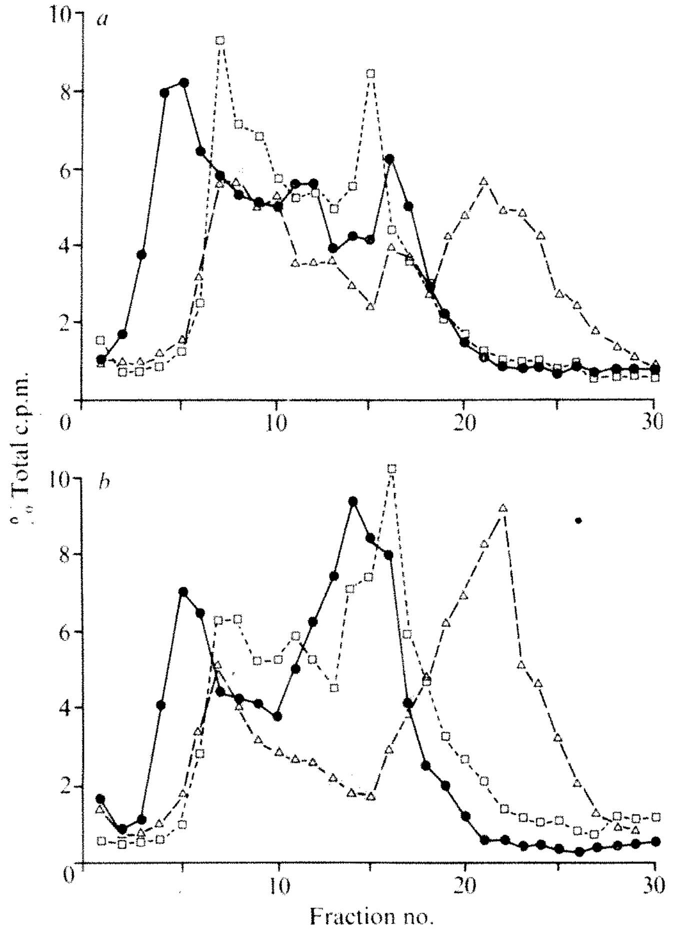

Fig. 4 Alkaline sucrose gradient profiles of DNA newly synthesised, either in the absence or presence of caffeine by ultraviolet-irradiated control (●), BS, (□) and XP variant cells (△) labelled and chased as in Figs 2 and 3. Experiments were carried out either in the absence (*a*) or presence (*b*) of caffeine (0.3 mg ml^{-1}), throughout the period after ultraviolet irradiation.

particularly growth retardation and light sensitivity. In contrast to XP-variants, when BS cells are exposed to 12.5 J m^{-2} of germicidal ultraviolet light they do not seem to have difficulties in bypassing ultraviolet-induced lesions in the course of DNA replication and they seem to respond normally to the inhibitory action of ultraviolet light on DNA synthesis.

Data of Hand and German[8] suggest that movement of DNA replicating forks is slower in BS than in control cells. By their autoradiographic technique, they could measure DNA chain growth of relatively small samples of replicons from a few replicating cells. Our sedimentation experiments, however, compare the average rate of maturation of DNA chains attaining a maximum size of 150 μm (approximately 5 replicons 30 μm long) from whole cell populations[5,9].

Our results therefore are in line with and extend those of Hand and German[8]. Because their technique depends on cellular uptake of ^{3}H-Tdr, they considered the possibility that their results reflect impaired uptake of ^{3}H-Tdr by BS fibroblasts. We excluded this possibility because, after a 2.5-h chase (during which DNA synthesis was not dependent on exogenous ^{3}H-Tdr), differences in molecular weight of BS and control DNA were even greater than immediately after the pulse (data not shown).

DNA synthesis in mammalian cells is initiated in a preprogrammed fashion at different sites of the same molecule and proceeds bilaterally from each origin[9-11]. The rate of movement of the growing fork may change during the S phase[10] and the distance between initiation points may vary between cells of the same organism according to the stage of differentiation and development[11]. Our data for BS cells suggest that the fundamental defect involves a step in DNA replication, but we cannot exclude the possibility that the impaired growth of new DNA chains is secondary to a disturbance of other metabolic processes. The abnormal sensitivity of BS fibroblasts to ultraviolet light cannot yet be explained by a defect of DNA repair, for analysis of the first steps of excision repair has given negative results[12,13] and our observations suggest that the bypass of ultraviolet lesions is not impaired as in XP-variants. The association of ultraviolet-sensitivity and delayed maturation of DNA chains in BS fibroblasts, however, suggests that the metabolic defect in BS involves a factor or step important for DNA synthesis and for the repair of ultraviolet-induced damage.

Chromatin dispersal and DNA synthesis in G1 and G2 HeLa cell nuclei injected into *Xenopus* eggs

IF HeLa cells that are synthesising DNA (S phase) are fused with others in the G1 phase of the cell cycle, DNA synthesis is prematurely induced in the G1 nuclei. But if S-phase cells are fused with G2 phase cells, which have already replicated their DNA, synthesis is not induced in the G2 nuclei, although it continues in the S-phase nuclei[1]. Evidently nuclei of G2 cells contain components that prevent replication of their DNA even in the presence of the enzymes and substrates. If cell nuclei are injected into eggs of *Xenopus laevis* they usually swell within 1 h to many times their original volume, the chromatin becoming dispersed throughout the swollen nucleus. Simultaneously, DNA replication begins in the nuclei[2]. We have injected nuclei of G1 and G2 HeLa cells into *Xenopus* eggs in a study of the relationship between this chromatin dispersal and DNA synthesis, and the restriction to DNA synthesis in G2 nuclei.

Figure 1 shows the size distribution of G1 and G2 HeLa cell nuclei 5, 60 and 120 min after injection of ruptured HeLa cells into *Xenopus* eggs. At 5 min, before the nuclei had swollen appreciably, they were all below 17-μm diameter. Also, the distribution of G1 and G2 nuclei between the two size groups was roughly the same (although a small but significantly higher percentage of G2 nuclei than G1 were greater than 12-μm diameter ($P = 0.05\%$)). By 60 min some of the G1 and G2 nuclei had swollen above 17 μm, and by 120 min many more had done so and also many of the smallest nuclei had moved into the middle size group. At 120 min any differences in size distribution between G1 and G2 nuclei were of little significance ($P > 20\%$). Hence G1 and G2 HeLa cell nuclei swell to a similar extent in *Xenopus* egg cytoplasm.

Xenopus egg cytoplasm, however, does not induce similar rates of DNA synthesis in the nuclei of these ruptured G1 and G2 HeLa cells. Figure 2 shows the number of silver grains over sections of HeLa nuclei in *Xenopus* eggs which were fixed for autoradiography 60 min after injecting ruptured G1 and G2 HeLa cells and ^{3}H-thymidine. The number of grains over the most swollen G1 nuclei was comparable with that counted over the pronuclei of the *Xenopus* eggs, namely a mean of 26.6 over 10 pronuclei. Precise comparisons from these counts of rates of DNA synthesis between the HeLa cell nuclei and *Xenopus* pronuclei are impossible because of the different concentration of DNA per unit area of cross-section. But, because the egg pronuclei completely replicate their DNA within about 45 min of activation of the egg by pricking[2], it is clear that the largest G1 nuclei must also have replicated a large part of their DNA. As the size of the G1 nuclei decreases, the number of silver grains per nuclear section also decreases (and hence the ^{3}H-thymidine incorporated per nucleus must decrease more rapidly still, since the sections of smaller diameter contain a higher proportion of the nuclear DNA).

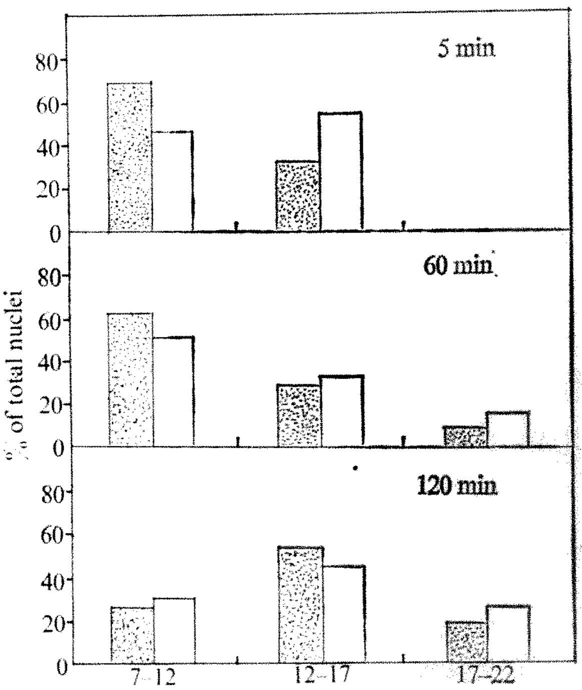

Fig. 1 Size distribution of HeLa cell nuclei at intervals after injection of ruptured HeLa cells into *Xenopus* eggs. G1, stippled; G2, plain. HeLa cells were grown as monolayers in Eagle's medium with added foetal calf serum, and synchronised by double thymidine block[3]. Cells were suspended for injection in a solution of sucrose (1.2 M), $MgCl_2$ (1.5 mM), vinblastine sulphate (0.625 mM) and Tris-HCl (1 mM) *p*H 7.2. *X. laevis* females were induced to ovulate[4], and the eggs dejellied[5]. About 20 cells were injected[6] into each egg in 50 nl of medium which also contained ^{3}H-thymidine (25 nCi, 0.4 ng Radiochemical Centre, Amersham). Vinblastine was present to retain the egg pronucleus at the animal pole. After 5, 60 or 120 min at 18 °C the eggs were fixed in a modified Perenyi's fluid and sectioned at 5 μm. Sections were mounted and subjected to autoradiography with Nuclear Emulsion L 4 (Ilford) with 7-d exposure at 0–2 °C. They were then stained with Mayer's haematoxylin and eosin. Nuclear diameters of over 100 G1 and G2 nuclei in over 20 eggs were measured at each time with a calibrated eyepiece graticule as the mean of the longest and shortest axis.

In contrast, all G2 nuclei incorporated little thymidine, so the block to DNA replication of even the most swollen G2 nuclei has largely been retained, and is effective against the replicating enzymes of the *Xenopus* egg.

In these experiments ruptured whole HeLa cells were injected into the eggs. Figure 3 shows the results of an experiment which was identical except that before injection the G1 and G2 HeLa cell nuclei were isolated by a standard procedure. The G1 nuclei incorporated roughly the same amounts of ^{3}H-thymidine as before, but the G2 nuclei incorporated almost as much as the G1, showing that their block to DNA replication has been lost.

DNA replication in the egg and sperm pronuclei after fertilisation is always accompanied by swelling of the pronuclei[7], and previous work has suggested that there is a causal connection between the two processes. Thus, when

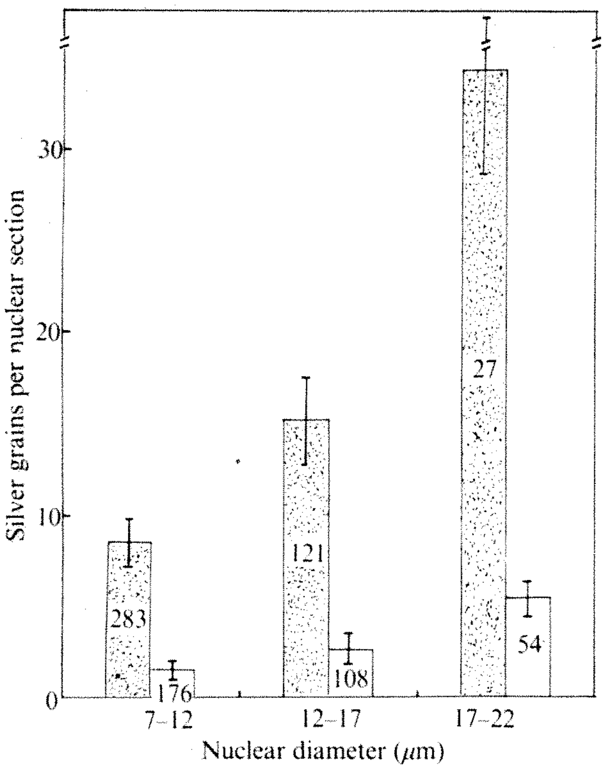

Fig. 2 ^{3}H-thymidine incorporated into nuclei of ruptured HeLa cells by 60 min after injection into *Xenopus* eggs. G1, stippled; G2, plain. The experiment was performed as described in Fig. 1. The number of silver grains per nucleus is the number over each nucleus less the number over a similar area of egg cytoplasm in the same section, values are mean ± s.e. The number of nuclei scored is shown in each column.

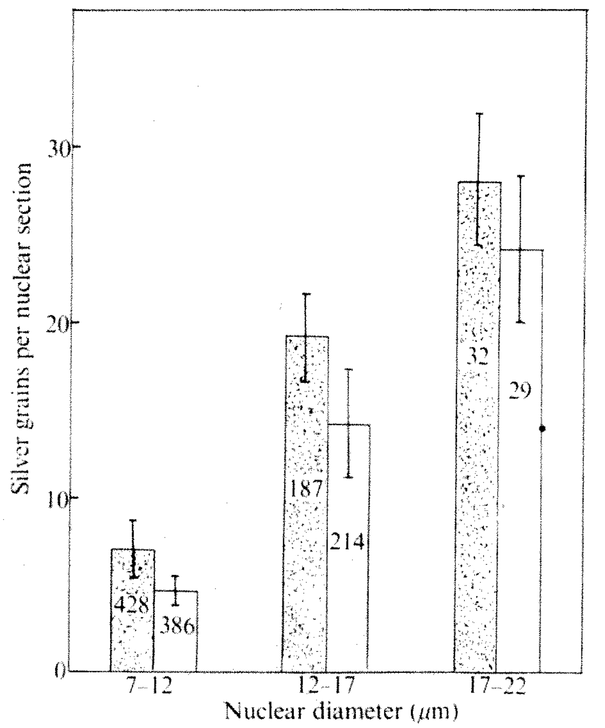

Fig. 3 ^{3}H-thymidine incorporated into isolated HeLa cell nuclei by 60 min after their injection into *Xenopus* eggs. G1, stippled; G2, plain. HeLa cells were suspended in a solution of $MgCl_2$ (3 mM) and Triton-X100 (0.1%) and, after 15 min, homogenised in a glass tube with Teflon plunger. The homogenate was centrifuged for 10 min, at 900*g*, resuspended in sucrose (0.32 M) and $MgCl_2$ (3 mM) and centrifuged again. The pellet was suspended in a little sucrose (2.1 M) and $MgCl_2$ (1.5 mM), layered on top of the same solution, and centrifuged for 1 h at 100,000*g*. The nuclei were suspended for injection as described in Figs 1 and 2. Data are mean ± s.e.

somatic cell nuclei were injected into *Xenopus* eggs, nuclei that did not incorporate ^{3}H-thymidine were little if at all swollen, and the average volume of the nuclei increased at the same rate as the proportion that replicated DNA[2]. Also, those parts of injected brain nuclei which were the first to swell were the first to synthesise DNA[3]. It has not been clearly demonstrated, however, whether swelling is an essential prerequisite for DNA replication, or merely a consequence of it. Our finding that when ruptured HeLa cells are injected into *Xenopus* eggs G1 and G2 swell to the same extent, but only G1 nuclei replicate a significant portion of their DNA, strongly suggests that swelling is not merely a consequence of DNA synthesis, but is a prerequisite for it. Nuclear swelling in the *Xenopus* egg, with its associated chromatin dispersal, seems to be dependent on a lowering of the unbound cation concentration of the egg cytoplasm to a level at which bound cations dissociate from the DNA of chromatin[4,9], but seems to be independent of the discharge of cortical granules at activation[10].

The ability to inhibit DNA replication is thus retained in the nuclei of ruptured G2 HeLa cells injected into *Xenopus* eggs, but almost completely lost if the nuclei are isolated before injection. Hence the inhibition is most probably caused by a loosely bound constituent not normally reckoned among the components of nuclei and chromatin, or by a labile modifying group attached to a known component. Alternative methods of isolating G2 HeLa cell nuclei may retain the ability to block DNA synthesis and facilitate identification of the components involved.

Evidence for cytoplasmic control of gene expression in higher plants

ONE of the difficulties of studying regulatory gene function in higher eukaryotes is the lack of genotypes with single gene differences in constant genetic backgrounds. In the Triticinae, however, the construction of a series of aneuploids[1,2] makes it possible to monitor the activity of single gene loci in different genetic backgrounds. With these genotypes we have been able (unpublished results with T. Lelley) to localise the structural genes for phosphodiesterase (PDE, EC 3.1.4.1.) on chromosomes 3A, 3B and 3D of wheat, *Triticum aestivum* ($2n=6x=42$). We also showed that regulatory genes located on chromosomes 5A, 5B and 5D enhance the activity of the structural genes. We now report that extrachromosomal control of the PDE isoenzymes is another component of this complex regulatory system.

Reciprocal hybrids were constructed between hexaploid wheat and its diploid relative, *Secale cereale* ($2n=14$), resulting in amphidiploid derivatives with wheat cytoplasm in

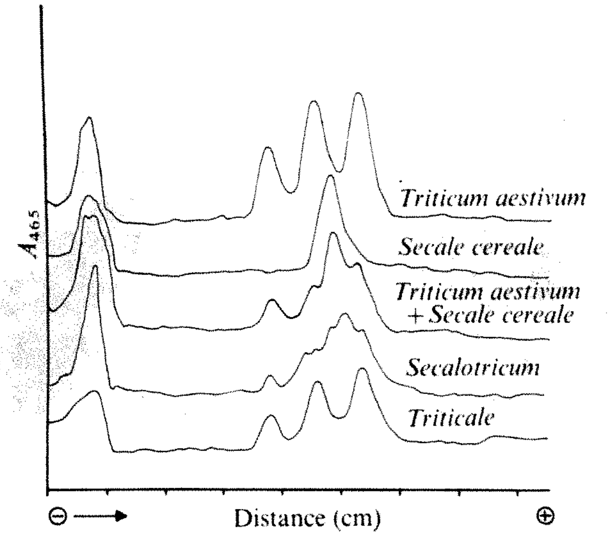

Fig. 1 Densitometer tracings of PDE isoenzyme patterns of wheat, rye, and wheat/rye hybrids. Extraction from leaves with 3 × (w/v) 0.05 M Tris-HCl, *p*H 7.5, at 4 °C. Centrifugation was at 20.000 *g* for 10 min. This crude extract was used for separation in 7% polyacrylamide gels, 0.6 × 9 cm, according to Davis[9]. The gels were stained for 5′-phosphodiesterase by incubation in 0.05 M Tris-HCl, *p*H 7.5, and 2′-deoxythymidine-5′-phosphoric acid-1-naphthylester and Fast Blue RR for 30–60 min. The gels were scanned in a Joyce–Loeble densitometer at 465 nm. (The peak in the upper part of the gels is caused by an unspecific adsorption of Fast Blue to fraction-I protein).

Triticale ($2n=8x=56$) and with rye cytoplasm in ***Secalotricum*** ($2n=8x=56$). We used several individual plants per genotype with cytologically verified chromosome numbers.

Polyacrylamide gel electrophoresis patterns of the PDE isoenzymes of both genotypes were compared with those of the parents (Fig. 1). The wheat pattern showed the well known three isoenzymes[3,4]. The slow-moving enzyme is a product of the gene on chromosome 3D (*Pde-D3*); two fast-moving isoenzymes with an identical mobility are produced by the structural genes *Pde-A3* and *Pde-B3* on chromosomes 3A and 3B, respectively, and the hybrid enzyme is composed of the product subunits of the genes *Pde-D3, Pde-A3 and Pde-B3.* Rye possesses only one PDE enzyme. Its mobility was identified by coelectrophoresis of wheat and rye extracts (Fig. 1) as being between those of the fast moving isoenzyme and hybrid enzyme of wheat. The *Secalotricum* pattern clearly shows the wheat and rye isoenzymes while the pattern of the *Triticale* with wheat cytoplasm does not exhibit the rye band. Thus the rye gene is expressed in the presence of rye cytoplasmic factors but not in the *Triticale* with wheat cytoplasm. Two additional isoenzymes in *Secalotricum* were not present in the parent species. The number, positions and dimeric nature of the PDE isoenzymes (unpublished work of G. W.) makes them likely to be hybrid enzymes composed of wheat and rye monomers (Fig. 2). Further evidence for the cytoplasm-dependent expression of the rye PDE gene came from wheat cytoplasmic wheat rye addition lines[2], where the seven rye chromosomes were added separately to the wheat genome. No difference in PDE activity was found between any of the seven addition lines and wheat or *Triticale* (not shown). Thus it is clear that the structural gene for the rye PDE enzyme is under cytoplasmic control. This gene cannot be expressed in genotypes with wheat cytoplasm. The structural and regulatory genes of wheat, however, are active in the presence of the rye cytoplasm.

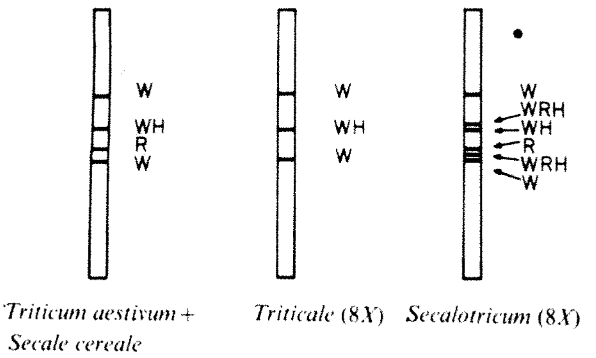

Fig. 2 Diagramatic interpretation of the PDE isoenzyme patterns in wheat/rye hybrids. W, wheat enzymes; WH, wheat 'hybrid' enzymes; R, rye enzyme; WRH, wheat/rye 'hybrid' enzymes.

In summary our studies on the genetic control of the PDE isoenzymes in the Triticinae reveal a complex system of regulation of gene expression. Our earlier studies (unpublished) showed that (1) the activity of the isoenzymes depends on the dose of the structural genes; (2) the activity of the structural genes is regulated by separate nuclear genes; (3) the effect of the regulatory units is also dose-dependent; (4) the regulatory and structural units are located on different genomes (B and D) of the allohexaploid wheat: thus, the complexity of regulation seemed to have increased with polyploidisation. We have now shown further that (5) in rye corresponding structural genes for PDE activity are under cytoplasmic control.

There have been several reports of the location of structural genes coding for enzyme proteins in wheat[5–7]. Also, cytoplasmic control of the expression of nuclear genes has been observed in cereals[8]. The effects described, however, were only quantitative and reflect a type of gene control which is well documented. Our study also demonstrates qualitative effects- the absence of isoenzymes—of cytoplasmic factors on the expression of a nuclear gene with a well defined product. The PDE isoenzymes of wheat and rye are sufficiently homologous to form hybrid enzymes (Fig. 1), and so it is surprising that the corresponding regulatory factors of the wheat and rye cytoplasm are apparently quite different in their function. The fact that the nuclear structural genes of wheat are expressed in the presence of the rye cytoplasm may be a consequence of the polyploid nature of wheat where enhancing regulatory genes are present in triplicate (for example, on chromosomes 5A, 5B and 5D, unpublished results with T. Lelley). Our results strongly suggest that there is a complex interaction of structural genes not only with nuclear regulatory factors but also with cytoplasmic control factors, which are inherited from the female parent only. We therefore suggest that future experiments on gene regulation should take into account the existence of (as in this case) strong extrachromosomal control factors, so that existing models on regulation of gene expression (see, for example, refs 10 and 11) may be extended. Our hypothesis of gene regulation can be tested further using haploid hybrids, rye cytoplasmic wheat and rye cytoplasmic addition lines which are now being constructed.

High resolution detection of DNA–RNA hybrids *in situ* by indirect immunofluorescence

WE describe here a new method for the detection of RNA–DNA hybrids in cytological preparations with which we have revealed the locations of hybrid molecules on polytene chromosomes. The critical reagent is an antiserum raised in rabbits against poly(rA)·poly(dT) complexed with methylated bovine serum albumin, originally described by Stollar[1]. The specificity and resolving power of the indirect immunofluorescence procedure are demonstrated using *in situ* hybridisation of 5S rRNA (ribosomal RNA) to polytene chromosomes of *Drosophila melanogaster* as a model system. The method has significant advantages over the autoradiographic procedures[2–5] used so far.

The procedure for visualising the *in situ* hybrids follows Alfageme *et al.*[6] It consists of exposing the cytological preparation to the rabbit anti-hybrid antiserum, then to anti-rabbit IgG prepared in goat and tagged with rhodamine, followed by examination in a fluorescence microscope (see legend to Fig. 1). Our test objects were polytene chromosomes of *Drosophila melanogaster* (giant phenotype) to which 5S rRNA had been hybridised *in situ* (see legend to Fig. 1). The two glands from a single larva either were used as duplicate samples or one gland served as a 'control' for the other. The preparations were not air dried at any time during the procedures. Test slides which were air dried at some stage before the immunological reactions were inferior to their controls either in the morphology of the chromosomes, the background fluorescence levels, the uniformity of the fluorescence staining or a combination of defects.

In situ hybridisation followed, in general, the recipe of Pardue and Gall[7] with modification by Alonzo *et al.*[8] (see legend to Fig. 1). The reaction was effective with 1.0 μg and with 0.2 μg 5S rRNA per slide. It is likely that much smaller amounts could be used if applied in a smaller volume and, perhaps, for longer times[7,9].

The specificity of the immunological reagents in the cytological reaction is demonstrated by the confinement of chromosomal fluorescent label to the 56F region when 5S RNA is included in the *in situ* hybridisation medium (Fig. 1) and by the absence of chromosomal fluorescence when 5S rRNA is omitted (not shown; would be black). Further evidence that the anti-hybrid antibodies are responsible for the chromosomal site of the positive fluorescence reaction is provided by the absence of fluorescence in chromosomes to which 5S RNA had been hybridised but which were treated with antiserum absorbed with poly(rA)·poly(dT) (5 μg poly(rA)·poly(dT) per μl serum for 24 h at 4 °C, centrifuged for 10 min at 6,000*g*). Thus the immunological reagents revealed only DNA–RNA hybrids within the nuclei of polytene cells prepared for *in situ* hybridisation.

The specificity was demonstrated further by analyses of the immunological properties of the antiserum. As described previously, several-thousand-fold dilutions of serum reacted in complement fixation assays with poly(rA)·poly(dT), poly(I)·poly(dC) or hybrids of natural RNA and DNA (ref. 1). A 1/50 serum dilution did not react with any single-stranded form of RNA or DNA or with double-stranded RNA or native DNA. When serum was assayed undiluted in counterimmunoelectrophoresis, weak reactions were seen with poly(rA) and with denatured DNA. Both these reactions were eliminated when the serum was passed through a poly(rA)–Sepharose affinity column prepared as described by Poonian *et al.*[10] (Fig. 3). With absorbed serum, which gave the same immunofluorescence as unabsorbed serum, the hybrid was the only reactive polynucleotide class, even in assays with undiluted serum.

There is a variable amount of fluorescence in cytoplasmic components, the origin of which is not yet known. Experiments are projected to attempt to block it while leaving the activity against hybrid nucleic acids intact. Occasional pale fluorescence observed in nucleoli is attributed to contamination of the 5S rRNA probe with fragments of 18S and 28S nucleolar rRNA,

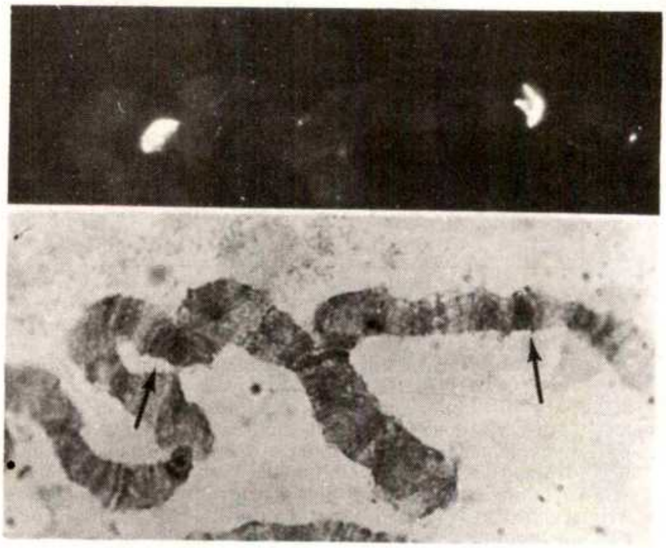

Fig. 1 5S rRNA genes revealed in polytene chromosome 2R of *Drosophila melanogaster* by indirect immunofluorescence detection of RNA–DNA hybrids formed *in situ*. The two homologous 2R chromosomes are not paired except in their most distal portions. The 5S genes (56F on Bridges' standard map) are in the unpaired portions, those derived from one parent to the right, the other parent to the left. In each homologue at least two fluorescent cross-bands are visible. Arrows indicate the 56F regions in the upper photograph of the same chromosomes taken after staining with aceto-orcein. A salivary gland from a fully grown larva of *D. melanogaster* (giant phenotype) was fixed in 50% (v/v) aqueous acetic acid and squashed under a siliconed cover glass, then the slide was frozen on solid CO_2. After snapping off the cover slip, the slide was post-fixed in 3 : 1 ethanol–acetic acid (v/v), rinsed twice in 95% aqueous ethanol (v/v) and stored in 95% ethanol until used. Subsequent treatments were carried out in a moist chamber consisting of a 90-mm square culture dish containing a few leaves of bibulous (or filter) paper saturated with the solvent and two plastic strips to raise the slides above the wet paper. The reagent was placed between the slide and a cover slip. For hybridisation *in situ*, slides were first treated with pancreatic ribonuclease, 100 μg ml^{-1} of 2 × SSC (SSC is 0.15 M NaCl and 0.015 M sodium citrate) for 2 h at 25 °C, then with 90% formamide in 0.1 × SSC for 2 h at 65 °C followed by ice cold 0.1 × SSC rinses. The hybridisation reaction was carried out for 22–24 h at 37 °C in 50% formamide in 4 × SSC using either 1.0 or 0.2 μg 5S RNA per slide—highly purified 5S rRNA, extracted from *D. melanogaster* Oregon R embryos[11]. After the annealing reaction, the slides were treated with pancreatic ribonuclease (15 μg ml^{-1}) in 2 × SSC for 2 h at 25 °C, rinsed with phosphate-buffered saline (PBS, 0.14 M NaCl, 0.01 M phosphate, *p*H 7.2) and exposed for 2 h at room temperature (21–23 °C) to rabbit anti-DNA–RNA hybrid serum reconstituted from a lyophilised state by solution in water and diluted for use in PBS (1 : 20 for Fig. 1). After thorough rinsing in PBS, the slides were finally exposed to a rhodamine-labelled goat IgG fraction of anti-rabbit-IgG (Miles-Yeda) reconstituted to approximately its original concentration, then diluted in PBS for use (1 : 20 for Fig. 1). The photographs were taken with a microscope equipped with a Zeiss epi-illumination fluorescence module using a 546-nm excitation filter, a 580-nm chromatic splitter and a 580-nm barrier filter for rhodamine fluorescence on 35-mm Eastman Tri X Pan film exposed at ASA 1600 (Diafine developer) at magnifications of approximately × 150 (× 40 objective) or × 370 (× 100 oil immersion objective). Fluorescence exposures were in the range of 1–8 s and phase contrast illumination was adjusted to require approximately the same exposure time so that a single frame could be exposed in both modes simultaneously (not shown here). In some instances, slides were stained with aceto-orcein after fluorescence photography had been completed, then photographed through a No. 58 filter (green) on Plus-X-Pan film at ASA 400. Approx. × 1,000.

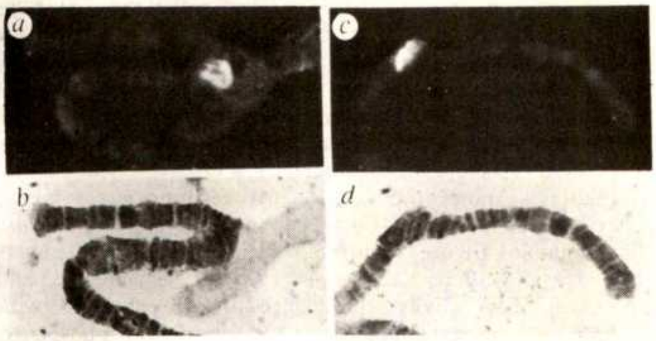

Fig. 2 5S rRNA genes revealed in *D. melanogaster* polytene chromosome 2R as in the legend to Fig. 1. The two chromosomes are unpaired in a single nucleus. The upper chromosome (*a* and *b*) is associated with the nucleolus (nu) at the locus of the 5S genes, fluorescent in (*a*). The homologous chromosome (*c* and *d*) is not visibly associated with the nucleolus; its 5S locus, indicated by the fluorescence in (*c*), is less disperse than that in its homologue (*a*). (*b* and *d*) Photomicrographs of the same fields as in (*a*) and (*c*), respectively, after staining with aceto-orcein. × 630.

but the possibility that 5S DNA templates occur in nucleoli cannot be excluded.

The spatial resolving power of the immunofluorescent probe is equal to that of the optical system used to observe it. Autoradiographs can at best reveal a cluster of silver grains adjacent to, or covering, a labelled region which results in a resolving power of the order of 1–3 µm. So far the precise localisation of the 5S genes within the 56EF region has been equivocal for *D. melanogaster* using autoradiography[1-9]. The images we obtain are of two kinds. In some nuclei, the fluorescence is restricted to a relatively narrow transverse 'band' which is often clearly made up of two subunits and is localised in the 56F region, distal to the puff usually present in 56E (Fig. 1). The possibility that the two subunits reflect the organisation of the 5S locus into the two separable sets of repeated sequences recently reported by Procunier and Tartof[12] is under investigation. On the other hand, the 5S region of chromosome 2R sometimes sticks to the nucleolus as in Fig. 2 (ref. 9) or is ectopically paired to other chromosome regions. In those cases, the fluorescence may be distributed in a network of fibrils extending longitudinally along a much longer segment of chromosome (Fig. 2*a*). When that is true, the morphology in phase contrast and/or after post-staining with aceto-orcein is atypical in that the subsections 56E and F cannot be clearly demarcated and the region does not appear to be organised into distinct bands. Such dispersion of the *in situ* hybrids into fibrils is consistent with the suggestion of Steffensen and Wimber[9] that the 5S genes may have been active in those chromosomes[13]. But the possibility that our 5S probe contains traces of contaminating nucleolar rRNA fragments that could reveal nucleolar rDNA adhering to chromosome 2 has not been entirely excluded.

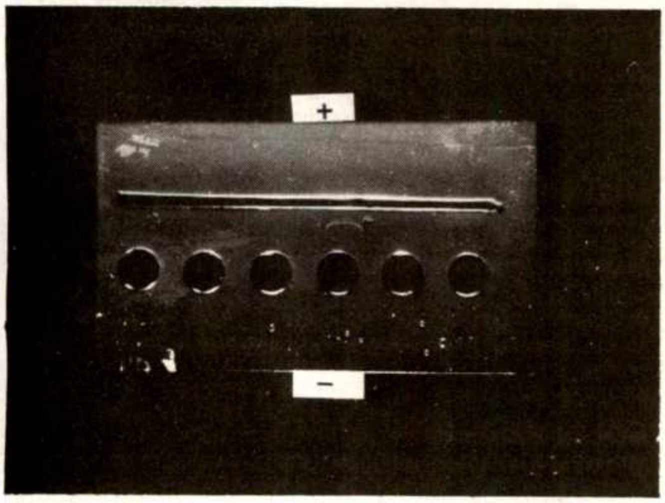

Fig. 3 Specificity of the absorbed antiserum. A sample of 7 ml of anti-poly(rA)·poly(dT) antiserum was absorbed by passage through a 1.2-ml column of poly(rA)–Sepharose equilibrated with 0.1 M NaCl, 0.01 M phosphate, *p*H 7.2. The undiluted absorbed serum (200 µl) was placed in the trough; the wells contained 0.5 µg polynucleotide in 50 µl running buffer (0.05 M Tris-HCl, *p*H 8). The polynucleotides were, from left to right: poly(rA); denatured DNA; poly(rA)·poly(dT); poly(dT); poly(I)·poly(C); and poly(dA). The gel medium was 0.8% agar (Difco, purified agar) in running buffer; 7 ml of gel was poured on each 2 × 3 inch glass plate. Electrophoresis was run at 220 V (10 m per plate) for 45 min.

The sensitivity of the technique has not yet been fully explored. At serum dilutions of 1 : 40 for the anti-hybrid rabbit serum and an equivalent concentration for the fluorescent reagent, the fluorescence intensity in the 5S region was very high. Photographic images should still be easily recordable at brightnesses one to two orders of magnitude lower. Thus, the possibility to detect the hybridisation of RNA copies of a unique gene in a polytene chromosome appears to be real. On the other hand, genes present in a size and multiplicity equivalent to the 5S of *D. melanogaster* may be detectable in uninemic chromosomes. An attempt is in progress to detect the 5S locus in human chromosomes at the pachytene stage of meiosis.

The technique is being used to study the distribution of naturally occurring chromosomal RNA detected as hybrid molecules. Polytene chromosomes mounted out of 50% acetic acid display a pattern of fluorescent regions when treated only with the immunological reagents. The regions do not fluoresce if the anti-hybrid serum is blocked with poly(rA)·poly(dT) or if the chromosomes are treated to remove indigenous chromosomal RNA (as in preparation for *in situ* hybridisation), indicating that they are sites of hybrid molecules. Since the locations of the sites change during larval and prepupal development, their RNA moiety could be involved with the control of transcription or of replication or both.

We thank Dr L. Cohen for bringing us together, Dr K. D. Tartof for highly purified *D. melanogaster* 5S RNA, Dr C. R. Alfageme for rhodamine-tagged goat anti-rabbit IgG and for the use of a Zeiss epi-illuminator fluorescence attachment, all three colleagues for useful discussions and technical advice, and Miss D. J. Hazler for technical assistance. This work was supported in part by grants from the NSF and NIH and by an appropriation from the Commonwealth of Pennsylvania.

Anion modulation of the negative Bohr effect of haemoglobin from a primitive amphibian

THE Congo eel (*Amphiuma means*) is a primitive salamander that respires through its lungs, gills and integument. It lives in swamps, ditches and rice fields in the south-eastern USA. When pools and swamps become stagnant and water levels drop, *Amphiuma* will burrow and hibernate in the mud. In this letter we report that when organic phosphate cofactors are low or absent, as might be true during hibernation, the haemoglobin of this amphibian has unusual properties which may help the animal to extract oxygen from a low *p*H environment. The molecular adaptation exhibited by *Amphiuma* haemoglobin is a *p*H dependence of oxygen binding that is reversed relative to that of most haemoglobins. Low *p*H brings about a large increase in the oxygen affinity of stripped *Amphiuma* haemoglobin. This negative Bohr effect indicates that protons are bound as oxygen is bound. This is in contrast to the release of protons that usually accompanies oxygenation. New Bohr groups must be present in this amphibian haemoglobin, or the normal Bohr groups must be drastically modified. From a physiological viewpoint it is of interest that the Bohr effect *in vitro* is subject to regulation by organic phosphate cofactors.

Haemolysates from the two *Amphiuma* studied gave single somewhat broadened bands on polyacrylamide disc gels, indicative of a single major haemoglobin. There were no minor components, even on overloaded gels. Haemoglobin solutions were prepared by the ammonium sulphate procedure and stripped of organic and inorganic ions by treatment with a mixed-bed ion exchange resin[1]. Oxygen equilibria were done spectrophotometrically using a tonometric procedure[2], and flash photolysis and rapid mixing experiments were done as described before[3].

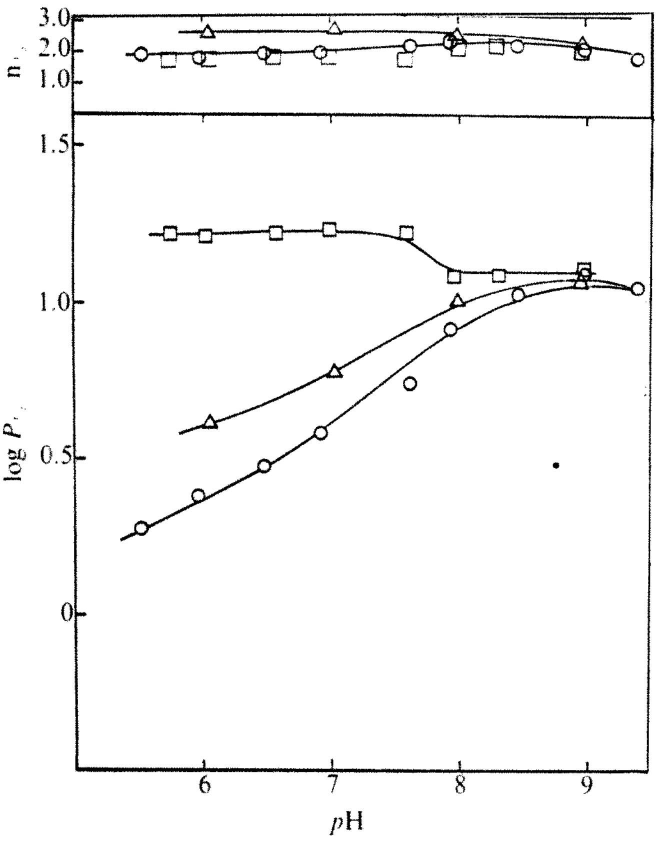

Fig. 1 Effect of *p*H and cofactors on the oxygen affinity and cooperativity of *Amphiuma* haemoglobin (~60 μM in haem) in 0.05 M bis-Tris or Tris buffers at 20 °C. Solutions of stripped haemoglobin were examined in the absence of cofactors (○), with 0.3 M NaCl (△), and with 100-fold excess of ATP:tetramer (□). Oxygen pressures measured in mmHg.

Figure 1 shows the large negative Bohr effect which characterises oxygen binding to stripped *Amphiuma* haemoglobin. Figure 1 also shows that 0.3 M NaCl lowers the oxygen affinity, decreases the *p*H dependence and increases cooperativity. Similar results are obtained with *Amphiuma* haemoglobin in 0.2 M inorganic phosphate. Organic phosphates cause an even greater decrease in oxygen affinity, although they do not appreciably alter the degree of cooperativity. Table 1 summarises these results and presents data on human haemoglobin A (HbA) for comparison. There are significant quantitative differences between HbA and *Amphiuma* haemoglobin in the relative effectiveness of various organic phosphates.

Table 1 Effects of anions and *p*H on the oxygen affinities of stripped preparations of *Amphiuma* hemoglobin at 20 °C in 0.05 M bis-Tris or Tris buffers (except for experiments in 0.2 M phosphate)

Haemoglobin	Cofactor	$P_{\frac{1}{2}}$(mmHg) *p*H 7	$P_{\frac{1}{2}}$(mmHg) *p*H 8	Bohr effect $\Delta\log P_{\frac{1}{2}}$ (*p*H 7–8)
Amphiuma	none	4.0	8.3	−0.32
	0.3 M NaCl	5.9	10.2	−0.24
	0.2 M phosphate	5.1	8.9	−0.24
	2,3-diphosphoglycerate	6.7	—	—
	adenosine triphosphate	17.4	12.3	+0.15
	inositol hexaphosphate	20.0	13.5	+0.17
HbA	none	2.0	0.5	+0.56
	1.0 M NaCl	7.9	3.1	+0.41

	2,3-diphosphoglycerate	12.6	3.1	+0.60
	adenosine triphosphate	10.0	2.2	+0.66
	inositol hexaphosphate	38.9	11.5	+0.56

Data on human haemoglobin (HbA) are presented for comparison.

Enzymatically modified haemoglobin has been used to probe the mechanism of ligand binding. The properties of HbA after digestion with carboxypeptidase A and B, in particular, helped establish the important role played by its carboxyl-terminal residues[4–6]. Properties of carboxypeptidase A and B digests of *Amphiuma* haemoglobin, prepared as described elsewhere[7], are shown in Fig. 2 and Table 2. The functional properties of the digestion products differ from those of carboxypeptidase digests of HbA. Interpretation of these differences is difficult because there are no structural data available on *Amphiuma* haemoglobin. We presume it to be an $\alpha_2\beta_2$ tetramer largely by analogy with other amphibian haemoglobins, and in part because of the identity of the amino acids released as the result of carboxypeptidase digestion[8,9]. Carboxypeptidase B digestion of HbA removes arginine from its alpha chains. Similarly, arginine is the only residue released from a comparable digest of *Amphiuma* haemoglobin. Digestion with carboxypeptidase A causes β146 histidine and β145 tyrosine to be cleaved from the C-terminus of the beta chain of HbA. A comparable digest of *Amphiuma* haemoglobin releases only tyrosine.

The β146 histidine of HbA is thought to be responsible for much of the positive Bohr effect of HbA[4,5]. Consequently, absence of C-terminal histidine in *Amphiuma* haemoglobin may help explain its altered *p*H dependence. It is interesting that stripped tadpole haemoglobins show negative Bohr effects even though they possess a C-terminal histidine[9]. Amphibian haemoglobins typically have low Bohr effects[8], and absence of the C-terminal histidine in *Amphiuma* haemoglobin may therefore only accentuate a common divergence from mammalian haemoglobins.

The β145 tyrosine of HbA is thought to play a major role in stabilisation of the low affinity (T) conformation[4]. Removal of this residue is responsible for the high affinity and lack of cooperativity exhibited by HbA after digestion with carboxypeptidase (refs 4–6). A Carboxypeptidase A digestion of *Amphiuma* haemoglobin does not eliminate cooperativity or greatly increase its oxygen affinity, which suggests that the C-terminal tyrosine of this haemoglobin is not as important in stabilisation of its low affinity state. Sensitivity to organic phosphates is maintained by the carboxypeptidase A digest and the Bohr effect is rendered positive by the addition of adenosine triphosphate or inositol hexaphosphate.

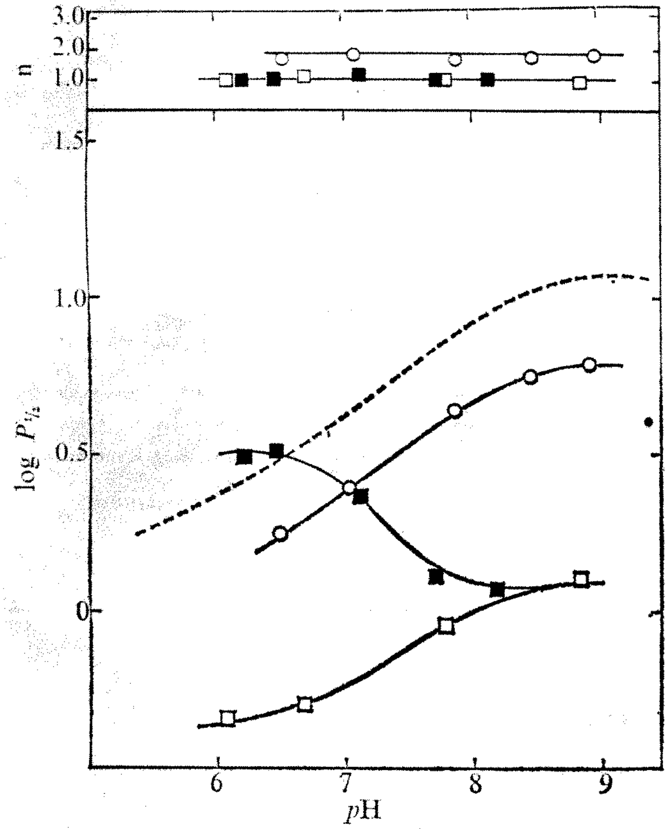

Fig. 2 Effect of *p*H on the oxygen affinities of carboxypeptidase A (○) and carboxypeptidase B (□) digests of *Amphiuma* haemoglobin. The effect of inositol hexaphosphate (■) on the CPB-digested material is also shown. Stripped *Amphiuma* haemoglobin – – –. Other conditions as in Fig. 1.

The β141 arginine of HbA is thought to contribute to stabilisation of the low affinity (T) conformation by formation of ligand-linked salt bridges[4–6]. Loss of this residue after carboxypeptidase B digestion of HbA causes a moderate increase in affinity and a decrease in cooperativity. In *Amphiuma* haemoglobin the C-terminal arginine is much more important, as demonstrated by the greatly increased oxygen affinity and loss of cooperativity which accompany digestion with carboxypeptidase B. It is remarkable that this non-cooperative digestion product has a strong negative Bohr effect. In the presence of inositol hexaphosphate, however, the carboxypeptidase B digest of *Amphiuma* haemoglobin shows a positive Bohr effect, comparable to that of HbA.

The kinetics of ligand binding by *Amphiuma* haemoglobin differ greatly from those of most other haemoglobins in that the typical *p*H sensitivity is reversed. For most haemoglobins the rate of oxygen dissociation is much faster at *p*H 7 than at *p*H 9, while the rate of ligand combination is slower at *p*H 7 than at *p*H 9. These kinetic factors work together in generating the positive Bohr effect of most haemoglobins. In contrast, Fig. 3 shows that low *p*H favours a slow rate of oxygen dissociation and a fast rate of CO combination for stripped *Amphiuma* haemoglobin. The *p*H dependence of these processes adequately accounts for the negative Bohr effect (Fig. 3). In accord with the equilibrium data, adenosine triphosphate (Fig. 3) alters these kinetic processes at neutral *p*H, with little effect at high *p*H.

At neutral *p*H the time course of CO binding to a concentrated solution of HbA shows an increasing rate as successive ligands are bound, indicative of cooperative subunit interactions[1]. Similarly, the apparent rate constants increase 1.5–2-fold during the process of CO binding to *Amphiuma* haemoglobin. Flash photolysis of *Amphiuma* haemoglobin at low heme concentration (~ 0.5 μM) gives no indication of quickly reacting material, and the autocatalytic character of the time course is maintained. This suggests that liganded *Amphiuma* haemoglobin does not readily dissociate into non-cooperative subunits. It will be of considerable interest to determine if *p*H or cofactors affect the state of aggregation of the protein. The time course of O_2 dissociation from stripped *Amphiuma* haemoglobin was also somewhat autocatalytic, although this was not as pronounced as in the kinetics of CO combination.

The foregoing serves to illustrate the unusual *p*H sensitivity of *Amphiuma* haemoglobin. Bohr effects that are low or slightly negative have been reported for haemoglobins from a number of other amphibians[8], and we suspect that this characteristic may be a molecular adaptation to meet respiratory requirements during hibernation. None of the amphibian haemoglobins so far investigated has a negative Bohr effect as pronounced as that of *Amphiuma* haemoglobin, and no other cases of reversed *p*H sensitivity of both CO combination kinetics and O_2 dissociation kinetics have been reported.

The flexibility of haemoglobin function is brought into focus by this study by the fact that homotropic and heterotropic interactions can vary independently of one another. This is significant because homotropic and heterotropic interactions are tightly linked in normal human haemoglobin. Our functional studies with *Amphiuma* haemoglobin illustrate that the Bohr effect can be positive or negative without appreciable alteration of cooperative

Table 2 Effects of anions and *p*H on the oxygen affinities and cooperativity of stripped preparations of chemically modified forms of *Amphiuma* haemoglobin. Data collected at 20 °C in 0.05 M bis-Tris or Tris buffers

Modification	Cofactor	$P_{1/2}$ (mmHg) *p*H 7	$P_{1/2}$ (mmHg) *p*H 8	$n_{1/2}$
Carboxypeptidase A digest (des Tyr)	None	2.5	4.42	1.7
	Adenosine triphosphate	7.4	—	1.5
Carboxypeptidase B digest (des Arg)	None	0.6	1.0	1.0
	Adenosine triphosphate	1.7	1.0	1.0
	Inositol hexaphosphate	2.6	1.2	1.0

interactions and that these changes in *p*H sensitivity can occur even in the absence of cooperative oxygen binding. In *Amphiuma* haemoglobin the separation of heterotropic and homotropic interactions is much more evident than in most other haemoglobins. Further study along these lines should contribute to our understanding of the flexibility of haemoglobin function in response to environmental pressures.

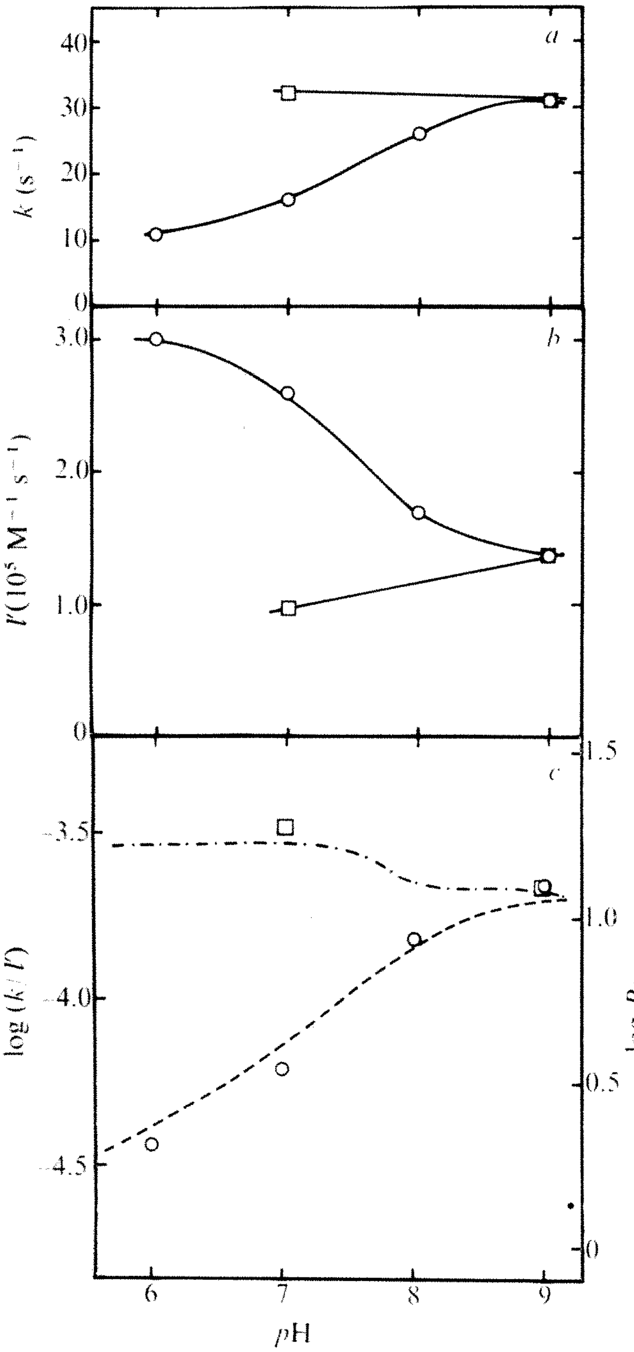

Fig. 3 Effect of *p*H on the apparent velocity constants at 20 C for oxygen dissociation (*a*) and CO combination (*b*) for stripped *Amphiuma* haemoglobin (○) and for the haemoglobin in the presence of 1 mM ATP (□). *c*, The log of the ratio of the kinetic constants (symbols) is compared to the equilibrium data of Fig. 1 (dashed lines).

The complete **Index** for 1975 is available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* **fits** into four binders).
Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

reviews

Hard reason and deep humanity

J. W. S. Pringle

Insects and the Life of Man: Collected Essays on Pure Science and Applied Biology. By Sir Vincent Wigglesworth. Pp. 217. (London: Chapman and Hall, 1976. Distributed in the USA by Halsted Press, a Division of Wiley: New York.) Paperback £3.25; hardback £6.

THIS book is a collection of essays or addresses published over a period of nearly forty years. Many of them are concerned with aspects of applied entomology and its relation to 'pure' science, but the life of man means more than just his material needs. So it is appropriate that the volume includes some of the contributions which Professor Wigglesworth has made to the history and philosophy of science and, in the widest sense, to its art.

The introductory chapter gives a guide to what follows. The earliest contribution is an article published in 1935 on malaria in Ceylon, which may well have stimuated the successful WHO campaign after the war. Wigglesworth did not foresee the problems that would arise from the resulting population explosion, but he did clearly forecast in 1945 the ecological effects that would result from widespread use of DDT. By 1951 he was acknowledging that "there can be no immediate prospect of abandoning the use of insecticides" but was pleading for more knowledge, with which "we should be able to devise methods of cultivation which would favour the crop and discourage the insect pest to the point where a satisfactory balance is established". This was well before the invention of "integrated control".

The essays are not primarily autobiographical, but chapter 12—an address to XIIth International Congress of Entomology in 1964—does start with a brief summary of Wigglesworth's career. Few people know that the *Rhodnius* cultures now so widespread in biological laboratories derive from a small stock imported from Venezuela about 1924 and laboratory-bred ever since. There follows a review of fifty years' progress in many fields of insect physiology since 1912—"impressive examples of the potential contribution of insect physiology to general biology". Yet, "I believe that the great era of insect physiology is yet to come": with the fertile observation that metamorphosis is a genetic switch, a step-wise activation of particular components of the genetic code, and that because in insects the switch is controlled by a single chemical, the juvenile hormone, "there is no more promising medium than the insect, in which this problem can hopefully be studied".

There is a stimulating essay (given to the British Association in 1948) on the history of entomological studies in Britain and the relationship between applied entomology and research. I particularly like the remarks about administration: "The keynote [of administration] should be the safeguarding and encouragement of research. Anyone who has tried both knows that administration is so immeasurably easier than research that it becomes the line of least resistance, and that is why research needs encouragement". Entirely historical is a sketch of the contributions of Sir John Lubbock (Lord Avebury) to insect physiology, "to put the record straight". "If Lubbock had held an academic appointment, he would have been accorded a high place among the biologists of the nineteenth century. But, like Darwin, he was an amateur; and unlike Darwin, he devoted only a minute fraction of his time to scientific pursuits".

Chapter 13 reprints a remarkable article on the epidermal cell, which is often overlooked since it was published in a *Festschrift* after delivery as a lecture to the Royal Society. The diversity of functions which these cells can perform is one of the most remarkable phenomena in the whole of biology. There is material here for a generation of PhD theses.

The man behind the words comes through most clearly in chapter 16 (Wordsworth and Science) and in chapters 4 and 17 (Science, Pure and Applied; The Religion of Science). He admires Wordsworth "who, standing at the threshold of the Industrial Revolution . . . can compare with true scientific objectivity, though with all a poet's feeling, the evil of the factory child with the grinding penury of rural England" and who can, in 1810, find a solution and a hope in "a System of National Education established universally by Government". In chapters 4 and 17, Wigglesworth sets out clearly his faith, on which science is founded and by which it lives. "Without a deeply rooted instinctive belief in the existence of laws which reign throughout nature, the incredible labours of scientists would be without hope". Some rude things are said about philosophers, but the lecture was "anti-philosophical only to the extent that it takes the view that science and idealist philosophy have different ground rules and therefore cannot play together". The picture is of a man of hard reason, coupled with deep humanity.

I have only sampled some of the gems in this book. □

J. W. S. Pringle is Linacre Professor of Zoology at the University of Oxford, UK.

Epidemics and pestilences

Insects and History. (The World Naturalist Series.) By J. L. Cloudsley-Thompson. Pp. x+242. (Weidenfeld and Nicolson: London, 1976.) £8.50.

THIS is a history book about pestilences, from the dawn of history to the present day. It is vividly written and well documented. Much of it makes horrifying reading. As the story progresses it seems to support the popular view that great epidemics are a thing of the past. But that past is not so very distant: the influenza pandemic of 1918 is thought to have resulted in 20 million deaths—a larger number than any other pestilence in history. The chapter headings read like an account of medical entomology. But the value and interest of the book is enhanced by the large amount of space given to smallpox, scurvy, syphilis, famine and, of course, to the mixed infections and unidentified diseases which defy diagnosis at this distance in time.

The author is cautious in his attributions of historic change to specific insect-borne diseases. The well known idea of W. H. S. Jones that the loss of vigour among the Greeks when the power of Rome was increasing, was the result of malaria. But the vigour of a people can be sapped from other causes; and when malaria does increase it is not always easy to distinguish cause and effect. Did the collapse of the Sinhalese civilisation in Ceylon result from the introduction of malaria? Or did malaria increase because the repeated Tamil invasions from the mainland disrupted the elaborate system of irrigated agriculture established by the Sinhalese. After all, it was probably improved and intensive agriculture which dispelled malaria from East Anglia in the last century. There seems little doubt that malaria in the Pontine marshes was a real factor among the epidemics which destroyed successive armies invading Rome. But in the inverse relationship pointed out by Celli between agricultural productivity in the Roman Campagna and the incidence of malaria, it may well have been intensive agriculture which was controlling malaria in ancient times as well as in the time of Mussolini.

It is a popular idea that malaria and swamps go hand in hand, and nothing is said in this book to dispel this belief. It happens to be true for much of Europe; but it is the reverse of the truth in most of the tropics, where the Anopheline mosquitoes which infest swamps and paddy fields are usually not carriers of malaria at all. The roadside puddle and the grassy streamlet are infiinitely more dangerous. It came as a surprise to all sides in World War I to discover that in the Mediterranean area the mountain streams were often the major source of malaria.

This is a book about epidemics and pestilences, it is not about medical entomology. The insect carriage of disease is a subtle matter. Even the subtleties that are known scarcely appear in this book; and there is much that is not known. The author makes no pretence that the epidemiology of infectious diseases is a simple matter: he could hardly have covered the complexities of insect transmission as well as the rich history of epidemics that he provides. When the International Health Board of the Rockefeller Foundation was set up, it decided to make a big splash by tackling a project which it knew would be successful. General Gorgas had saved the labour force of the Panama Canal from yellow fever by first-class organisation of simple procedures. The International Health Board would banish yellow fever from the New World. That was in about 1912. In 1917 they claimed complete success, but a year or so later a small outbreak occurred and they had to do it again. And so it went on for years, until it was discovered by Soper in 1935 that the yellow fever virus was being maintained in the Amazon jungle by forest mosquitoes feeding on monkeys in the treetops. When small clearings were made men were infected and returned to the towns, where they started epidemics carried by the urban mosquito *Aedes aegypti*. The Rockefeller Foundation had been unlucky; they had chosen a disease the eradication of which was impossible.

The author is an assiduous quoter of chapter and verse. There are times when the reader becomes tired of the repetitive statistics of horror. The effect, however, is cumulative, and the docketing of the fate of successive naval expeditions from the sixteenth century onwards, when faced with malaria, yellow fever, scurvy and the rest, bring home the facts in a way that no general account could do. The same applies to the figures for the incidence of typhus deaths in the wars of the eighteenth and nineteenth centuries. We all know that until recently the major cause of death in war was epidemic disease. But when the figures are set out as here in detail, they are staggering.

In a concluding chapter the author deals with insects harmful to agriculture, concentrating his attention on the plague locusts which, as a major cause of famine, contribute greatly to the incidence of epidemic disease in man. He sketches also the former role of insects in commerce—as a source of dyes, waxes and lac, honey (for long the main source of sweetness) and silk, which played such an important part in the world trade of ancient China. All these products have receded in importance in modern times, but their impact on economic history as here recorded is fascinating.

Altogether this is a book that is full of intriguing information which cannot fail to interest both the general reader and the informed entomologist.

Sir Vincent Wigglesworth is Emeritus Professor in the Department of Zoology, University of Cambridge, UK.

Man's ectoparasites

Insects, Hygiene and History. By J. R. Busvine. Pp. 262. (Athlone: London, 1976. Distributed by Tiptree Book Services: Tiptree, Essex, and Humanities: New Jersey.) £6.95.

MOST of us who have lectured in medical entomology have tried to enliven our discussion of human ectoparasites by including a few anecdotes such as that demonstrating the holiness of St Thomas of Canterbury, whose garments, after his murder in the cathedral, "boiled over with lice like water simmering in a cauldron". This was, of course, in an age when cleanliness was considered to be the antithesis of godliness. We realised that there was a wealth of entertaining and instructive fact and fiction buried in the literature from the times of classical antiquity to the present day. A few writers—for instance, Hans Zinsser in his famous book *Rats, Lice and History* —have hinted at the richness of the information waiting to be revealed by some student of the byways of parasitology, but others, up till now, have not had the patience to follow his lead.

At last Professor J. R. Busvine has accepted this implicit challenge, and has written the first comprehensive account of the history, and the mythology, of man's ectoparasites. He has produced a most entertaining text, full of tales of observation and of misunderstanding, of ribald verse and donnish pornography. Future lecturers will have no excuse if they make parasitology a dull topic.

Hair hygiene to eradicate lice

Hortus Sanitatis (1491)

This book has clearly been compiled during a lifetime study of insects and disease. James Busvine is not primarily a historian although he has done his historical research thoroughly and competently. He has systematically noted down each reference he has come across, sometimes by chance, often only after considerable searching, during the course of his major studies. But the great value of the book is that its author has himself contributed substantially to modern knowledge of its subject, so that he relates the historical observations, with all their curiosity, to the situation as understood by modern science.

This book is, however, more than an entertaining account of man's frailties. It shows how science progresses, and how this progress is often delayed. It is

IN TWO VOLUMES

Estuarine Processes

Edited by MARTIN WILEY

These two volumes report on the Third Biennial Estuarine Research Conference that was held at Galveston, Texas, in October 1975. An attempt is made to summarize recent advances, to evaluate emerging problems and current concepts, and to stimulate exchange among scientists, managers and others interested in estuaries or coastal areas.

In Volume 1, the section on rehabilitation contains discussions on how estuaries are manipulated by man, how they might be managed, and how they can be rehabilitated. The sections on nutrient cycling, population dynamics, behavior as a measure of sublethal stress, and cycling of pollutants are composed mostly of original research papers, while the sections on wetlands uses, and physiological and biochemical adaptations contain mostly review papers.

Volume 2 contains many papers that are reviews but that also report on original research. The topics are: the effects of physical alterations on estuaries, sedimentary processes, interactions between tidal wetlands and coastal waters in the transfer and utilization of nutrients and organic matter, circulation models, and tools and methods.

VOLUME 1/**USES, STRESSES, AND ADAPTATION TO THE ESTUARY**
1976, 588 pp., $22.00/£15.65 ISBN: 0-12-751801-0

VOLUME 2/ **CIRCULATION, SEDIMENTS, AND TRANSFER OF MATERIAL IN THE ESTUARY**
1976, 444 pp., $19.50/£13.85 ISBN: 0-12-751802-9

WILEY
INTERSCIENCE

ENCYCLOPAEDIA OF ANTIBIOTICS

by **J. S. Glasby,** *I.C.I. (Organics Division), Ayrshire, Scotland.*

The encyclopaedia lists entries in alphabetical order for easy reference and gives, for each antibiotic, the formula, structure, melting point, elaborating organism, methods of preparation and purification, those organisms against which the antibiotic is effective, and toxicity, where these properties are known. The voluminous scientific and patent literature has been reviewed and major papers are referred to in the entries for each compound. The encyclopaedia will prove an invaluable reference book to workers in chemistry, biochemistry, microbiology, pharmacology and medicine.

0471 01818 X 378 pages December 1976 £17.50/$39.00

GENERAL EPIDEMIOLOGY

by **H. Sinnecker,** *Humboldt University, Berlin.*

Translated from the German by **N. Walker,** *Rothamsted Experimental Station.*

This book presents a general theory of epidemiology. In developing his theory, the author draws upon the widely scattered information on various aspects of infectious and non infectious diseases.

0471 79318 3 228 pages December 1976 £8.50/$17.00

ADVANCES IN CHEMICAL PHYSICS VOL. 35

edited by **I. Prigogine,** *University of Brussels and University of Texas,* and **S. A. Rice,** *University of Chicago.*

Experts in the field explain their views on different aspects of chemical physics; eg Theories of Chemically Induced Electron Spin Polarization; Kinetic Theory and Rheology of Macromolecular Solutions; Kinetic Theory of Gravitational Systems; Magnetic Circular Dichroism; Time Dependent Perturbation of a Two State Quantum System by a Sinusoidal Field.

0471 69937 3 368 pages August 1976 £22.50/$39.30

ORGANIC PHOSPHORUS COMPOUNDS VOL. 7

edited by **G. M. Kosolapoff,** *Auburn University,* and **L. Maier,** *Monsanto Research S.A.*

This is the concluding volume in the Organic Phosphorus Compounds series which lists more than 100,000 compounds and gives references for their preparation and to all their physical properties.

0471 50446 7 880 pages March 1976 £25.85/$44.90

BIOCHEMISTRY OF PHOTOSYNTHESIS 2nd ED.

by **R. P. F. Gregory,** *Department of Biological Chemistry, The University of Manchester.*

The aim of this book is two fold; first, it is intended for use in undergraduate courses in biochemistry, in the belief that an understanding of the metabolic pathways of photosynthesis form a valuable complement to an understanding, say, of the pathways of glycolysis and the pentose cycle or of NADP reduction and photophosphorylation. The second aim of this text is to review the most recent research findings in this field to provide a background for anyone beginning research into some aspect of photosynthesis.

0471 32676 3 236 pages January 1977 £8.50/$16.50

ANALYSIS OF VERTEBRATE POPULATIONS

by **G. Caughley,** *School of Biological Sciences, University of Sydney.*

This book is an introduction to methods of analysis of vertebrate populations for ecologists and wildlife managers as well as students of these subjects. A wide range of examples drawn from mammals and birds in different parts of the world is used to illustrate these methods. The book shows how population analysis can be applied to practical problems of wildlife management such as reducing a population, stimulating it to increase or taking from it a sustained yield.

0471 01705 1 244 pages January 1977 £8.75/$16.50

THERMOMETRIC TITRATIONS

edited by **J. Barthel,** *Universitat Regensburg, Germany.*

A comprehensive discussion of the theoretical background of thermometric titration methods and techniques. Furnishes information on construction of suitable titration calorimeters and recent analytical methods. (Chemical Analysis: A Series of Monographs on Analytical Chemistry and Its Applications Vol. 45).

0471 05448 8 224 pages February 1976 £15.55/$27.15

HANDBOOK OF PROTON IONIZATION HEATS AND RELATED THERMODYNAMIC QUANTITIES

by **J. J. Christensen,** *Department of Chemical Engineering Science,* **L. D. Hansen** and **R. M. Izatt,** *Department of Chemistry, Brigham Young University, Utah.*

The book brings together a complete listing of the heats of proton ionization, ΔH, together with the related thermodynamic quantities, pK, ΔS, and ΔCp, where available, and should be a valuable reference source for either practical or research scientists in both physical and biological sciences.

0471 01991 7 286 pages October 1976 £16.75/$28.50

often surprising to find that the same person could make accurate observations and draw the correct conclusions from them, and at the same time seem to be quite blind in another, though similar, field. Thus Aristotle was in some ways the father of scientific zoology, and many of his descriptions of animals and plants need little modification today. Yet, although he described the nit (the egg of the louse), he was convinced that it had no generative function, and that these insects arose only from the putrefaction of human flesh. This view was held for centuries, and to deny it could lead to a charge of heresy by the mediaeval church. Before the invention of the microscope naturalists could be excused for many misunderstandings, but it is difficult to comprehend why they were so badly mislead regarding this parasite, which can be so easily studied throughout its life history with the naked eye.

But the situation may not have changed as much as we may like to think. Scientists and clinicians still find it difficult to accept new evidence and relinquish long-held beliefs. I well remember how incredulous some dermatologists were when, during the last war, we demonstrated that the itch mite, the cause of the disease of scabies, was usually transmitted by close personal contact and seldom by blankets and other inanimate objects. One leading physician stated publicly that these scientific experiments were all very well, but he *knew*, from a lifetime of clinical experience, that blankets and other fomites were of major importance. Fortunately he could not call on the inquisition to stifle our results, which were soon accepted by his colleagues and by the Ministry of Health, so that treatment was improved and the disease was, temporarily, nearly erradicated in Britain.

Kenneth Mellanby

Kenneth Mellanby was Reader in Medical Entomology in the University of London (1945–47) and Professor of Parasitology in the University of Ibadan (1948–53).

How behaviour works

The Hungry Fly: A Physiological Study of the Behaviour Associated with Feeding. By V. G. Dethier. Pp. 489. (Harvard University: Cambridge, Massachusetts, 1976.) £20.40.

THE appetites for sex and food are the two most important driving forces in animal behaviour, the one to maintain the species and the other to enable the performance of the first. Research on these appetites is therefore central to the study of behaviour. Most of our knowledge of the mechanisms involved in the appetite for food derives from work on the rat—an animal whose mentality is perhaps dangerously too near our own for complete objectivity. Some 30 years ago Dethier chose to work on the hunger of a simpler organism, the blowfly, with whom he and his students were less likely to identify. The result has been a volume of research scarcely less impressive than that on the rat, and in some respects much better in quality, notably on the electrophysiological correlates of taste and feeding.

The Hungry Fly is a kind of autobiographical account of these 30 years of research. It is difficult to categorise precisely, since the author seems not quite to have made up his mind whether to write a popular text or an advanced treatise. Thus, each chapter opens with a few rather elementary pages, some sprinkled with statements that will seem either banal or erroneous to the professional biologist; but then plunges into the technicalities of chemosensory transduction or perseverating central excitatory states. The professional may be irritated by the introductions, the lay reader surely rapidly lost by the rest.

As one reads through the minutiae of experiments carried out in the 1950s that have since been superseded, one does begin to wish that the account was slightly less full. The book could surely have been slimmer, cheaper, and more assimilable if these false trails and some of the other fine detail had been omitted. Chapter 12, for example, describes at great length the neuroanatomy of the fly's brain with the aid of over 40 light micrograph serial sections (incidentally, without indicating scale, section position or thickness) and then ends frustratingly by saying that nothing whatever is known about the functional organisation of the dipterous brain.

Dethier uses the Lorenzian concepts of 'appetitive behaviour' and 'consummatory act' throughout his book, but the reader should not be thereby misled into thinking that he is still of that school of behaviourists who believe in these psychological notions of drive and motivation. His last chapter, perhaps the best in the book, spells out in brief, eloquent simplicity why there is no need to invoke these anthropomorphisms to explain the workings of behaviour, and why there is no need to consider the behaviour of the rat as qualitatively different from the simpler behaviour of the insect.

In effect, the book is a three-fold filling out and up-dating of Dethier's long 1969 review on the same subject. He says it is not about chemoreception and neurophysiology (though much of it is), but is a description of behaviour in terms of physiological mechanisms. In this respect it is a superb account, and will surely remain a classic on the shelves of behaviourist-physiologists for many years to come. It will probably also provide the more general biologist with insights into how behaviour works and what it is made of. Whether a wider public will be very much enlightened by it is less clear.

Economic geology and tectonics

Metallogeny and Plate Tectonics. Edited by D. F. Strong. Pp. vii+660. (Geological Association of Canada: Department of Earth Sciences, University of Waterloo, Waterloo, Ontario, 1976.)

In some areas, the plate tectonic bandwagon must be approaching its elastic limit as more and more ideas and interpretations are heaped on it, yet surprisingly little attention had previously been paid to corallaries of this model for economic geology and Precambrian tectonics. Major progress in both aspects have now been made with the almost simultaneous publication of the proceedings of two separate NATO conferences—B. F. Windley's *The Early History of the Earth* (Wiley, 1976) and D. F. Strong's *Metallogeny and Plate Tectonics*. The latter comprises 26 papers and six abstracts concerned mostly with either general concepts or specific locations, with the main emphasis on attempts to interpret different metallogenies in terms of the current plate tectonic framework. The standard is inevitably variable, but generally very good. The papers are in English, with both English and French abstracts, and it is a credit to the editor that his work on the 'foreign' contributions is undetectable yet must be there for them to flow as well as they do. Similarly the editor must have worked hard to keep out too many pictures of subduction zone models which, although the dominating figure, do not obtrude.

The production is generally good, the only major flaw being that there is no index. This omission is particularly serious for such a heterogeneous collection of papers which, although grouped into sections, contain numerous cases of partial or even complete discussion of features which belong in other sections. This is further aggravated by the order in which the sections are presented: metal deposits in convergent plate margins, intraplate environments, orogenic belts and ores of Precambrian age. This order presumably reflects the fact that orogenic belts contain both subduction and intraplate ore bodies, and Precambrian deposits may contain all forms and also be characterised by modified plate tectonic models resulting from, for example, the much higher average geothermal gradients of Archaean times. Nevertheless, present day subduction zones, such as the Andes and Japan, which form the majority of the areas discussed under convergent zones, also contain pre-existing ore bodies in the same way as the Canadian cordillera, which are discussed under orogenic belts. Such difficulties in grouping the papers would not have mattered so much if the whole volume was indexed, even in a coarse fashion. Under the circumstances, it would have been better to commence with accretion zone deposits, and then have orogenic belts following convergent zones.

Most of the early proponents of metallogeny and plate tectonics have contributed to this publication, but it is significant that the 'grey-beards', in this subject, such as R. H. Sillitoe, must be considered those who published on the subject in or before 1973, and sufficient credit is still not given to those geochemists who determined the zonations in island arc environments well before the discovery of plates. Those papers by E. Horikoshi (north-eastern Japan), A. Y. Glikson (Archaean to early Proterozoic Shield structures), T. Sato (green tuff province, Japan), F. J. Sawkins (massive sulphides), R. A. Stacey (Canadian cordillera) and H. S. Swinden and D. F. Strong (Appalachians, North American cordillera, south-eastern Australia) are particularly interesting. Others are disappointing rather than unimportant. For example, that by P. Laznicka (lead deposits on global plate model) could have been of major significance, but is marred by dogmatic classification of specific ore deposits—such as the Red Sea as intra-continental rather than an incipient ocean rise, the southern European Permo–Triassic deposits as a trailing edge, and so forth. This may all be correct but is certainly arguable, yet the final conclusions are quoted to 0.01%; and one major environment, with 37.69% of world reserves, occurs in trailing margins—an environment which seems to be defined as one into which sedimentary ores are placed together with those which are not obviously in any other category. The conclusion should be that some one-third of the world's lead occurs in sedimentary forms of uncertain origin.

The general lack of consideration of sedimentary ores is understandable, although disappointing. There is evidence that most of these have been strongly influenced by palaeoclimatic conditions and hence palaeolatitude. As this is determined by the motions of the plates, these ores are as related to plate tectonic motions as subduction zone metals. Other gaps, however, include kimberlites, which are not merely important economically but have major implications for upper mantle evolution. Nevertheless this publication is obviously essential to even the smallest geological library. The hope is now that some future NATO conference will turn to consider energy resources in the same context. The seafloor conveyor still has some way to go before all of the ideas have been sweated out of its subducting melange! **D. H. Tarling**

D. H. Tarling is a Senior Lecturer in the Department of Geophysics and Planetary Physics at the University of Newcastle upon Tyne, UK.

Opisthobranch molluscs

British Opisthobranch Molluscs. (Synopses of the British Fauna, No. 8.) By T. E. Thompson and G. H. Brown. Pp. 203. (Academic: London, New York and San Francisco, 1976.) £3.50.

This is a very welcome addition to the recent series of Synopses of the British Fauna. The book is well designed and attractive to look at. There is less restriction on size than in previous numbers and this has enabled the authors to have, for most species, a large drawing occupying one page and on the opposite page a brief but adequate description of external features necessary for identification, notes on biology and worldwide distribution. Technical terms have been kept to a minimum and the introductory pages and descriptions are designed to cater for the non-professional zoologist.

The complementary talents of both authors are well exhibited. Gregory H. Brown's drawings set forth the salient features of each species and the life-like posture. T. E. Thompson, a well known specialist on opisthobranchs and an aqualung enthusiast, is familiar with the habitats of many species and has examined nearly all the 135 which are described. When opisthobranchs have to be identified it is now no longer necessary to search the classical works and paraphrase the language of nearly 150 years ago. In this synopsis concise keys lead to family and species. Ideally such attractive molluscs would be depicted in colour, but the cost is prohibitive. The single plate that is provided, although valuable in displaying their beauty of form, whets the appetite for more.

In such a detailed compilation it is difficult to prevent a few misconceptions: the eyes of *Stiliger bellulus* are lacking in the description and the figure; the dorsal surface of *Limapontia capitata* is figured with a pale cross, but this is of rare occurrence.

Tidal project worth support

SITTING somewhere in the Department of Energy is a proposal by a team of engineers known as the Severn Barrage Group for a major study of the feasibility of extracting substantial amounts of tidal energy from the flow of water in the Bristol Channel/Severn Estuary region. The outcome of the request for £1.2 million to do 18 months' investigative work will be watched with great interest by all who have a concern that no energy option should be closed out without some pretty sophisticated analysis and without an extended time being available for public debate.

Tide mills are a pretty old concept. T. L. Shaw, writing on the Severn scheme in *Nature*, **249**, 730 (1974), remarks that they can be traced back to 1180, and the idea of harnessing the unusually high tidal range in the Severn Estuary (mean range 7 metres) was first given detailed engineering study as far back as 1933. Even when nature conspires to provide as favourable a site as the Severn Estuary, however, everyone knows that tidal energy suffers from the severe defect that if turbines are simply driven by the flow of water into and out of the estuary, the periodicity of the daily demand for electricity is only spasmodically in phase with the times at which tidal power can make a useful contribution. There are enough thermal generating sets around the country suffering reduced efficiency because of this daily demand cycle for there to be little enthusiasm simply for the addition of another cyclic term, and, what's more, one with a 29-day spring/neap periodicity to bedevil operating conditions even more. It is for these reasons that the French, who have successfully run a 240-MW tidal generator at La Rance, Brittany, for many years, have never proceeded to the larger scheme for which La Rance was the pilot.

The Severn Estuary scheme as now proposed would, however, not be tied to delivering energy in phase with the tides, but would be part of an integrated scheme providing pump-storage facilities for conventional thermal stations. A barrage would close off the estuary between Cardiff and Weston; above it would be the primary basin in which the water level would fluctuate between the present mean sea level and the high spring-tide level—that is, there would be no flooding of land. Just seaward of the barrage, in deep water, would be a secondary basin, maybe 5 kilometres across. Water from this basin could be pumped up into the primary basin using electric power from thermal power stations. Electricity would be generated both by the fall of seawater at high tide into the (drained) secondary basin and also by the fall of water in the primary basin back into the sea at low tide. Electricity would be generated during the daytime and consumed in pumping at night. In this way a scheme combining tidal energy extraction and pumped storage would take electricity from thermal stations at times at which they might otherwise have to close down.

Rough estimates put the cost at £2,000 million to generate around 4,000 MW during the day (nearly a tenth of the nation's load at present)—in itself rather an expensive investment, though less so when the advantages of the pumped storage scheme are incorporated and consideration is taken of the price, or lack of it, of fuel.

Until now studies on the Severn Barrage have been conducted at a fairly academic level, and only recently has much serious work been done on the obviously major environmental impact; a cursory examination of material published suggests no overwhelming environmental objections. The time looks ripe therefore for a much more extensive feasibility study. Around £1 million has recently been committed to exploratory research for geothermal energy sources which seem less likely to make a major impact on the nation's energy requirements; a similar sum on tidal energy and the effect that the scheme could have on the environment does not look to be out of line.

If a study is funded and finds that the case for some sort of barrage is strong and that environmental objections can be met, there is still bound to be one major question mark hanging over the project. Once into such a scheme there is little benefit gained in calling it off on the way to completion. If costs go awry, if major problems arise, if the energy scene changes dramatically, there is little that a half-completed barrage can be used for. This will doubtless be used as ammunition by those who have a distaste for large technological projects, so it would be more than usually necessary that both the feasibility survey be done exceptionally well, and that the politicians who make the ultimate decision be thoroughly open with the public about the basis of their decision—since they probably won't be around at the time when nerves are being tested. ☐

Keeping in touch with Soviet colleagues

Miles Reid, Royal Society Visiting Fellow in the Department of Mathematics at Tokyo University and Fellow of Christ's College, Cambridge, writes an open letter to scientists interested in maintaining and improving contacts with their Soviet colleagues

THE growth of international scientific and cultural ties is potentially of enormous value in developing the spirit of cooperation and friendship between nations. I personally believe we scientists can make a contribution towards making this world a safer and a more decent place to live in. But it is also my opinion that Western scientists do not make full use of existing channels of communication, perhaps due to traditional western misinformation as to what is or is not feasible.

Invitations to the West. The majority of Western scientists are probably familiar with the frustrating fact that senior (non-party) Soviet scientists invited to Western conferences find it impossible to take up the invitation.

The first step for any Soviet citizen in obtaining a visa to travel abroad is to get a reference from the Party Committee of his place of work recommending the visit; there are several subsequent steps where hitches may occur, but I believe the first step to be the essential obstacle, since if the *Partkom* is prepared to give its backing the remaining problems may turn out to be soluble.

Now there is some reason to believe that this obstacle may be less serious for younger scientists. This optimistic view is suggested partly by analogy with the case of visits from the USSR to the countries of eastern Europe (a closer analogy than most people in the West will be aware of); and partly by speculation as to the nature of the decision-making procedure within the *Partkom* of universities and institutes.

I would thus like to urge that every possible opportunity be taken to invite the younger generation of Soviet scientists to meetings in the West or to Western universities. In my field of mathematics (algebraic geometry) there is certainly no shortage of excellent young scientists, and visits to the West by such people, even for short periods, should provide for an extremely stimulating flow of ideas and information in both directions.

I would like to suggest that as a matter of form every invitation to a senior scientist should contain a clause to the effect that if the person invited feels unable to take up the invitation, he suggests the name of a junior colleague or research pupil who could be interested in coming in his stead. Of course, one does not necessarily expect that a research student of a particular scientist would be able to do more than give a token representation, but his presence will allow a flow of ideas, and will do something towards correcting the balance in the make-up of Soviet delegations.

As far as I am aware almost any young Soviet scientist would jump at the opportunity of travelling to the West, and be extremely keen to attempt the considerable task of applying for permission. There is probably a practical upper bound of about two months on the length of time a Russian scientist would be allowed out, and one should allow for some uncertainty in the time of arrival.

> 'It seems to be the case that Western organisers who have had repeated failures in attempts to invite Soviet colleagues sometimes get discouraged and give up trying. This is obviously wrong on probabilistic grounds'

Contrary to what is commonly supposed in the West, there is no reason of principle why a Soviet citizen having obtained permission to travel abroad should not support himself on the issue of dollars he is entitled to under the currency regulations, although I am informed that university authorities may be very much more impressed by an invitation promising support and even a contribution towards travel expenses.

Even for a (non-party) scientist with an impeccable student and *Komsomol* background the probability of being allowed out is probably no greater than one-tenth, and it seems to be the case that Western organisers who have had repeated failures in attempts to invite Soviet colleagues sometimes get discouraged and give up trying. This is obviously wrong on probabilistic grounds, since if the probability of success is small one should clearly make more attempts rather than fewer. And if one draws a blank after taking reasonable measures over a period of several years (such as writing periodic supporting letters to individual members of the university or institute management urging the advantages to both Western and Soviet science to be gained by some particular visit), then one is in a stronger position to complain that the Soviet side is being uncooperative.

There is certainly no way in which invitations addressed to an individual scientist, or letters enquiring as to the best way of inviting either him or one of his students could compromise him or lead to retaliation from the authorities.

I regard suggestions sometimes made that we take a hard-line attitude and boycott delegates we regard as too 'official' as potentially extremely harmful and counterproductive. It is my firm conviction that success in this matter will be directly proportional to the amount of patient effort which we are willing to exert.

The copyright convention. In 1973 the Soviet Union signed the Geneva copyright convention, thus bringing to an end the tradition of publishing pirate translations of Western books and journals. The potentially damaging effect of this on Soviet mathematics doesn't seem to have been generally realised. Before the copyright convention any important textbook was published in an edition of 10,000 (say), ensuring that every college, university or technical school was able to obtain a copy for its library. Similarly important Western articles found their way into libraries across the country in the form of translations in *Matematika*. Since the convention the number of textbooks translated has dwindled to an insignificant trickle, and *Matematika* has ceased publication.

Important university or institute libraries get an issue of foreign currency with which they can buy a selection of the essential literature; but this may have the effect of reducing contact with Western scientific ideas down to the scientists at a few major centres. An important additional source of foreign journals costing nothing in dollars is the exchange of publications, and every attempt should be made to extend the existing exchanges. The use of the photocopying machines at the major Soviet libraries remains at present expensive and inconvenient.

Contact by mail. A visitor at a Russian scientific centre is constantly embarrassed by being pumped for information about what's going on in the West; and the plea for preprints, lecture notes and copies of letters is invariably repeated in any discussion. I am not necessarily implying that the Western scientific community has been mean in this respect in the past, but I'd like to emphasise the desirability of sending as much information as possible.

Although it is true that every item of news received from the West is circulated and discussed with great interest, it is also true that even within Moscow there are many different institutes at which scientists are employed, and there may not be very close contact between them; *a fortiori* this applies to provincial universities. Western scientists need only consider how frequently they make photocopies of preprints or letters for their own use or for passing on to a colleague or student to realise the inconvenience of being deprived of this facility; so it doesn't seem unreasonable to suggest sending a larger number of preprints to a Russian university than one would to the corresponding Western university.

It is perhaps quite striking the extent to which the average scientist depends for his general outlook on informal contact. Thus one might discuss in conversation the work in progress of some colleague and gain thereby an overall impression of some new field of research without having to wait for the precise results to appear as preprints or articles. For a while now I have been trying to apply this principle in written form to try to bridge the gap between Soviet mathematicians in my field and the West, writing with occasional news of new developments (sometimes of which I have only the sketchiest knowledge myself). A slight difficulty is that there are in principle and in practice restrictions on one's correspondents' replies (see below), and one sometimes has to content oneself with the abstract knowledge that the communication is well received, and somehow get over the psychological difficulty of corresponding with someone whose replies are infrequent.

This idea has a potentially invaluable application to an international gathering at which no Soviet delegate is present, and I would like to suggest that if maybe two or three of the participants write their impressions of a few of the most exciting new results, and send three or four copies to interested colleagues in the Soviet Union, then this will do something towards correcting the isolation of Soviet science.

This problem has a converse: Russian scientists also complain that it is very difficult for them to send round copies of their recent work; some of the controversy about Russians not getting fair recognition for their original work perhaps stems from this difficulty.

An article prepared for publication in a Soviet journal will be typed, with three or four carbon copies made, of which several have to be submitted. It would be useful to have some system whereby a Soviet author who so desires could send out a carbon copy of his typescript to be copied and distributed in the West. This could perhaps be done officially, for example in connection with the translation schemes, or unofficially by private arrangement; those of us who are in correspondence with Soviet scientists should at any rate offer to perform this function.

> 'It would be useful to have some system whereby a Soviet author who so desires could send out a copy of his typescript to be distributed in the West. This could perhaps be done officially, for example in connection with the translation schemes, or unofficially, by private arrangement'

There are in principle two legal restrictions on what can be sent out of the Soviet Union. Firstly, the State holds the copyright on anything written by one of its citizens. And secondly an archaic clause of the State Secrets act requires that before sending abroad any written item containing mathematical formulae the sender must obtain the explicit permission of a scientific establishment—which involves the completion of exhaustive formalities, and is usually only possible if the item is already cleared for publication. In practice, however, scientific manuscripts and short items containing formulae are sent abroad rather frequently, as shown for example by the fact that Soviet scientists review regularly for Western journals and translate for the AMS. In general I am impressed by the amount of material that has been permitted in recent years to pass through the mail in both directions, and I would like to interpret this as an indication of the genuine application of one of the clauses of the Helsinki agreement.

It could be argued that the postal regulations, which make it impracticable for papers submitted to Soviet journals to be sent to a reviewer outside the USSR, are partly responsible for the uneven quality of some of the papers appearing in the Soviet scientific press.

Visits to the Soviet Union. The possibilities are as follows: as a tourist; by formal invitation; under the international Cultural Exchanges.

- It is perfectly feasible to visit, say, Moscow or Leningrad as a tourist, and nowadays the tourist gets a very reasonable deal (travelling with a group may be very much cheaper, and the group activities are not compulsory). When applying for a visa one is required to name the Soviet citizens one intends to meet, but there can be no objection to a scientist who intends to get in touch with colleagues declaring only one name.

It is perhaps worth pointing out in connection with the forthcoming International Congress of Mathematicians that Leningrad is just one night on the train away from Helsinki, and is a town that has considerable attraction to the tourist.

- Soviet scientists may be very willing to attempt to get an invitation made out to a Western colleague to visit them for periods of up to two months. However, it is fair to say that this is not necessarily straightforward. Certainly any Western scientist interested in this possibility should in the first instance write well in advance to a Soviet colleague with whom he has good scientific relations to discuss tactics.
- There are cultural exchanges in operation between the Soviet Union and every Western country. They take place both at the level of visiting fellowships (organised through the Academy of Sciences) and visiting studentships (through the Ministry of Higher Education), and represent almost the only practical possibility for a Western scientist to spend a long period (six months or a year) in contact with a Soviet scientific centre.

I would strongly recommend the latter to any Western research student of recent PhD who is interested in some aspect of Soviet science, is willing to learn Russian, and is prepared to face the difficulties as well as the varied delights of Soviet life. Copies of my report to the British Council containing some of the fruits of my two years' experience in the USSR will be available on request. The very least that Western universities can do to encourage the use of these exchanges is to display the advertising matter relating to them.

In conclusion I would remark that there are many countries in the world where the working conditions of scientists, and the ways in which contacts with the world scientific community can be improved, are subjects which certainly deserve further study. But it seems fair to say that the Soviet Union, the People's Republic of China and Czechoslovakia stand out as the three major countries of the world whose minimal cooperation in maintaining scientific contact amounts to a deliberate affront to the world academic community on the part of their governments. ☐

Three years after Allende

Alwyn Eades, recently in Chile, assesses the state of the physical sciences there

DURING the past three years, research in physics in Chile has suffered set-backs from which it will recover only with difficulty. University physics departments have been especially hard hit; they have no protection from the severe budget reductions and loss of staff brought about by the political upheavals. In materials science the position is less bleak and people are hanging on, if only by the skin of their teeth. This is because the centres of applied science have partial independence. The Institute of Materials Testing and Research of the University of Chile, for example, is in a stronger position than the physics departments because it is able to pay (and has to pay) the whole of its research budget from contract work. Only staff salaries are paid by the University.

This reversal is in marked contrast with the previous steady growth of research. Twenty years ago there was little or no research in physics in Chile. Then in the mid-1950s a small number of physicists, trained abroad mainly in England, began to set up research programmes. This effort was initially slow and precarious, but by the late 1960s they had met with such success that the two most important physics departments in the country (both in the University of Chile, one in the Engineering School, the other in the Faculty of Sciences) each had about 40 academic staff including graduate students, nearly all of whom were involved in research.

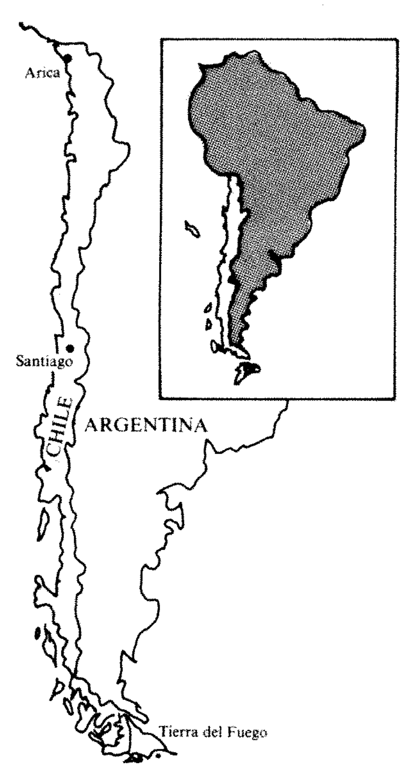
At this point it began to seem for the first time that there were enough research physicists in Chile to form a stable nucleus for future development, and that some kind of critical mass had been achieved. Evidence for this lay in the establishment of a doctoral programme; until that time Chilean students were obliged to go abroad to get a higher degree. In the early 1970s people felt such confidence in this stability that there was a lot of talk of developing a science policy for Chile in a way which was unthinkable previously. For the first time, Chilean physicists began to feel secure that no longer could an arbitrary administrative decision or the departure of one man have a disastrous effect on the nation's research effort. It was therefore bitterly ironic that the military coup of September 11, 1973 should, almost incidentally to its many brutal acts, set physics research back nearly two decades.

It is worth pointing out here that the election of Allende did not directly affect science in Chile very significantly. The presidency of Salvador Allende represented much more of a continuation and natural extension of previous government policy in Chile than is usually recognised outside the country. In any case, the principal effects on science research were, initially, considerable governmental encouragement to make research relate to problems relevant to Chile and, later, a reduction in the budget available in hard currency. The latter was a result of economic problems rather than an attempt to restrict science.

The fate of the two physics departments mentioned above since the coup has been quite different. The Department of Physics in the Faculty of Sciences lost most of its staff within a very short time of the coup. Many left voluntarily to seek employment in other countries. Some were imprisoned and/or expelled. In the three years since the coup there has been a bare handful of staff and there has been no research. I was told, for example, that the two main experimental areas, the cyclotron and a low temperature facility for solid state research, have remained closed down. In the past few months, however, new staff members have been contracted and attempts made to restart research. It is surprising to find that those involved seem confident that stable conditions suitable for research may now prevail.

In the other physics department, that of the Engineering School—a right-wing stronghold in a largely left-wing university—the coup had little immediate effect. My own departure two months later was one of the few obvious results. Over the three intervening years, however, the situation has deteriorated very greatly. There have been several waves of sackings for a mixture of political and economic reasons, as a result of which the number of academic staff has dropped from 45 to about 25. Many research groups have completely vanished.

For example, a very impressive semiconductor and microcircuits facility, set up with substantial funds from the Organisation of American States and the Ford Foundation with the support of the Chilean Development Corporation, now lies virtually abandoned. One of these two laboratories is a complete manufacturing facility for microcircuits; the other is a well equipped laboratory for basic research into semiconductors with no one to use it.



Chile is a large, sparsely populated country. Three million of its ten million inhabitants live in Santiago, the capital city, where virtually all economic activity except mining and agriculture is concentrated.

A former Spanish colony, Chile gained her independence at the beginning of the nineteenth century. Subsequently she maintained a remarkable record (indeed a record unique in Latin America and scarcely matched anywhere) for unbroken democracy and liberal government. She was, for example, among the first countries to abolish slavery, and her social services were very well developed for such a poor country. From the 1930s consistent policies by successive governments succeeded in achieving a substantial degree of industrialisation, though mostly with production on a rather small scale and using imported technology.

The country's stability was broken in September 1973 when a military junta overthrew the leftist government of Dr Salvador Allende, who was killed. In the years since the coup the junta has followed a policy of repression and infringement of human rights, and an economic policy which has caused both a large reduction in production with many companies both large and small going bankrupt, and very high unemployment.

Alwyn Eades, who wrote the accompanying article, is at the University of Bristol and worked in Chile from 1967 to 1973. He recently returned there for the first time in three years to attend a scientific congress and work with his former colleagues. He spent two weeks in the Department of Physics of the Engineering School and visited four other institutions. Together the five laboratories represent a very large proportion of the nation's research effort in physics, materials science and related areas. "It is very easy to be misleading about Chile", he says, "and very easy to be misled".

This particular state of affairs is still more disconcerting for another reason. Chilean physics has been characterised by too many groups of too few people covering too wide a spectrum of research; moreover, research topics have been chosen because of the training received by staff abroad rather than because of any relevance to Chile. The now-abandoned semiconductor facility was the beginning of an attempt to change this.

The pattern occurs elsewhere. Thus the plasma laboratory, equipped with a well instrumented shock tube and once with six staff members, is now deserted. The only remaining member of the group is completing postgraduate study in London University and is reluctant to return to work alone instead of rejoining an active group with research in progress. Laboratories for Mössbauer spectroscopy and nuclear magnetic resonance also lie idle.

Some groups are not so unfortunate, and in particular X-ray crystallography, biophysics and theoretical physics remain active. The first is particularly important because Oscar Wittke and his team not only do good crystallography but also carry out invaluable service work for industry. This long standing work is unique as an example of collaboration between industry and a physics group in Chile. But even these more fortunate groups are building up problems for the future because of their stagnation and the lack of young people receiving training. They are also handicapped by an arbitrary and inefficient administrative structure and erratic finance. This is not new, of course, but it is an increased handicap when conditions are precarious for other reasons.

Three non-university research laboratories have had mixed fortunes. CIMM is the Centre for Research in Mining and Metallurgy. It is financed by the national Copper Corporation, and since copper mining plays such a dominant role in the Chilean economy, CIMM enjoys a privileged position. In the laboratories the equipment is in use and a large research team is not only providing a service to the mining industry, it is also pursuing a number of exciting original lines of research. I gained the impression that recent events have hardly affected them. One of the very few foreign research workers to enter Chile since the coup, John Burley, an Englishman, is helping to build up the microscopy section.

Two other institutions—INTEC (The Technological Institute) and CESMEC (The Centre for Testing and Quality Control)—have been less fortunate. They were set up by the United Nations Development Programme (UNDP) which provided the basic facilities and equipment and were subsequently financed by the Chilean Development Corporation (CORFO). In the three years since the coup there has been no direct interference in the running of the laboratories, perhaps because of the quasi-international status deriving from their UN association, but the financial support from CORFO has been cut.

In the case of CESMEC it has been withdrawn completely and they have been forced to become entirely self-supporting from the contract work undertaken for industry. This has necessitated substantial reductions of staffing levels and all projects other than the contract work itself have been abandoned. Moreover, they are functioning entirely on capital, in the sense that they are using the equipment provided by UNDP with little possibility of proper maintenance or purchase of spares and none at all of purchasing new equipment.

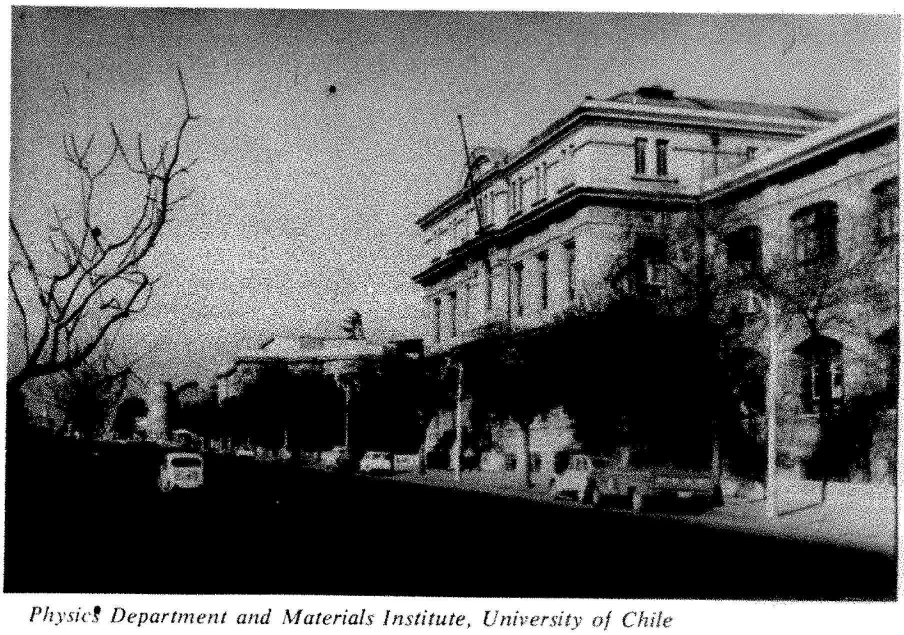
The future of both institutions is very precarious. It is possible for contract research organisations in the developed world—Battelle Labs in the USA, for example, or the Fulmer Research Institute in Britain to be successfully self-supporting—but to expect the same in a semi-industrialised country like Chile is a pipe-dream. Nonetheless, both organisations are doing good work and playing an important role in the industrial development of the country. If government financial support is not restored, both organisations may not survive more than a year or two—another reversal of progress in the country which will bring the return to a time when all expertise has to be bought outside the country; even for certain kinds of routine analysis, specimens will once again have to be sent abroad.

CIMM, CESMEC and INTEC were all founded within a decade, which might be a surprise since they now contribute so much to the mining industry which is the mainstay of the economy. However, it is only recently, a century and a half after political independence, that colonial attitudes have faded sufficiently that Chileans have begun to recognise that their own expertise can be as valuable as that purchased overseas.

Repression remains severe in Chile, but in many ways the country is back to normal and on the whole people are not nervous about discussing the situation in an open way. 'Normal' in this context means that there are no longer heavily armed police at every turn, nor military vehicles conspicuous in the streets; despite the continuation of the curfew there is once more a normal, if curtailed, night-life and the public does not in general, show signs of tension or strain. It would be possible for a tourist to get no hint from what he sees of how things are below the surface.

The recent release of prisoners held without trial under the "State of Siege" legislation, however, does not mark the end of repression. Those people who are taken prisoner now are taken in secret and the authorities do not admit to holding them; this is, of course, worse than before. Although I heard of a number of such cases, I am not aware of any scientist who is held prisoner now.

Unemployment in Chile has been extremely high since the coup. Even on official figures it now stands above 15% and is probably higher. But this figure hides enormous variations. An international official, who knew from first-hand experience in voluntary social work, said that in some working class areas unemployment runs at 90%. On



Physics Department and Materials Institute, University of Chile the other hand there seems to be very little unemployment among the professional classes. The very extensive sackings and cut-backs in all government departments as well as in private industry have reduced employment, but amongst professionals there seems to have been enough mobility and opportunity for them to move overseas. The ex-Dean of the Engineering School was reported as saying that of 11,000 Chilean engineers, 4,000 are now in Venezuela.

The Chilean Physical Society (SOCHIFI), under its president Claudio Gonzalez, continues to function and hold its scientific meetings in the usual way, although with considerable difficulty because of the loss of members and reduced financial support. One of its present preoccupations is that, since all elections are prohibited in Chile, it is unable (like many other organisations) to replace those committee members who leave the country or retire. It may shortly find itself with no committee at all. □

USA

Overheads: a growing problem

Colin Norman reports from Washington on a growing dispute involving overhead costs associated with government-funded academic research

THE federal government in the United States will spend about $3,000 million this year to support research and development in colleges and universities. According to one widely accepted estimate, however, between $600 and $700 million of those funds will be taken up by overhead costs such as heating and lighting, university libraries, departmental administration and so on.

The size of those costs has long been a source of irritation between researchers and university officials, and between the universities and the federal government, but there are signs that the irritation may develop into a serious dispute when the budgets of some research agencies are considered by Congress later this year. Moreover, the universities have been expressing considerable concern about a review of overhead costs which has been under way in the Executive branch for the past 18 months. Important principles underlying the support of research in the United States are involved, and university officials are now preparing for battle.

It is easy to see why concern about overhead costs is growing. Overheads—which are usually referred to as indirect costs—have been rising faster than the direct costs of doing research in the past few years, which means that indirect costs have been taking up a steadily increasing share of the federal support for academic research. Since, until very recently, total federal funds for basic research have been declining in purchasing power, university scientists are alarmed that the universities are taking an increasingly large bite out of already scarce resources.

And there seems to be a feeling among conservatives on Capitol Hill that the universities may be using federal research grants as a way to obtain revenue to support a variety of questionable activities. A staff aide to one right-wing Congressman argued in an interview last week, for example, that "the taxpayer is getting ripped off because the universities are turning basic research into a porkbarrel" for higher education. Indirect costs, he opined, are "a giant subsidy to the universities".

Such sentiments naturally touch a raw nerve among university administrators who are already grappling with steeply rising costs and diminishing federal support. They generally argue, however, that much of the criticism is based on a misunderstanding of the nature of indirect costs and the manner in which they are calculated. Though a number of extremely complex accounting procedure are involved, the basic concept is relatively simple. Procedures differ from one institution to another, but it generally works as follows.

When a researcher applies for a grant for a particular project, he calculates the direct costs of salaries, equipment, technicians' time, computer use and so on. The university then adds a fixed percentage for overheads, and the application is submitted to the federal government. If the grant is awarded, the university keeps the overheads and passes the funds for direct costs to the researcher.

The indirect costs are supposed to cover items and services which are shared by a number of research projects and which cannot be charged to any individual grant. Each university calculates its own indirect cost rate each year, but it is allowed to include only certain items specified by the federal government in a document known as FMC 73–8. The rate charged by the university is subject to audit to ensure that no unallowed costs are included. The rates differ from university to university, with the private universities generally charging the highest overheads and the large state universities, which receive some state subsidies and where economies of scale apply, charging lower rates. At Stanford, for example, the rate is 58%, which means that for every $100 required for the direct costs of a research project, the university adds $58 to the grant application to cover overheads.

A good deal of confusion has arisen because different universities express their indirect cost rates in different ways, with some expressing it as a percentage of researchers' salaries and others as a percentage of total direct costs, but there is one inescapable fact: however they are expressed, indirect cost rates are increasing sharply. According to a Congressional staff investigation published last year, for example, the average overhead cost rate has increased from about 30% in 1970 to about 35% in 1975. At Stanford, the rate has gone from 47% to 58% in the past six years.

The universities can cite good reasons for the increases. Charles V. Kidd, executive secretary of the Association of American Universities, notes, for example, that a number of recent federal regulations, such as equal pay requirements, privacy legislation, occupational safety and health regulations and so on, have placed considerable cost burdens on the universities, and many items, such as fuel costs, have been rising particularly steeply. According to William F. Massey, Vice-Provost of Stanford, for example, the university's fuel bill alone has climbed from $800,000 to $5.5 million in four years. Moreover, Kidd argues that because of the general financial squeeze on the universities in the past few years, institutions have been more diligent in claiming their legitimate costs from the government, and that has tended to push the cost rates up.

Nevertheless, in response to concerns over rising indirect costs, the Department of Health, Education and Welfare (HEW), which is the largest federal sponsor of academic research, has been reviewing the ground rules governing indirect cost rates. In July 1975, HEW proposed a number of revisions to FMC 73–8 which would have placed severe restrictions on the types of services which the universities could claim as indirect costs. Under the HEW proposal, for example, the universities would no longer have been able to include the costs of libraries in their indirect cost calculations, and some administrative expenses would also have been excluded.

The universities complained bitterly, and last month HEW revised the proposals to make them a little more palatable. The proposed revisions are now under consideration in the Office of Management and Budget, and it will be several months before any formal changes, if any, are made to FMC 73–8. If any revisions are made, they will inevitably restrict the amounts which can be claimed by the universities.

There are indications, however, that some stiff criticisms of indirect research costs may break out on Capitol Hill this year. Some of the Congressmen and Senators who in the past few years have poured scorn on research projects with trivial-sounding titles and who have criticised the National Science Foundation (NSF) for its grant review procedures, are beginning to take a critical look at the increasing indirect cost rates. Thus, for example, Robert Michel, a Republican from Illinois who was instrumental last year in blocking funds for a behavioural science project which he found distasteful, questioned the rapid escalation of indirect costs in NSF grants when the agency's budget was before Congress last year. He indicated that he would take a closer look at the matter this year. And George Archibald, a key staff assistant to former Representative John Conlan, NSF's chief critic in recent years, is now administrative assistant for Conlan's successor and has already begun to investigate the matter of research overheads for his new boss.

Some of the criticisms are likely to surface when a subcommittee of the House Committee on Science and Technology holds a public hearing on indirect costs on February 22. And the House Appropriations Committee is also expected to probe the matter when the budget for the National Institutes of Health is under consideration.

Few observers here are willing to predict the outcome of these various executive and legislative investigations, but one veteran science policy watcher, now working for the White House, notes that skirmishes over indirect costs have erupted at various times since the federal government became a major sponsor of academic research in the second World War and he speculated that this skirmish will follow the familiar pattern: there will be considerable argument, the federal ground rules will be tightened and the dispute will die away until the next skirmish arises.

This time, however, there is a potent combination of irritants arising from the steep increase in overhead rates, the serious financial situation of many universities, and a strong desire among fiscal conservatives in Congress to seek ways to cut the federal budget. The dispute goes to the heart of the system by which the federal government supports university research, and it is thus of considerable importance to the overall health of American science. □

Taking politics out of health

Keeping an earlier pledge to "de-politicise" the National Institutes of Health (NIH), Joseph A. Califano, the new Secretary of Health, Education and Welfare (HEW), last week paid a visit to the NIH campus to announce that the Carter Administration has decided to retain Dr Donald S. Fredrickson as NIH Director. The announcement, delivered to a packed audience of research workers, was included in a gentle pep talk in which Califano again promised to insulate NIH from partisan politics, and gave assurances that he would personally seek more resources for biomedical research.

The announcement, and the fact that Califano went to NIH to deliver it, should help to soothe complaints from biomedical researchers that NIH has been subjected to unwelcome political pressure in recent years. During the Nixon Administration, for example, candidates for NIH advisory committees were screened for their political affiliations, and two NIH directors have recently been fired, reportedly for political reasons. The first, Dr Robert Q. Marston, was dismissed by Mr Nixon in January 1973 for opposing budget cuts and the elimination of some cherished training programmes, and his successor, Dr Robert S. Stone, was fired by Mr Ford in January 1957 for alleged administrative incompetence.

Dr Fredrickson, a well respected scientist and administrator, made known his desire to stay on as NIH Director, but there was widespread speculation over whether the Carter Administration would retain him or replace him with a political appointee. In announcing the decision to keep Fredrickson as Director of NIH, Califano said that the Administration had looked "only for excellence" and he had not asked any candidate for a post in HEW about his or her political views. Frederickson, he said, had been selected because he is "the best person to do the job that has to be done".

Although Califano's remarks went down well with his audience, he himself acknowledged that the problems which have been afflicting NIH in recent years cannot be cured simply by ending the political screening of candidates for NIH posts. NIH has been suffering from a combination of budgetary stringencies and rapidly shifting priorities as funds have been channelled into cancer research and, to a lesser extent, heart research at the expense of some other programmes. To a large extent, those shifts in priorities have resulted from legislation which has given the National Cancer Institute a privileged political status in NIH. And there has also been a trend which has resulted in a growing proportion of NIH funds being disbursed as contracts rather than grants—a trend which has increased the central management of biomedical research, but which has met with stiff resistance from academic scientists.

In response to some of the concerns which have been expressed in the past few years about the growing politicisation of NIH and the disparities in funding, Congress established a Presidential commission under the chairmanship of a former medical school dean, Franklin Murphy. The Murphy panel last year issued a number of recommendations designed to reduce the privileged status of the cancer institute and to ease the strains within NIH. The Ford Administration made no move to implement the proposals, however, and the question now is whether or not Califano will act on them.

As for funds for NIH, although they have been increasing in the past few years, they haven't kept pace with inflation. According to an analysis recently completed by NIH's budget office, for example, the proportion of research grants approved by peer-review committees which have actually been funded has declined from 58% to 35% over the past three years, and it will drop to 32% next year if Mr Ford's final budget proposals are implemented. Califano said, however, that "I believe the work you do here, and that basic research generally in health, is critical for our society and needs additional support and resources, and I'll do my best to try and get them for you".

That went down particularly well with his listeners.

Colin Norman

SEVESO

Seven months on

Alastair Hay updates developments since the Seveso disaster in northern Italy last year

SEVEN months after the explosion in the trichlorophenol reactor at Seveso which resulted in the release of tetrachlorodibenzo-*p*-dioxin (dioxin), more details of its consequences are becoming apparent. The large number of organisations involved in assessing damage and formulating policy for decontamination of the area has prevented a crash programme. There has, however, been considerable agreement as to a general plan of action—a 'clean-up' operation to try to remedy damage, the full extent of which is still unknown.

According to Mr Alex Rice of Cremer and Warner—the British firm of consulting chemical engineers acting as 'technical auditors' of the decontamination programme—the work of removing dioxin

> "is proceeding, and there will be a high degree of reclamation of property and land in a reasonable period of time. The nature of the discharge of the reactor contents resulted in a differential degree of dioxin contamination in different areas. It has been necessary, therefore, to arrive at a graded response to solve the problem of decontamination.
>
> At the moment, in the most severely contaminated area designated as 'Zone A', hard surfaces are being cleaned and it is hoped that some 80% of the residents evacuated from the area will be able to return to their homes in a few months. Meanwhile, in 'Zone B', less severely affected by dioxin and where inhabitants have been able to remain in their homes, vegetation in certain selected areas is being cut down and incinerated".

From the evidence available at Seveso, Cremer & Warner estimate that 2.5—3 kg of dioxin was released in the reactor discharge. On this basis and through information obtained from a model simulating the explosive reaction at the ICMESA chemical plant, they suggest that only a few hundred grams of dioxin was actually deposited on vegetation and other surfaces. They maintain that the majority of dioxin was too finely dispersed and in a particulate form too small to permit precipitation to occur, with the result that thermal air currents carried the material high into the atmosphere. Conditions on the day of the explosion were ideal for the photochemical decomposition of dioxin at these altitudes, but there is no evidence to substantiate that such a degradative process actually occurred.

Earlier reports suggested that the dioxin was percolating through the soil at Seveso more quickly than recorded on previous occasions in different localities. More recent investigations, however, confirm that 98% of the dioxin is strongly adsorbed on the top 4cm of soil. Some of the methods of soil sampling in the earlier stages of the decontamination programme were not rigorous enough to exclude contamination of lower layers by material on the soil surface. The later investigations confirm previous reports in the literature that dioxin is relatively immobile in soil.

The question of the teratogenic properties of dioxin is still causing considerable anxiety to women in Seveso. The Lombardy regional government ruled last August that pregnant women from the contaminated zones around Seveso could have legal abortions, but local doctors have in many instances consistently refused to terminate pregnancies, and only a small proportion of pregnant women from Seveso have had abortions in Italy. The foetuses from these women are currently being examined for any signs of abnormalities and the results of the investigations should be available by March.

The reluctance of the Italian doctors to perform abortions has forced many Seveso women to seek a termination in other countries. It is doubtful whether any of the foetuses from these abortions will be examined for malformations. Doctors in Britain have voiced their concern over this loss of potentially valuable information on human teratology. They argue that there should be some agreed international code of practice on the matter to prevent it recurring and add that in Britain in particular there are arrangements to facilitate abortions and examination of the aborted foetuses for signs of abnormalities.

In the next few months women from Seveso who were in the first trimester of pregnancy in July last year will reach full term. The children born to them and to the mothers who conceived after the explosion are those most at risk from the teratogenic properties of dioxin. It is proving an agonising time for these mothers as no one can reassure them that their 'dioxin children', as they are known locally, will be unaffected. For them, as for all the people of Seveso, certain reassurances are impossible; it is just a matter of waiting.

- A report in the Turin paper *La Stampa* this week says that many children at a school in the Seveso area are suffering from skin rashes.

IN BRIEF

European energy policy moves

Several important aspects of European energy policy were discussed in talks in London last week between Mr Anthony Wedgwood Benn, the UK Energy Minister, and his West German and Dutch counterparts. The meeting was part of a series Mr Benn is having as chairman of the EEC Council of Energy Ministers.

The ministers agreed that an early decision was needed on the question of increasing the uranium enrichment capacity of Urenco, the consortium established by the three countries which is facing problems because of Dutch concern about Germany's controversial nuclear deal with Brazil. The ministers also tacitly confirmed that the European Community fusion project, JET, was far from dead by agreeing that an early decision on its siting was needed.

No official comment was available from the UK Department of Energy on an appeal last week from the EEC Energy and Research Commissioner, Guido Brunner, who urged Britain to drop its opposition to a Euratom loans plan and its insistence on a minimum safeguard price for oil. These issues could become politically connected with the JET issue.

Brunner also appealed to the USA and Canada to maintain nuclear fuel supplies to the Community, and detailed the Community's efforts in reactor safety and nuclear export controls. A Community team of experts is shortly to visit Washington to discuss these matters.

UK mercury report

"Reassuring" is the word coming from the UK Department of the Environment (DoE) on the environmental impact of mercury in Britain. A report released last week (*Environmental Mercury and Man*, HMSO, £1.40) is the department's tenth pollution paper, and the product of an interdepartmental working group on heavy metals.

The average person in the UK, it says, is "at no discernible risk" from exposure to mercury, but for environmental and health reasons a comprehensive knowledge of the concentration and distribution of mercury must be developed and the toxicology of mercury understood. The report says more research is needed on both the conversion of mercury to and from methylmercury compounds and the environmental pathways of mercury across the water-sediment interface in the aquatic environment; research on the mechanisms of its toxic action and on low level exposure to it over long periods is also necessary.

Help for computer industry

UK government plans to concentrate on electronics as part of its drive to boost exports were revealed last week. The proposal, part of the Labour government's overall 'industrial strategy', followed an announcement that the National Enterprise Board (NEB) is to become involved in the computer industry through a newly-created NEB subsidiary, INSAC Data Systems. The idea initially is to stem fragmentation in the software sector, and later to become involved in minicomputers and peripherals. The news coincides with the publication of details of a consultant's report on the European computer industry which forecasts a bleak outlook for microelectronics in the absence of a radical restructuring of the industry.

New genetics draft

The consultative document drawn up by the UK Health and Safety Commission (HSC) last August containing draft regulations for the control of genetic manipulation experiments in Britain is thought to be still under discussion with the principal scientific interests concerned.

A report appeared last week stating that the HSC's controversial all-embracing clause, requiring notification from any person carrying on "any activity intended to alter, or likely to alter" the genetic constitution of any microorganism, has now been rewritten. The new notification clause which, it was said, the HSC intended to put in its place, reads:

> "No person shall carry on any activity which, by using biochemical manipulation of extra-cellular nucleic acids, is intended or likely
> (a) to insert genetic information into organisms, and
> (b) to circumvent the natural barriers to such insertions, and
> (c) to propagate that information, unless notice has been given . . ."

This proposal, which went out before Christmas, was a new draft for comment, and does not necessarily represent the HSC's final proposed definition of genetic manipulation experiments.

Mediterranean discussions

Representatives from fifteen of the 18 nations surrounding the Mediterranean met last week in Split, Yugoslavia, to discuss proposals for combating pollution of the sea they all share. They meet again in Athens this week.

Agriculture 1977

THOMAS H. JUKES

THE production of food is bound to overshadow many other human activities increasingly in years to come. Scientific agriculture is currently beset with many problems and would-be interveners. A trend in recent years has been to take away the authority of agriculturists over the methods used in agricultural production. The excuse seems to be that those who till the soil cannot be trusted either to 'protect the environment' or to produce food that is sufficiently free from 'contamination' to satisfy the ideals of consumerists.

An inevitable result of these bureaucratic machinations is an increase in the cost of producing food. The advent of a new administration in Washington has given rise to gleeful anticipation of more power by those who oppose many of the technological practices used in agriculture. Such opposition will increase the cost of food production further.

The success of scientific agriculture has made groceries so cheap and plentiful in the USA that the food supply is taken for granted. This may be attributable to the fact that food is so easily obtained that it has lost its aura of being a treasured gift of beneficent Mother Nature. The urban population, now two generations removed from farm life, knows very little about food production. As a result, consumerists, defined as individuals who are quite certain of what is best for the interests of consumerists, hold sway increasingly over consumers, who are apparently somewhat bewildered by it all.

For example, the successful campaign to cast out Red Dye No. 4 from maraschino cherries was based upon the finding that the dye produced tumours in laboratory rodents, and a grateful populace should have thrown the deadly preserved fruit into the garbage. However, we learn that in the supermarkets there was a run on red maraschino cherries by hoarders who feared an impending ban.

Consumerists seem not to realise or acknowledge the basic facts of agriculture and nutrition. Some of these are that food contains substances that are toxic at high levels but are sufficiently harmless in the amounts actually present that they offer no finite hazard to health. Such substances include pesticide residues as well as other adventitious contaminants. Food can be produced without such residues, or it may in some instances be refined to remove them, as in the case of sugar.

But such finickiness, carried out to quieten the apprehensions of an opulent minority, do not fit the pattern of making an effort towards achieving abundance and low cost of food in the face of a rapidly-increasing requirement by a burgeoning global population. A few months ago, there was an uproar by consumerists over the FDA tolerances for 'filth' in foods. This was a great source of amusement to anyone who had worked on a farm, and who knew, as a fact of life, that grain and rats are constant companions. Indeed, some accident of design has made rat faeces the size and shape of wheat kernels, and hence the two items are virtually inseparable by the usual screening processes. Canned vegetables and tomatoes have always contained insect parts, more so in pre-pesticide days.

A misapprehension in some quarters is that food of plant origin is somehow 'purer', 'closer to Mother Earth', and 'more healthy' than food derived from animal products. Actually, toxicants, including oestrogens, goitrogens, alkaloids, and fungal carcinogens, occur naturally far more often in plant foods than in animals. Domestic animals, serving as sources of meat, milk and eggs, can serve as 'filters' to metabolise and remove such substances, or to reduce their levels in the human diet. Cereal grains, of course, will continue to be the prime source of calories for human beings throughout the world. The business of feeding people must go on apace, and, to this end, let us hope that the 'Washington consumerist crowd' will not be given the opportunity to pour any more gravel in the gears that they introduced in 1976.

Nuclear pros and cons

SIR,—As one of the large group of Nobel prize winners having a strong aversion to nuclear energy and its consequence but no "technological background in fields relevant to nuclear technology," I would like to express agreement with a portion of the article by Jan M. Döderlein[1] entitled "Nuclear power, public interest and the professional," but strong disagreement with much of the rest.

His point about uninformed sponsors of statements was also emphasised in 1973 by the late Eugene Rabinowitch, a person concerning whose judgment and expertise in the area of science and public policy no one could quibble: "If, at a certain point, their conclusions begin to be affected by extrascientific reasons, they must have sufficient intellectual honesty to state: 'Up to this point, I spoke as a scientist; from here on I will speak also as a politically, ethically or ideologically committed citizen . . .' " Still, anyone but the most naive petition signer must understand that sponsors of socio-scientific news releases are, and always will be, selected on the basis of the fact that the general public tends to be influenced by lists of the names of 'dignitaries' of one kind or another (perhaps I should add "so far").

One particular paragraph in Dr Döderlein's essay seemed to me to be especially noteworthy:

> Probably no technological decision in the history of mankind has been the subject of so many detailed studies, so much open discussion and such broad public participation. Amongst it all, some nuclear critics have given prominence to ethical aspects of the nuclear decision. This is justifiable to a certain extent since the application of nuclear power—indeed of any power—raises ethical questions. To carry this view to extremes in the way it is sometimes done, however, represents a vain attempt to set aside fundamental laws of nature and society.

One of the hitherto inevitable consequences of the "laws of nature and society" has been war. Given enough time, conviction and willing hands, and enough spears or rocks, the human species could certainly be doggedly annihilated. However, the existence of nuclear weapons, and the proliferating capacity to make more, makes ultimate mass slaughter not only possible but probable—I know of no technical fixes for human madness and misjudgment. Surely this statement requires no knowledge of the technology of nuclear power. The ethical and social consequences of the impending plutonium economy are at the very core of the problem[2,3]. We cannot rely, in a world of easy overkill, on "political decisions made in the face of uncertainties". The "uncertainties" associated with nuclear power, both of the electric and military variety, are unfortunately of much larger potential danger than those we have faced in our previous history.

Evolution and growth

SIR,—One can agree with Professor Tuzo Wilson (January 20, page 196) that, on the Earth, economic growth cannot continue for ever. But can we plan for stability? It is just not true to say that "undisturbed Nature is stable". Evolution has proceeded as a result of instability. Ecosystems approach stability when they are in a steady state, but even in the steady state phase they are not in fact stable, but oscillating between quantifiable limits. Sudden increases in the size of both populations and of the area they occupy are characteristics of species in an active state of evolution; these are phases of multiplication during which selection pressure is reduced. They alternate with phases of division, in which population size and area of colonisation shrink, and during which selection pressure is increased. As a result, the phyletic line splits, isolation occurs, and new species may arise. Perhaps humanity will be moving into such a phase in the immediate future—but not necessarily so. For evolution in Man is not only controlled by biological processes. Civilisations evolve as a result of psycho-social controls. Under such conditions natural selection no longer operates within a gene-pool, but within an "idea-pool" and it is competition between ideas that leads to evolutionary progress.

Wilson may well be right when he claims that it is the exploitation of energy that has resulted in the sudden increase in the size of the human population. Certainly we can argue that traditional energy supplies must become scarcer in the future. But psycho-social evolution does not necessarily proceed in phase with biological evolution. If our technological advance continues, it may well solve the energy problem. However, it must do more than that if there is to be any further growth of population. We must also solve the problem of living space and the problem of material resources.

On the Earth there is a limit to growth imposed by the fact that both living space and resources are finite. No such limits are imposed in outer space. The only possibility of continued growth would seem to depend on space colonisation. G. K. O'Neill's space colonies (*Physics Today*, September 1974) could in their first generation exploit solar energy and lunar and asteroidal materials. They could overcome all the constraints that prevent growth on Earth.

So maybe the future of Man will lead to a bifurcation. Some of us will go into space and multiply; the rest of us will stay on the Earth, and divide.

Journal abbreviations

SIR,—The abbreviation of periodical titles is a chore to authors and editors, and their secretaries. Abbreviations are also a source of confusion to readers, whom one hopes outnumber the authors. The saving in type-setting which is achieved by the use of abbreviations probably does not justify all this effort.

The British Standards Institution has published a word-abbreviation list (BS 4148: Part 2: 1975) but, like the *World List of Scientific Periodicals*, this does not always provide unique or unambiguous abbreviations. The French *Industrie minérale*, for example, shares the abbreviation *Ind min* with the British *Industrial minerals; J math phys* stands equally for *Journal of mathematical physics* or *Journal of mathematics and physics*.

I suggest that the practice of abbreviating titles should be discontinued, in favour of full and accurate citations.

Yours faithfully,

ADRIAN SMITH

news and views

Mars: questions and answers from Viking

from Geoffrey Eglinton and James R. Maxwell

THE Viking mission has been a remarkable success. So much so that NASA recently announced the start of an extended mission whereby the four spacecraft will continue to gather data on and around Mars for the next one and a half years to see out a complete Martian year of 687 Sols, each of 24.6 hours. But what of the all-important question: "Is there life on Mars?" NASA's official view of the results of the life detection experiments is that ". . . they have been puzzling. They neither prove nor disprove the existence of life on Mars". Indeed, the soil is surprisingly "active" but the question is whether this activity is chemical, biological, or possibly both. In fact, most of the researchers involved claim that none of the responses observed necessitates a biological explanation. Appropriately reactive species can be invoked in terms of a surface chemistry controlled by interaction with the atmosphere and with ultraviolet light from the Sun. Thus, understanding the properties of the Martian soils seems to be the province of physicists, chemists and geologists rather than biologists.

It is difficult not to wax lyrical about the Viking mission, with so many 'firsts' for planetary exploration. The mission has simultaneously supported four sophisticated interactive spacecraft at an interplanetary distance. The landing sites were chosen by teams only after study of radar surveys made from Earth and of detailed photography from orbit. In effect, the teams have used the orbiters as their eyes and have directed them to inspect likely sites.

The two spacecraft arrived at Mars last summer. Viking I went into orbit on June 20 and released its lander on July 20, while Viking II arrived on August 7 and sent in its lander on September 3. Pictures and data continued to flood into the Jet Propulsion Laboratory at Pasadena, California until late November when Mars passed out of effective radio contact behind the Sun. The main findings to date have been published in NASA SP-408 and in three issues of *Science* (August 27, October 1 and December 17, 1976). On December 16 the orbiters were signalled to resume photo coverage and the landers to start up their operations once again. The 18-month extended mission will provide surface and orbital photographic coverage, temperature and water vapour observations of the surface and atmosphere, seismic monitoring and additional analyses of soil and rock, including further life detection experiments. The landers may experience the onset of a planet-wide dust storm when Mars nears perihelion this spring. As part of the new phase of exploration, Viking orbiter II's orbit was changed on December 20 to give a closer approach of 800 km and a higher inclination orbit of 80°. As winter approaches in the northern hemisphere, the north polar cap should grow and the south polar cap recede, while the orbiters keep a detailed watch on changes in surface features, temperatures and water vapour concentrations. Some time this month, Viking I's orbiter will skim by the Martian moon, Phobos, and radio back pictures and thermal measurements taken from only 48 km (30 miles) distance. Rocks less than a metre across should be visible and an explanation found for the mysterious lineations apparent in the photographs transmitted last September. It is likely that the lineations—layers, flow lines, impact or volcanic crater chains . . . ? —hold the key to the origin of this small moon and its partner, Deimos.

The biological experiments are continuing on both landers with fresh soil being tested in each case. These experiments seem unlikely, however, to do little more than harden up the picture already obtained, that is, rapid release of oxygen after contact of the soil with water vapour, absorption and evolution of carbon dioxide, the oxidation of organic nutrients to carbon dioxide, and the synthesis of small amounts of organic matter from carbon monoxide/dioxide mixtures. These positive results contrast with the molecular analysis of the surface dust by pyrolysis-gas chromatography-mass spectrometry which show that it is virtually free of all pyrolysable carbon compounds. For example, no nitriles, which are pyrolytic products of amino acids were observed at detection limits of ~ 1 part in 10^9. One possibility that has been suggested is that there is a minute population of microorganisms not detected by the pyrolysis technique and which is unresponsive to the biological tests. It is more likely that the 'biology' can be treated in terms of photochemical weathering and surface chemistry.

The basic need now is to know more about the geochemical circumstances at the surface of Mars. These are clearly very different from those on Earth and a valid interpretation of results from life detection experiments needs an understanding of this chemical environment and of the processes involved in the synthesis and destruction of organic material at the Martian surface. The considerable quantities of carbon which must have been present in the early Martian surface and atmosphere and have arrived in meteorites remain to be accounted for. Certainly some is in the atmosphere and, possibly, mixed in the polar caps as CO_2 and a little CO; some carbonates may also be present in the surface materials. Presumably the processes of surface weathering, which occur in an environment dominated by ultraviolet, low temperatures and the absence of liquid water, are such that any organic compounds formed are rapidly oxidised. These processes would also erase any organic geochemical evidence of past life.

The recent paper by Oyama in *Nature* (**265**, 110; 1977) highlights the problems facing chemists and biologists. To explain the evolution of oxygen and the evolution and absorption of carbon dioxide in the Gas Exchange Experiment, Oyama proposes that nascent oxygen from ultraviolet irradiation of CO_2 diffuses to react with alkali and alkaline earth metal oxides, there, by generating peroxides and superoxides, which would be capable of evolving oxygen in the presence of water vapour. Alkaline sites would then be produced which could absorb carbon dioxide. Evolution of carbon dioxide is explained in terms of the presence of "coats" of sulphuric acid on mineral surfaces. However this scheme seems tortuous and premature when so little is known about the composition of the surface. Other hypotheses are appearing but this open-ended situation necessitates patient and detailed dovetailing of the Viking data with results drawn from laboratory simulation studies.

All of these considerations emphasise the tantalising nature of the Viking mission. The experiments on board are sophisticated in that they have revealed the complexity of the Martian surface–atmosphere relationship but they do not allow the more detailed studies which are now necessary to unravel the surface chemistry involved. Here a returned sample mission, as with the Apollo project, contrasts with the Viking type of remote analysis mission. In the case of the returned sample, new data lead to fresh hypotheses and models which can then be tested interactively, thus generating fresh data and fresh questions. With the Viking mission, the amount of testing that can be done to check on hypotheses or models is limited, though remarkable.

Fitting Flixborough into a pattern

from Henry Chilver

THE explosion of a chemical processing plant at Flixborough on June 1, 1974 was one of the most serious industrial disasters of recent times in this country. More than two years after the disaster, it is very interesting to read D. E. Newland's fascinating account (*Proc. R. Soc. Lond.* **A351,** 525; 1976) of the mechanics of the temporary pipework, the failure of which was the cause of the disaster. Catastrophes such as Flixborough raise important questions: are engineering skills adequate to build safe, complex engineering plant? What controls are introduced to ensure safe designs? Questions of these sorts raise complex issues, involving the safety of people and the supervision of engineering design and construction. All engineering disasters must be explored as thoroughly as possible and—it is hoped—understood. Each disaster has its own detailed explanation, in the case of Flixborough an explanation in terms of the structural mechanics of the temporary pipework. But how does the Flixborough disaster, seen as the failure of a vital structural component, fit into the general pattern of failures in engineering structures?

Before we attempt to answer this question it is important to try to identify some general pattern of engineering failures as a whole. A general pattern is certainly discernible in the field of construction engineering, where failures of large structures in particular are very spectacular. The first point to emphasise is that major disasters are of course rare events. This is a tribute to the quality of design and construction skills, which are generally of a high order; nevertheless, it is still important to learn, through the analysis of disaster, how we can further improve design, construction and operation.

Structural failures are of three main types, and may involve mixes of these:

(1) Unknown structural or material deficiencies; for example, the material used may be sub-standard or a vital component may be accidentally damaged.

(2) Unknown forces in the environment of the structure; for example, a long-span bridge may suffer exceptionally high winds, or a building may suffer unusually severe earthquakes.

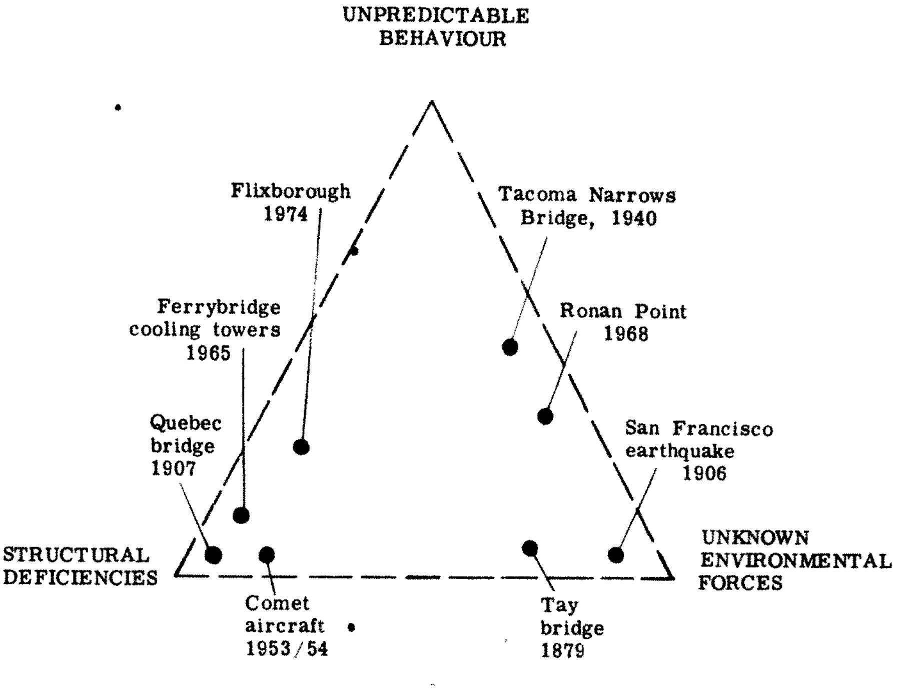
(3) Unknown forms of behaviour of the structure within its environment; for example, a new form of oscillation or buckling may occur for a new structural form.

Within the framework of these three main types of failure (and these concepts can be extended to other areas of engineering) we can construct a 'triangle' of failures, the corners of the triangle being the three main forms. Within this triangle we can locate failures of different sorts; where a failure involves 'mixes' of different types we can indicate the position appropriately within the triangle.

One of the early disasters of structural engineering was the collapse of the Tay railway bridge in 1879 (Sir Alfred Pugsley, *The safety of structures*, Arnold, 1966; this very interesting book gives more details of some of the failures described briefly in this note). In very high winds, this multi-span bridge across the Tay collapsed while a mail train was crossing; 75 people lost their lives. Although there may have been some design faults, the predominant cause was a lack of knowledge of the intensity of the actual wind forces on such a structure. This early disaster lies, therefore, towards the corner of "unknown environmental forces".

The San Francisco earthquake of 1906 is famous for many reasons, not least for the advances made, after this experience, in the design of structures against earthquake forces. But structural failures during the earthquake were predominantly due again to a lack of understanding of earthquake forces.

Taking again an example from the field of bridges, a famous accident was the Quebec bridge disaster of 1907, when a large cantilever bridge collapsed while under construction into the St Lawrence River with the loss of 75 workmen. This was caused by defec-



tive design of a member of the frame of the bridge. Good design would have shown this to be defective, and hence a basic structural deficiency was built into the structure. This disaster has a position towards the corner of "structural deficiencies".

In 1940, the suspension bridge, newly-built to span the Tacoma Narrows, near Seattle, in the US State of Washington, collapsed after violent oscillations of its deck and towers, luckily with no loss of life. Surprisingly, the failure occurred in what appeared to be only a moderate wind of about 40 mph. The cause of collapse was an inadequate understanding of the interaction of the structure with its environment, leading to large oscillations of the bridge. The resulting behaviour was unpredictable at the time, but became better understood subsequently, after research studies.

In 1953 and 1954, three accidents occurred to Comet civil airliners—all involving serious loss of life. These were caused by structural failure of the pressure cabin brought about by fatigue. The root of the trouble appeared to be cracking near one or other of the windows of the pressurised cabin. In this sense, the structure again had an in-built structural deficiency.

In 1965, a group of cooling towers at the electricity generating station at Ferrybridge in Yorkshire was blown down in a moderate gale, although they had apparently been designed to withstand high wind pressures. This failure is probably in the class of structural deficiency because the thin shells used had severe vertical cracking which probably lowered their stability.

In 1968, some multi-storey flats collapsed at Ronan Point in London after what appeared to be an explosion on one floor. The cause of collapse was traced to the explosion of leaking gas on one storey; the explosion caused structural failure on that floor which in turn led to further structural failures on other floors, rather like the collapse of a row of dominos. Although the gas explosion was unpredictable, there is a case for designing structures in such a way that collapse of one structural component does not lead to general catastrophic failure. This example lies predominantly near the corner of "unknown environmental forces".

How does Flixborough fit into this general pattern? The cause of collapse, as Newland now explains with fascinating detail and exactness, was due to the squirming and jack-knifing of some temporary pipework. The cause of failure was an inbuilt structural deficiency, not implied in the original design, in the form of the temporary pipework.

Can we make any general deductions about structural failures in the light of this very simple analysis? We begin by looking more generally at the three corners of the 'triangle' of failure. In any engineering design and construction, not all the environmental forces likely to be encountered are known, although designers hope to take account of all the relevant forces. These forces can only be found from experience and research. We must always accept some risk (although we hope this is very small) of encountering a hitherto unknown environmental force of serious magnitude. As design and construction progress, we may have to accept some unfortunate disasters towards the corner of 'unknown environmental forces' in the triangle. At the corner of 'structural deficiences' it should be possible to eliminate most disasters by thorough supervision of design and construction, particularly if conventional materials are being used. Where, as in the top corner of the triangle, an 'unpredictable behaviour' emerges, it is difficult to blame engineers for failures. In this area engineers have the responsibility, clearly, of ensuring that research is encouraged in directions in which more knowledge of behaviour is needed, but the risk of a hitherto unknown form of failure emerging should not be discounted.

The risk of structural failure is, in reality, very low. Failures frequently make headline news, and correctly so if lives are lost or put at risk. As engineering design and construction progress, so our experience of structures, of their environments and of their behaviour also evolves. We can only progress by combining experience with research into relevant problems. This is a field in which the scientific study of the natural phenomena involved has a vital role. ☐

Early assemblage of Carboniferous amphibians

from Andrew Milner

For those who are interested in the evolution of terrestriality and the early radiation of terrestrial vertebrates in the Palaeozoic, the fossil record remains frustrating. Although amphibians were present and diversifying in the Upper Devonian, it is not until well into the Upper Carboniferous that amphibians and reptiles are comprehensively represented by rich and diverse assemblages.

The five stages of the European Carboniferous are the Tournaisian, Viséan, Namurian, Westphalian and Stephanian and the majority of Carboniferous tetrapods known to us are of Westphalian age. The major Westphalian assemblages are the lake assemblage from Newsham, Northumberland, the pond assemblages from Linton in Ohio, Nýřany in Czechoslovakia and Jarrow in Eire, and the terrestrial assemblages from Joggins and Florence in Nova Scotia where the terrestrial tetrapods are found as small individuals trapped inside the hollow stumps of giant lycopods. The amphibians and reptiles from these and other contemporary localities are currently referred to about 30 families, most of which have no ancestors or close sister-groups among the known earlier tetrapods. Our concept of the coal-swamp fauna is based on the Westphalian tetrapod fauna which is of great inherent interest but is too late to be directly relevant to the fish–amphibian transition or the earliest adaptive radiation of tetrapods.

The tetrapod faunas of the Tournaisian, Viséan and Namurian are represented by a small number of specimens or restricted lake assemblages from West Virginia, Nova Scotia, Scotland and Germany. These are being restudied by several workers, in particular Panchen, Carroll, Andrews and Beaumont. Not merely are the early Carboniferous amphibians few in number but they also tell us little about the origin of later groups. Panchen (*Palaeontology* **16,** 179; 1973) has shown that *Crassigyrinus* from the Scottish Viséan, is an ichthyostegid-like relict. More recently he has studied *Pholidogaster* and *Otocratia* and found them to be colosteids with a referred specimen being an anthracosaur skull (Panchen *Phil. Trans. R. Soc.* **B269,** 581; 1975). The Viséan amphibians from West Virginia described by Romer and Hotton have proved to be all colosteids or anthracosaurs. The other major groups of this age, the loxommatids and adelogyrinids are currently being redescribed by Beaumont and Andrews respectively. But though the loxommatids, colosteids and anthracosaurs may each have a few known descendants, mostly confamilial with them, neither they nor such contemporaries as they have, shed light on the origin of most later tetrapods.

As a result of the work described above, the situation has been developing where all the early Carboniferous material which could be studied, was being studied, without any significant new material being discovered. The Namurian gephyrostegid from the Ruhr described by Boy and Bandel (*Paläontographica* **A145,** 39; 1973) was a significant find in a new area but, being a terrestrial erratic in a marine horizon, it is unlikely to be the precursor of further discoveries.

This then, is the significance of the discovery of a Namurian assemblage of fish and amphibians from Cowdenbeath announced by Andrews *et al.* in this issue of *Nature* (page 529). It has already produced as many specimens of amphibian as were previously known from the early Carboniferous of Europe and most of the bone-bed has yet to be prepared. It is still difficult to assess the diversity of the fauna for though some skeletal material is articulated, most is fragmentary and will take time to identify. So far, it appears to be a more extensive version of the Viséan assemblage from the Gilmerton Ironstone. If it is like other large assemblages from the Carboniferous, a carefull search may reveal the small and rare components of the fauna such as the occasional terrestrial reptiles now known as accidental occurrences from Linton and Nýřany (Carroll & Baird *Bull. Mus. Comp. Zool. Harv.* **143,** 5; 1972; Reisz *J. Paleont.* **49,** 522; 1975). The significance of the find is threefold. First, it offers the possibility of finding earlier, more primitive representatives of the many families of tetrapods which currently appear so suddenly in the Westphalian. Second, it will permit new morphological studies of these early tetrapods. The preservation is good and the specimens are not severely crushed. Specimens such as the nearly complete anthracosaur will yield much information. Third, the assemblage may provide some palaeoecological information about these animals. Most Carboniferous amphibian material was collected in the last century from restricted exposures and is now only available in museum collections, having been through the filter of morphologically orientated collectors. One cannot be certain what was collected and what was missed. This new find was systematically collected by gridded squares and offers the possibility of a quantitative ecological study of a Carboniferous lake fauna.

The Cowdenbeath fauna may only take us back one step from the Westphalian, but it is a long awaited step. However the most relevant amphibians to the water–land transition remain the Upper Devonian ichthyostegids from East Greenland. Although they were collected nearly fifty years ago, little progress can be reported in our understanding of them as much of their anatomy remains undescribed and no first-hand study of them has been published for twenty-five years. ☐

Bleak outlook for superheavy nuclei

from P. E. Hodgson

THE announcement by Gentry *et al.* (*Phys. Rev. Lett.* **37,** 11; 1976) of the detection in the mineral monazite of the superheavy nucleus with charge 126, and possibly of other superheavy nuclei as well, has stimulated a series of experiments to confirm this startling discovery, and also many theoretical calculations of the stability of such nuclei. Several of these have been published very recently: the experiments provide no evidence for superheavy nuclei, and the calculations make it very unlikely that they are stable enough to be observed.

The first experiment, by Bosch *et al.* in Germany (*Phys. Rev. Lett.* **37,** 1515; 1976) is very similar to that of Gentry *et al.* They irradiated small grains of monazite with 2 MeV protons, and examined the spectrum of the emitted X rays. They found no sign of a peak in the region where one would be expected if the superheavy nuclei had been present in the same proportion as claimed for the sample studied by Gentry *et al.* They go on to suggest that the peak observed by Gentry *et al.* is really due to the gamma decay of the first excited state of ^{140}Pr, produced in their sample by protons on traces of ^{140}Ce. This contaminant peak should have been removed along with the background due to other contaminants, but Bosch *et al.* claim that the background subtraction was not done correctly.

The second experiment used quite a different technique. Stephan and his colleagues from France and Poland (*Phys. Rev. Lett.* **37,** 1534; 1976) have made a mass spectrographic analysis of about one gram of a sample of monazite from the same place as the original sample. After the mass separation, the ions were collected on a quartz plate, and this was subsequently irradiated for one week in a nuclear reactor. Superheavy nuclei are expected to undergo fission when hit by a neutron, and this is very likely in the high neutron intensities to be found there. The fission fragments would make tracks in the quartz plate which would be visible under the microscope after etching. Careful examination of the quartz plate showed no fission tracks in the region where they would be expected from superheavy nuclei.

The original measurements of Gentry *et al.* were made on small inclusions of monazite in mica at the centre of the so called 'giant haloes'. The quantity of superheavy nuclei that they claimed to have found corresponds to about 10^{-4} g of monazite. The mass spectrographic analysis sets an upper limit to the amount of superheavy nuclei in monazite of 10^{-12} g per g. Thus to maintain the original result one would have to say that the concentration of superheavy nuclei in the giant halo inclusions is about 10^8 that of normal monazite, which seems very unlikely.

C. Holbrow of the California Institute of Technology has now studied haloes in detail and finds that some of the naturally-occurring haloes could be produced by ^{244}Pu (this issue of *Nature*, page 504). Although there is very little of this isotope remaining now because of its relatively short half life of 82.8 Myr, there could have been enough of it present when the mineral was originally formed for it to make haloes before it decayed. Giant haloes could also be produced by the alpha particles that are sometimes emitted during the spontaneous fission of ^{244}Pu. The X rays observed after proton bombardment of the inclusions could also come from Te fission fragments and not from superheavy nuclei. This work therefore provides an alternative explanation of the giant haloes that does not involve superheavy nuclei. Confirmation of this possibility requires mass spectrographic identification of the very small amounts of ^{244}Pu that still remain, or of its decay product ^{236}U, or of the fission fragments of ^{244}Pu.

The theoretical calculations of the stability of the superheavy nuclei of $Z=126$ are mainly concerned with the half lives for fission and for alpha and beta decay. For the nuclei to be detectable on naturally-occurring minerals the shortest of these half lives must be comparable to the estimated age of the Solar System, or about 10^8 years. If any of the half lives were shorter, the nuclei would have all decayed long ago.

Some very thorough calculations have recently been published by Möller and Nix (*Phys. Rev. Lett.* **37,** 1461; 1976) following earlier calculations by Wong (*Phys. Rev. Lett.* **37,** 644; 1976). The first calculated the single-particle energies in a spherical one-body potential and found that there is a well-marked neutron magic number at 228, but no proton magic number at 126. There is proton shell closure at 124, so on this evidence alone the nucleus with $N=228$, $Z=124$ is the best candidate.

The more detailed calculations of stability were made using the droplet model of Myers and Swiatecki (*Ann. Phys.* **84,** 186; 1974) with microscopic corrections evaluated by the Strutinsky method (Brack *et al. Rev. mod. Phys.*

44, 320; 1972). Essentially this method gives a soundly-based theoretical expression for the nuclear binding energies, and the fine adjustment of its parameters is made so that it gives the correct results for the heaviest known nuclei.

Brack *et al.* find that the nucleus with $Z=126$ and $N=228$ is stable against beta decay but has a half life against spontaneous fission of only 39 ms and an alpha-decay half life of only 18 yr. These half lives are extremely sensitive to the calculated binding energies, so that there are uncertainties in these figures of several powers of ten, but even allowing for this it seems that the nucleus is far too unstable to have survived. Major changes in the theories used in these calculations would be required to give sufficiently long half lives.

It thus seems at present that the evidence for superheavy nuclei has been seriously weakened. □

Viroids are covalently closed circular RNA

from Roger Hull

VIROIDS are one of the enigmas of plant virology. They are pathogens of higher plants and appear to exist only as self-replicating uncoated ribonucleic acid molecules with many unusual properties.

Much of the knowledge of these properties is based on studies on two viroids, the causal agents of potato spindle tuber (PSTV) and citrus exocortis (CEV) diseases. Using gel electrophoresis and electron microscopy, T. O. Diener and coworkers reported the molecular weight of PSTV to be about 80,000–90,000 (*Virology* **53**, 70, 359; 1973); J. S. Semancik and coworkers determined a molecular weight of 125,000 for CEV (*Virology* **53**, 448; 1973). These molecular weights are much smaller than those of the RNAs of plant viruses. Thermal melting curves, resistance to nucleases and gel electrophoretic behaviour show that viroids are compact highly structured molecules with a considerable amount of base pairing which makes it difficult to obtain reliable molecular weight estimates using gel electrophoresis. Several models for the molecular structure have been proposed, the most recent suggesting that they are single stranded RNA, base-paired to form hairpin-like shapes (*Virology* **55**, 70; 1973; *Virology* **63**, 160; 1975).

In a recent paper (*Proc. natn. Acad. Sci. U.S.A.* **73**, 3852; 1976) H. L. Sänger *et al.* describe the results of experiments which lead to a different interpretation of the structure of viroids. They confirmed that viroids were single-stranded molecules by showing that native undenatured nucleic acids had similar molecular weights to denatured molecules. Using sedimentation equilibrium analysis they obtained molecular weight values of 127,000 for PSTV, 119,000 for CEV (from two different hosts) and 110,000 for the viroid causing cucumber pale fruit disease. This confirms the previous estimates of the small size of viroid RNA and shows that they have genetic information to code for a protein no larger than 10,000 daltons. In fact protein synthesis experiments (*Virology* **61**, 486; 1974) indicate that viroid RNA is not translated *in vitro*.

Sänger *et al.* went on to determine the structure of viroids. Thermal denaturation showed that each of the viroids they studied had considerable base pairing and that there was one relatively long double helical region and not short hairpin sections as in tRNA. Electron microscopy of native nucleic acid revealed that all three viroids have rod-shaped or dumb-bell shaped molecules, as had been previously reported for PSTV (*Virology* **55**, 70; 1973). When viroids which had been treated under strongly denaturing conditions were examined in the electron microscope a variety of structures ranging from rod-like molecules (renatured during the preparation process) to single-stranded circles were found. Sänger and his colleagues then attempted to analyse the nucleotides at the 5′-end and 3′-ends of the viroid molecules. Using standard techniques (phosphorylation of the 5′-end with 5′-polynucleotide kinase and ^{3}H-labelling of oxidised 3′-end and capped 5′-end by reduction with ^{3}H-borohydride) they were unable to detect either 3′- or 5′-nucleotides. From these and other observations (resistance of viroids to snake venom phosphodiesterase) they concluded that viroids are single-stranded, covalently closed circular RNA molecules.

So far in nature, circular molecules have been found for double-stranded and single-stranded DNA and have been suggested for some double-stranded RNA replicative intermediates (for example, *Virology* **70**, 360; 1976). Viroids therefore appear to be the first examples of a new class of molecule. Sänger *et al.* point out that they differ from other naturally occurring covalently closed circular molecules in that they are much smaller and that the base pairing is not between complementary strands but within one strand. This structure would also explain why viroid RNA is not translated using *in vitro* systems.

The observations of Sänger *et al* should help in the current investigations in several laboratories into the origin, mechanisms of replication and pathogenicity of viroids. One major question is whether this new class of molecule occurs normally in uninfected plants; if so, how do they become pathogenic? It is already thought that DNA might be involved at some stage in viroid replication (*Virology* **64**, 106; 1975; *Nature* **256**, 753; 1975); in fact there are sequence homologies between PSTV RNA and DNA from both infected and healthy plants (*Proc. natn. Acad. Sci. U.S.A.* **73**, 2453; 1975). The search is now on to find circular single-stranded RNA and DNA molecules of viroid size in both infected and healthy plants. I feel that the search should not be restricted to plants. It will be interesting to know how widespread is the occurrence of single-stranded circular RNA molecules and whether they are involved in diseases of organisms other than higher plants. □

Most leptons come in pairs

from W. T. Toner

THERE was a precursor to the discovery of the ψ: muons and electrons were found in such large numbers in proton–nucleus collisions that a new interaction or particle had to be invoked to account for them. (Boymond *et al. Phys. Rev. Lett.* **33**, 112; 1974; Appel *et al. ibid*, 722; *News and Views* **254**, 103; 1975). Many new studies were begun whose results continue to accumulate. Much of the data can be understood in terms of known processes once the ψ (and perhaps a small amount of charm) is included, but not all.

The large effect is small in any absolute sense, being of the order of one part in ten thousand of the production of the strongly interacting particles whose decays constitute the main experimental background to be subtracted.

The most illuminating results concern the production of pairs of oppositely charged muons or electrons. Several groups find that a substantial fraction of the leptons does come in pairs (see for example Kleberg *et al. Phys. Rev. Lett.* **37**, 1451; 1976) and that the muons are unpolarised as would be the case for electromagnetic production (Leipuner *et al. Phys. Rev. Lett.* **36**, 1011; 1976), although a Russian group has reported a large negative polarisation which is difficult to understand.

The Chicago–Princeton group (K. J. Anderson *et al. Phys. Rev. Lett.* **37**, 799 and 803; 1976; Branson *et al.* to be published) have measured muon pairs and single muons in the same apparatus so that systematic effects in any comparison are much reduced. Readers who watched *The Key to the Universe* may remember seeing this spectrometer in action in an experiment by H. L. Anderson *et al.* (*Phys. Rev. Lett.* **36,** 1422; 1976) who built it around the 184-inch diameter magnet taken from the old Chicago cyclotron. Branson *et al.* find that 0.7 ± 0.2 of all the muons they observe come from pairs. This is near enough all of them that it will not be easy to decide whether any true single muon production takes place.

The mass spectrum of pairs from this and other experiments shows peaks for the known vector mesons (ρ, ω, φ, ψ and ψ') superimposed on a continuum which drops steeply as mass increases. Earlier suggestions of a new particle with a mass of 6 GeV have not been confirmed (Hom *et al. Phys. Rev. Lett.* **36,** 1236; *ibid,* **37,** 1374; 1976). It is striking how many of the pairs have masses less than the ρ or ω mesons. These are most likely due to three-body decay modes of the eta. The effect of three body decay modes of π^0 and η can be seen even more strikingly in the results of Guy *et al.* (to be published) who studied electron production in a track sensitive hydrogen target within a neon–hydrogen bubble chamber at low (4 GeV) collision energy. They find no evidence of anomalous production. (A search at 0.8 GeV/c showed no anomaly down to the level of parts in a million (Browman *et al. Phys. Rev. Lett.* **37,** 246; 1976)).

All low energy or low transverse momentum experiments using electrons must deal with the low mass background and it takes little imagination to realise how easy it would be to underestimate the subtraction. Nevertheless we must wait for a more direct confrontation before dismissing the signals at 10 to 24 GeV of Beier *et al.* (*Phys. Rev. Lett.* **37,** 117; 1976) and at high energy and low transverse momentum of Baum *et al.* (*Phys. Lett.* **60B,** 485; 1976), or accepting the need for Lederman and White's provocative mystery particle (*Phys. Rev. Lett.* **35,** 1543; 1975).

The smooth continuum (minus decay background) is of great interest in its own right. It is thought to be due to the annihilation of a quark in the projectile with an antiquark in the target (or *vice versa*) to give a highly virtual photon which promptly materialises as a lepton pair (Drell & Yan *Phys. Rev. Lett.* **25,** 316; 1970). The theory is very far from being clear cut but is in quite surprising agreement with the overall magnitude of the effect. As this is one of the few places where there is a direct link between electron–positron annihilation, deep inelastic scattering and the collisions of strongly interacting particles, it will obviously repay further study. □

High pressure methods

from John Walker

The diamond anvil high pressure cell and its calibration by a ruby crystal are currently revolutionising the study of materials under high pressure. For the first time they have enabled pressures similar to those at the centre of the Earth to be generated and measured simply and conveniently in the laboratory, thus opening up a new realm of study.

Pressure can cause dramatic changes in physical properties such as structure, electrical conductivity and transparency. The difficulty has been that high pressures could be generated only by massive (and relatively expensive) apparatus, so experiments had to be constructed around the high pressure cell. This effectively ruled out many experiments such as those involving superconductivity, where the material has to be cooled to very low temperatures. The diamond anvil cell on the other hand is compact (15 cm long) and portable and can easily be incorporated into other apparatus. Another advantage over its ponderous predecessors is its transparency to electromagnetic radiation, which makes optical and X-ray experiments much easier.

The cell was invented at the United States National Bureau of Standards by Weir *et al.* (*J. Res. natn. Bur. Stand.* **A63,** 55; 1959). It basically consists of a pair of brilliant-cut diamonds pressed together, with the material under study in between (Fig. 1). A relatively small force applied to the large faces of the diamonds results in a large pressure between the small faces. The gasket helps to retain the specimen under study, reduces the risk of shattering the diamonds, and keeps the pressure equal and isotropic throughout the sample volume.

The diamond anvil cell thus made pressure generation much more convenient. But for some time there remained the problem of measuring the pressure exerted. Previously, one way was to measure the sudden change in resistivity of materials due to pressure-induced transitions into the metallic phase, but only certain fixed points on the scale are available. Another way is to measure the change in lattice parameter of sodium chloride crystals. This technique, however, is very slow—up to two weeks to measure a single pressure—and can only be used to measure pressures less than 291 kbar because of a phase change in NaCl at this pressure (1 bar = 1 atmosphere).

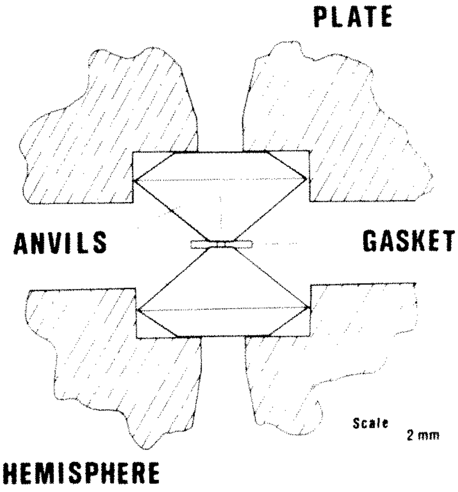


Fig. 1

In 1972 however, NBS solved the problem of pressure measurement (Forman *et al.*, *Science*, **176,** 284; 1972). The system can be calibrated by measuring the shift in the R_1 ruby fluorescence line (the ruby laser line) which is linear with pressure up to at least 300 kbars (Piermarini and Block, *Rev. sci. Instr.*, **46,** 973; 1975). The fluorescence is strong and easily excited, and the shift rate is quite large (0.036 nm kbar^{-1}). This technique has also led to a downward revision of the previously accepted pressure scale.

What are the fields of study that have benefited from these advances? In one study at NBS (Block and Piermarini, *Physics Today,* **29,** 44; 1976) the semiconductor-to-metal transition in silicon and gallium phosphide was observed by noting the pressure at which transparent crystals within the cell became opaque. A television camera enabled visual observations to be extended into the infrared. Simultaneous measurements of electrical resistance confirmed an order-of-magnitude conductivity change when opacity occurred.

The small size of the diamond anvil cell has great advantages in low temperature physics. One incorporated into a dilution refrigerator can apply pressures of 100 kbars at temperatures as low as 0.03 K (Webb *et al.*, *Rev. sci. Instr.*, **47,** 59; 1976), and has been used to study the way the superconducting transition temperature changes with pressure.

At the other extreme of temperature the transition of graphite to diamond has been studied at 260 kbars and 3,000 K (Ming and Bassett, *Rev. sci. Instr.*, **45,** 1115; 1974). Applications have also been reported in radioactivity, crystallography, optical spectroscopy and in the breakdown of lubricating fluids under high pressures (as found in bearing contacts).

The diamond anvil cell can easily equal pressures inside the Earth's crust (tens of kilobars). Hence geologists find the cell useful in experimental studies. Sung (*Rev. sci. Instr.*, **47**, 1343; 1976) has used the apparatus to study the kinetics of the olivine to spinel transition. Even pressures at the centre of the earth (3.6 Mbar) may soon be routinely available. Mao and Bell (*Science*, **191**, 851; 1976) have already broken the 1 Mbar barrier.

The technology of pressure generation and measurement has up to now lagged behind that of temperature, its complementary variable; the diamond anvil cell should help it to catch up. Every laboratory should have one. □

The sequence is not enough

from N. J. Proudfoot

An EMBO Workshop on Genes and Spacers was held at Davos, Switzerland on 10–17 January, 1977. It was organised by M. L. Birnstiel and S. G. Clarkson (Institut für Molekularbiologie II, Zürich, Switzerland).

THE aim of this meeting was clearly outlined by one of its organisers, M. Birnstiel (Institut für Molekularbiologie II, Zürich). In simple terms his message was that we had perhaps heard enough about eukaryotic gene isolation and that it was high time we actually compared data from structural or functional studies made on purified genes.

Two important contributions followed that described new DNA sequencing techniques which greatly speed up that once arduous process. First, W. Gilbert (Harvard University) briefly described the now well known, although as yet unpublished, Maxam and Gilbert chemical cleavage DNA sequencing method. By labelling the end of a DNA fragment (usually obtained by restriction enzyme digestion of DNA) with ^{32}P and then breaking it at base-specific sites using various chemical tricks, the partially degraded DNA fragments could be ordered on a gel and the DNA sequence established. Second, N. Brown from F. Sanger's laboratory (MRC Laboratory of Molecular Biology, Cambridge, UK) described the plus and minus gel sequencing method originally published by Sanger and Coulson (*J. molec. Biol.* **94**, 441; 1975). This method starts by actually synthesising ^{32}P-DNA in a test tube using *E. coli* DNA polymerase. Then with various combinations of dCTP, dTTP, dGTP and dATP (the four substrates used by DNA polymerase) the ^{32}P-DNA can be made to terminate at base-specific sites. Again, a DNA sequence may be deduced by fractionating the different DNAs on a gel. These two DNA sequencing methods have essentially increased the speed of DNA sequence analysis from the old rate of about 100 nucleotides a year to 100 nucleotides in a few 'good' days. Brown went on to show the essentially complete sequence of the bacteriophage ΦX174, 5,375 nucleotides in length at the last count. Happily for Sanger's group, their massive sequencing effort has been rewarded by the discovery of two overlapping gene systems, in which two proteins are read off the same DNA sequence, but in two different phases. That genes *E* and *D* of ΦX overlap has recently been published by Barrell, Air and Hutchison (*Nature* **264**, 34; 1976). Brown reported that two further genes *A* and *B* also overlap, so that two examples of this bizarre phenomenon occur in the same bacteriophage. Of course it remains an open and exciting question as to whether or not overlapping genes are present in other prokaryotic or eukaryotic organisms.

Two of the first eukaryotic genes to be isolated, frog 5S and sea urchin histone genes, both repeated many times over in tandem, are now well on the way to being completely sequenced. D. Brown (Carnegie Institution, Baltimore) gave an elegant report on the former system. After describing electron microscopy and restriction enzyme data on this DNA, he presented the complete sequence of the spacer in 5S DNA, showing very nicely the satellite 15-nucleotide repeat sequence originally discovered by Brownlee, Cartwright and Brown (*J. molec. Biol.* **89**, 703; 1974) and demonstrating how variation in the number of these repeats accounted for the variation in the absolute length of these genes. He went on to describe the sequence of the apparent promoter for 5S RNA, just beyond the spacer region, but apart from a repeated sequence of 10 nucleotides, no clues to its identity were observable. Several other possible eukaryotic promoter sequences, in yeast rDNA and SV40 DNA, were described by W. Gilbert and W. Fiers (Gent). Already it is becoming painfully obvious that no promoter-specific homologous sequences are generally present in eukaryotes. Histone genes from two different species of sea urchin were described by M. Birnstiel and L. Kedes (Stanford University). Long stretches of sequence from both coding sequences and spacers were presented, but even after computation (described by H. Smith (Johns Hopkins University, Baltimore)) little sense could be made. One of the great hopes for the histone gene system is that control signals before and after each of the six coding or mRNA sequences (present in each histone gene repeat unit) may be recognisably similar and that these control signals may be conserved between different species. But the data is as yet too fragmentary to be sure whether or not such hopes are justified. One such control signal, however, does appear to be generally present in eukaryotes. Proudfoot and Brownlee (*Nature* **263**, 211; 1976) recently described a sequence A–A–U–A–A–A presented in six different eukaryotic mRNAs close to their 3′-terminal poly(A) sequences. Fiers described the same sequence close to the poly(A) of EMC viral RNA and M. Billeter (Institut für Molekularbiologie, Zürich) suggested that this sequence was near the poly(A) of the related RNA tumour viruses RSV and AMV.

J. Rubin (Stanford University) presented some intriguing results on a gene from *Drosphila* of unfortunately unknown function. He described how the DNA sequences on either side of the transcribed positions of this gene appear to be nearly identical for as many as 500 nucleotides, on the basis of hybridisation data using restriction fragments and an ingenious heteroduplex experiment. More understandable were the interesting results reported by Gilbert on RSV. He described the sequence of complementary DNA made using the RSV RNA template with its natural tRNA primer and reverse transcriptase. This DNA, about 100 nucleotides long, is complementary to the 5′-end of the viral 30S RNA genome. For a long time the question has been, how is the rest of the virus copied into DNA, an essential requirement for viral integration into the host's genome. Gilbert's answer is simple. The sequence at the 3′-end of the virus contains a region of 19 nucleotides identical to the 5′-end sequence. Thus the tRNA primer may generate a second DNA primer allowing reverse transcriptase to copy the whole viral RNA.

With a few notable exceptions, the main lesson learnt from the extensive sequence data described at Davos is that knowing the sequence is not enough. Major breakthroughs must be made before any understanding of the relationship of sequence to function is achieved.

I will finish this selective account by describing two such possible breakthroughs. First, Gilbert described the use of various chemical reagents that modify DNA to locate the exact binding position of a particular protein on DNA. His model system was as usual the *lac* operon, *lac* repressor complex.

He showed very clearly, using a rather fearsome phosphate-specific reagent, that the *lac* repressor only binds on one side of the double helix. Second, both E. De Robertis (MRC, Cambridge) and D. Brown described experiments done in J. Gurdon's laboratory at Cambridge, which involved the injection of either frog 5S DNA or *Drosophila* histone DNA into the nuclei of frog oocytes (a seemingly impossible manipulation). Both experiments suggested that the foreign DNAs were transcribed specifically to generate in the first case normal 5S RNA and in the second histone proteins, detected by two-dimensional fractionation techniques. These exciting results suggest that frog oocytes may well provide an invaluable assay system for purified eukaryotic gene expression. ☐

Nova Sagittae 1977 and Vulpeculae 1976

from David W. Hughes

TENACITY and a truly astronomical memory are two attributes specifically required by the amateur astronomers who successfully search the sky for novae. Tenacity, because discoveries are few and far between—about 300 hours of painstaking observation being required to discover a nova. The encyclopaedic memory is also essential, the relative positions and brightness of about 10,000 stars must be known so that the interloper, the star which has suddenly and dramatically increased in brightness, can be easily recognised.

The last two novae found have been discovered by British amateur astronomers, the most recent one by John Hosty, a Huddersfield postman, on 7 January, 1977 in the constellation of Sagitta (the actual position is right ascension $19^h37^m08.18^s$, declination +18°00′58.2″, equinox 1950.0). This has been reported in *Circulars 3025/7* and *3030* of the *International Astronomical Union's Central Bureau for Astronomical Telegrams*. It was discovered at a magnitude of 7.2 (about three times less bright than stars visible to the naked eye, which have magnitudes less than 6.0) and has been getting steadily fainter since its discovery, as shown in Fig. 1. Most novae will decrease in brightness by about 3 magnitudes from their maximum value in about 40 d and then continue getting fainter at a slightly diminished rate.

The previous nova discovery was by George Alcock, a retired school master from Peterborough, his nova being in Vulpecula (right ascension $19^h27^m.04^s$, declination +20°21′43″) and was near its maximum brightness at magnitude 6.5 at discovery (*IAU Circular No. 2997*). As seen in Fig. 1 the nova became 3 magnitudes fainter than maximum in 42 d and 6 magnitudes fainter in about 68 d. Interestingly both novae are in the Milky Way and are very close to each other in the sky.

The instruments used to detect novae are relatively simple in comparison to other astronomical apparatus. Both Hosty and Alcock used binoculars, in fact Hosty used only half a pair of binoculars as the other half had been unfortunately broken at some time. The two instruments were 10×50 and 15×80 respectively, the first figure being the magnification and the second figure the objective lens diameter in millimetres. They would have fields of view of about 6° and 4° in diameter, the Hosty instrument detecting stars down to about 10th magnitude under excellent sky and seeing conditions. The field of view would contain, on average, 30 stars of 8th magnitude and just over 200 brighter than 10th. The daunting task of the nova hunter is to pick out the new star as he sweeps slowly over the 10,000 or so stars brighter than 8th magnitude that can be seen from a good observing sight at any one time.

What is the use of discovering novae? Well, apart from the sudden rise to fame for the finder, these stars are of considerable intrinsic interest, being at a fascinating stage in their evolutionary history. Novae occur just before a star finally dwindles to become a white dwarf. All the nuclear energy-producing reactions converting hydrogen and helium into higher atomic number elements have ended, and the star is getting its energy simply from the gravitational potential energy that is slowly released as it shrinks. The pre-nova star is typically of spectral type O or B, corresponding to a surface temperature of 20,000 to 40,000 K, with a radius about 0.3 solar radii and a mass between 0.2 and 2.5 solar masses. The absolute magnitude is around +4.5. On explosion the magnitude jumps by 11, equivalent to an increase in brightness of about 25,000 times. During the outburst the star loses on average 0.001 solar masses, the energy emitted in the few days of outburst being about 10^{45} ergs, corresponding to the energy emitted by the Sun over 2,000 yr. From spectral observations it can be seen that the luminous layers of the star are expanding outwards at velocities around 1,000 to 2,500 $\mathrm{km\,s^{-1}}$ in a rather non-uniform fashion, causing the superposition of absorption and emission features in the line spectra. At maximum the nova reaches an absolute magnitude of about −8.0 the expanding gas cloud having a radii of about 100 solar radii. After maximum the nova slowly fades into insignificance, back to the same magnitude as the pre-nova star. By carefully searching the Palomar Sky Survey photographic plates (*IAU Circular 2998*) the pre-nova star of nova Vulpeculae has been found and is a blue star of photographic magnitude 18.3. A search for the pre-nova of Sagittae 1977 has revealed three stars at the plate limit of about 20th photographic magnitude within $\sim 1''$ of the nova's position.

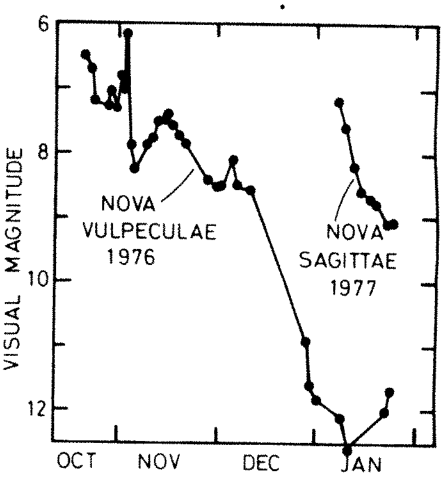

Fig. 1 The visual magnitude of the novae as a function of time. A change in magnitude by one unit is produced by a change in brightness by a factor of 2.51.

In the Galaxy there may be about 50 novae a year, only a few (2.2 yr^{-1} on average) being discovered, the rest being hidden behind dense interstellar dust clouds or being too faint at maximum.

The general excitement caused when one is discovered and the wealth of knowledge gained about this fascinating stage of stellar evolution is ample justification for the arduous and tireless search that worthy amateur astronomers like Hosty and Alcock conduct. It is very unfortunate however that so little is known about the pre-nova state of the star. So far only one spectrum, that of V603 Aquilae, has been recorded before the star became a nova. Our knowledge of what causes a star to suddenly explode in this unexpected way is thus pitifully small.

A hundred years ago

PROF. DIETERICI, of Berlin, sought to show in a public lecture, delivered a few days since, that the theories of Darwin were by no means novel, having been essentially published by learned Arabs in the tenth century.

review article

Octopamine

Julius Axelrod & Juan M. Saavedra*

The sympathomimetic amine octopamine (p-*hydroxyphenylethanolamine*) *has the properties of a neurotransmitter in many invertebrate species. In mammals it seems to be a cotransmitter with noradrenaline.*

THE actions of neurotransmitters are ubiquitous, influencing a variety of tissues and physiological functions. For a compound to be considered a neurotransmitter, it should be present in nerves, together with its biosynthetic enzymes. When the nerves are stimulated, the transmitter should be discharged from nerve endings. Once liberated, the transmitter should be recognised by and bind to its specific receptor on the postjunctional cell membrane and produce a biological response characteristic of that cell. Mechanisms should be available to terminate rapidly the actions of the neurotransmitter. Until recently, only acetylcholine and noradrenaline were established as neurotransmitters. However, many compounds, such as dopamine, 5-hydroxytryptamine (5-HT), histamine, gamma aminobutyric acid, certain amino acids and small peptides meet many of the criteria necessary for chemical neurotransmission. Recent work has indicated that octopamine fulfils the requirements for a neurotransmitter, especially in invertebrates.

Octopamine (*p*-hydroxyphenylethanolamine) was first detected in the venom-producing posterior salivary gland of *Octopus vulgaris* by Erspamer and Boretti[1]. Soon afterwards, Armstrong and co-workers noted that relatively large amounts of the deaminated metabolite of octopamine, *p*-hydroxymandelic acid, was present in the urine of man and other mammals[2]. However, with the methods available at that time (paper chromatography) octopamine could not be detected in tissues unless a monoamine oxidase inhibitor was previously administered[3]. The injection of radioactive tyramine into rats led to the formation of radioactive octopamine which was highly localised in nerves containing noradenaline[4]. Stimulation of the splenic nerves of cats previously given ^{3}H-tyramine resulted in the release of ^{3}H-octopamine[5]. It was also observed that dopamine-β-hydroxylase, the enzyme that converts dopamine to noradrenaline[6], and highly localised in sympathetic nerves[7] also hydroxylates tyramine to octopamine *in vitro*[8]. These observations suggested that octopamine, the monohydroxylated analogue of noradrenaline, might be a neurotransmitter.

The development of a sensitive enzyme isotope method for measuring octopamine in tissues made it possible to study its normal occurrence, physiological disposition and metabolism[9]. The method depends on the ability of phenylethanolamine *N*-methyltransferase to transfer the methyl group of ^{14}C or ^{3}H-methyl-*S*-adenosyl-L-methionine to octopamine present in tissues. Phenylethanolamine *N*-methyltransferase is highly localised in the adrenal medulla and can *N*-methylate noradrenaline as well as other β-hydroxylated phenylethanolamines, including octopamine[10]. A partially purified enzyme is incubated together with aqueous tissue extracts and radioactive *S*-adenosylmethlione. The radioactive *N*-methyl octopamine (synephrine) formed is then separated from other interfering compounds by selective extraction into a non-polar solvent (mixture of toluene and isoamyl alcohol) and the radioactivity measured directly in the solvent[9] or coupled with paper chromatography of the *N*-methylated amines[11]. These methods have been found to be specific, rapid and very sensitive. As little as 20 pg can be measured using ^{3}H-methyl-*S*-adenosyl-L-methionine of high specific activity[12].

Sensitive assays using specific methyltransferase enzymes and extraction by appropriate solvents and ^{3}H-methyl-*S*-adenosyl-L-methionine have been used to measure a number of biogenic amines in the picogram range. 5-HT is measured by acetylation with liver *N*-acetyltransferase followed by *O*-methylation with pineal hydroxyindole-*O*-methyltransferase[13], an enzyme that specifically *O*-methylates *N*-acetyl-5-HT. Noradrenaline and dopamine are *O*-methylated by catechol-*O*-methyltransferase and the ^{14}C methylated amine separated by cleavage of the β-hydroxylated amine with periodate[14]. Histamine is assayed by a highly specific histamine *N*-methyltransferase from the brain[15]. An enzyme from the lung is used to methylate tryptamine[16]. Phenylethylamine[17] and tyramine[18] can be measured by hydroxylation with dopamine-β-hydroxylase followed by methylation with phenylethanolamine *N*-methyltransferase.

Octopamine in mammals

Using the isotope enzyme assay, octopamine has been found in the peripheral tissues and brain of rats and other mammals (Table 1)[19,20]. It is present in sympathetically innervated organs such as the heart, spleen and salivary gland. With a radiochemical enzymatic assay which allows the simultaneous determination of *p*-octopamine and *m*-octopamine, equal amounts of these amines were found in rat salivary glands (H. A. Robertson, A. A. Boulton, J. C. David and T. J. Danielson, personal communication). In the cat's heart, octopamine is present mainly in the atria. Octopamine is also found in the brain of all mammalian species examined, including man[12]. It is unequally distributed in the brain; highest values are present in the hypothalamus, midbrain and spinal cord. The pineal gland had the greatest levels of octopamine.

In the foetal rat brain octopamine can be detected after 15 d of gestation[21]. Up to 17 d of gestation, octopamine is the predominant amine in the foetal rat brain and is twice as high as that of noradenaline. After 18 d of gestation, there is a precipitous decline of octopamine levels in the foetal rat brain, and this coincides with a rise in monoamine oxidase. The administration of phenylalanine together with drugs that block the hydroxylation of this amino acid results in

increases in the ratio of octopamine to noradrenaline from 2 : 1 to 12 : 1 in foetal rat brain.

Evidence that octopamine is present in nerves of peripheral tissue[19,20] and brain[22] was obtained by surgical and chemical denervation of sympathetic nerves. Denervation of the noradrenergic nerves of the rat salivary gland results in a partial disappearance of octopamine in this tissue. After the administration of 6-hydroxydopamine, a compound that destroys catecholamine-containing nerves, there is a marked reduction of octopamine in the rat heart, spleen, salivary gland and pineal gland[19,20]. An intracisternal injection of 6-hydroxydopamine causes a marked depletion of octopamine in all areas of the rat brain[22]. In the rat heart, octopamine is found in the same fraction of a sucrose density gradient as noradrenaline-containing vesicles[20]. All of these observations indicate that octopamine is highly localised in noradrenaline-containing neurons. Octopamine is present in small amounts relative to noradrenaline, yet it has a high rate of turnover in tissues, about six times that of the catecholamine[20]. Thus, the higher steady-state concentration of noradrenaline as compared to octopamine may not reflect the functional importance of each amine. Though the tissue concentration of octopamine is only a fraction of that of noradrenaline and 5-HT, the amount of the major metabolites of these amines, *p*-hydroxymandelic acid (from octopamine), 3-methoxy-4-hydroxymandelic acid (from noradrenaline and adrenaline) and 5-hydroxyindoleacetic acid (from 5-HT) are extracted in the urine of humans to the same extent[2,23]. This suggests rapid turnover of octopamine in man.

The biosynthesis and metabolism of endogenous octopamine in the rat and mouse brain has been elucidated by the administration of precursors and enzyme inhibitors[9,11,24,25]. An injection of a monoamine oxidase inhibitor causes more than fivefold elevation of octopamine in rat and mouse brain and peripheral tissues, indicating that deamination by monoamine oxidase is an important pathway for its metabolism[11,24]. A minor route of transformation *in vivo* is hydroxylation to noradrenaline[26]. The enzyme carrying out the latter reaction is localised in the liver microsomes[26]. Another minor pathway of metabolism of octopamine is *N*-methylation to synephrine by phenylethanolamine *N*-methyltransferase[10]. Tyrosine or tyramine together with a monoamine oxidase inhibitor result in a much greater increase in octopamine in rat[21] and mouse[11] brain than do monoamine oxidase inhibitors alone. In rats treated with a dopamine-β-hydroxylase inhibitor there is a considerable fall in the endogenous levels of octopamine in rat, brain, heart, and spleen[24]. An unusual metabolic route for the formation of octopamine is dehydroxylation of catecholamines[24]. The administration of L-dopa to rats leads to the increase of octopamine in the rat brain and urine of man. Dehydroxylation of catecholamines to octopamine was also demonstrated in germ-free rats, indicating that this transformation is not due to metabolism in the intestinal flora. Further evidence for dehydroxylation of catecholamines was obtained by the formation of octopamine and synephrine after an intraventricular injection of either ^{14}C-dopamine or ^{3}H-noradrenaline into the rat brain[27].

From the experiments described above, the pathway for the formation and metabolism of octopamine proceeds as follows

$$\text{tyrosine} \rightarrow \text{tyramine} \rightarrow \text{octopamine} \begin{array}{l} \nearrow \text{noradrenaline} \\ \rightarrow p\text{-hydroxymandelic acid} \\ \searrow N\text{-methyloctopamine (synephrine)} \end{array}$$

The release of octopamine from nerves was initially demonstrated by infusion of the radioactive amine into the cat spleen[5]. On electrical stimulation of splenic nerves there was a discharge of ^{3}H-octopamine into the perfusing fluid. Infusion of ^{3}H-tyramine into the spleen also resulted in the release of ^{3}H-octopamine. These findings indicate that tyramine is taken up by neurons where it is β-hydroxlyated to octopamine in the nerves. When these nerves are stimulated, the ^{3}H-octopamine is released presumably by exocytosis in the same manner as noradrenaline. Release of endogenous octopamine by nerves has been also demonstrated[22]. After stimulation of the splenic nerve of the cat there is a discharge of endogenous octopamine and noradrenaline[22]. The amount of octopamine released is only about 2–5% of that of noradrenaline. It is unlikely that octopamine and noradrenaline exist in separate neurones in the spleen and it is probable that octopamine is released from nerves as a cotransmitter together with noradrenaline. Octopamine has also been reported to coexist with noradrenaline and serotonin in vesicles of pineal adrenergic nerves[28]. After the administration of a monoamine oxidase inhibitor the amount of octopamine discharged from the cat spleen is 30–40% of the amount of noradrenaline[22]. The relatively large release of octopamine, a compound with weak pressor activity provides a mechanism for the blood pressure lowering actions of monoamine oxidase inhibitors.

Like noradrenaline, octopamine can be taken up by nerve endings of the rat brain by a temperature- and sodium-dependent process, and this process is inhibited by drugs that prevent the uptake of catecholamines[29,30]. When the brain tissue is stimulated electrically octopamine previously taken up is released. The uptake of octopamine by nerve terminals might serve as a means for rapidly terminating the actions of this amine.

In mammals, octopamine causes a transient elevation of blood pressure. The physiological actions of octopamine are similar to those of noradrenaline but it is only about 1/50 as effective[31]. Monoamine oxidase inhibitors elevate octopamine in nerves six times as rapidly as noradrenaline[20] and cause a disproportionate release of octopamine[22] and in a reduced response. Thus, octopamine because of its weaker physiological action, may modify the actions of noradrenaline.

The administration of phenylalanine and phenylalanine hydroxylase inhibitors, which results in high increases in tissue levels of octopamine[11,24], produces symptoms analogous to those of phenylketonuria. Thus, the symptoms of this disease might result from an accumulation of octopamine in the brain at the expense of noradrenaline. There is an elevation of octopamine in hepatic failure which may be associated with some of its neurological and cardiovascular pathology[32]. The levels of octopamine in the hypothalamus of children who died of acute hepatic encephalopathy (Reye's syndrome) are 12 times higher than that of age-matched controls[33]. It has been postulated that octopamine might accumulate as a false neurotransmitter and cause some of the pathology in these hepatic diseases[32].

Octopamine in invertebrates

Highest concentrations of octopamine have been found in the nervous system of octopus and other cephalopods (Table 1)[34]. The posterior salivary gland of the octopus contains as much as 1.3 mg g^{-1} octopamine. Subcellular studies showed that octopamine is localised in synaptosomes (nerve ending fractions) of the nerves[34].

Octopamine is found in relatively high amounts in single identified neurones of the *Aplysia californica* (Tables 1 and 2)[35,36]. In some nerve cells of the *Aplysia,* octopamine is present together with other putative neurotransmitters such as acetylcholine, serotonin and histamine but not dopamine or noradrenaline (Table 2). These findings indicate that in *Aplysia,* Dale's principle (one neurotransmitter for one nerve) may not hold. From these observations it is apparent that neurones containing octopamine can also exist in the absence of catecholaminergic neurones.

The nervous system of the lobster is rich in octopamine (Table 1)[19,37,38]. The amine is highly localised in the thoracic nerve cord[20] and is associated with groups of neurones along the proximal portions of the second root leaving the thoracic ganglia[38]. These octopamine-containing cells have the morphological appearance of neurosecretory cells[39] and receive synaptic inputs from the cholinergic nerves.

Relatively large amounts of octopamine are present in the central nervous system of the cockroach[40], locust[41], earthworm[42] and firefly lantern (Table 1)[43] and probably in nerves of many other invertebrates not yet examined.

Injection of ^{14}C-tyrosine into lobster nerve tissue results in the formation of radioactive octopamine and dopamine but not noradrenaline[37–39]. Dopamine-β-hydroxylase (the enzyme that converts dopamine to noradrenaline, and tyramine to octopamine), tyrosine hydroxylase and aromatic amino acid decarboxylase are also present in lobster nerves[38]. The ability of lobster nerves to synthesise dopamine and octopamine can best be explained by the occurrence of two types of nerve cells: octopaminergic cells that contain aromatic amino acid decarboxylase and dopamine-β-hydroxylase but not tyrosine hydroxylase and dopaminergic cells containing tyrosine hydroxylase and dopa decarboxylase but not dopamine-β-hydroxylase[38]. Thus nerves containing octopamine and nerves containing catecholamine seem to be spacially separated.

Octopamine-containing root cells of the lobster can synthesise ^{3}H-octopamine from ^{3}H-tyrosine[39]. When these neurones are depolarised with high concentrations of potassium there is a marked release of ^{3}H-octopamine[39]. The discharge of octopamine by potassium is highly dependent on Ca^{2+}. Thus, the octopamine-containing cells of the lobster exhibit the properties associated with the release of a neurotransmitter from nerves; liberation by depolarisation and a requirement for Ca^{2+}.

Table 2 Coexistence of octopamine and other putative neurotransmitters in single identified neurones of *Aplysia californica*

	R-2	R-14	L-11	C-1
Octopamine	2.5×10^{-6}	1.5×10^{-4}	9.1×10^{-6}	ND
5-HT	1.8×10^{-5}	3.4×10^{-5}	1.1×10^{-5}	9.4×10^{-4}
Dopamine	ND	ND	ND	ND
Noradrenaline	ND	ND	ND	ND
Acetylcholine	3.9×10^{-4}	ND	3.3×10^{-4}	ND
Histamine	3.0×10^{-6}	7.0×10^{-6}	4.5×10^{-6}	1.4×10^{-5}

Results are expressed in molarity. Molarity was calculated from volume estimation obtained by measurements of greatest and smallest cell diameters at the time of dissection (from Brownstein *et al.*[36]). ND, None detected.

Octopamine has been shown to have potent effects in insects. The local application of octopamine to the nerve cord of the cockroach causes an increase in cyclic AMP levels[44]. This, in turn, produces a stimulation of phosphorylase and a pronounced glycogenolytic effect[45]. Adenylate cyclase in cells of thoracic ganglia of the cockroach, that can be specifically stimulated by low concentrations of octopamine, has been identified[44]. Octopamine, dopamine and 5-HT are additive in stimulating adenylate cyclase activity suggesting that each of these amines activates separate receptor sites. Octopamine was found to be the most potent endogenous amine in eliciting the light-flash in the firefly lantern[46]. In locust and grasshoppers, octopamine inhibits the rhythmic contractions of muscles just as stimulation of neurones synthesising octopamine does[41,47].

The cyclic AMP levels in several lobster ganglia are elevated by octopamine which produces a characteristic pattern of nerve firing in certain ganglia cells[48]. When octopamine is perfused across the opener muscle in the walking leg of the lobster it causes a prolonged contraction[39]. This effect is stereospecific: the D(−) isomer of octopamine is 50 times more potent than the L(+) isomer.

Ionotropic application of octopamine to the nervous system of *Aplysia* revealed the presence of receptors that are very sensitive to octopamine and mediate a hyperpolarising-conductance increase in response[49]. These receptors showed a marked preference for octopamine and had an absolute requirement for a β-hydroxyl group. Cells in the cerebral ganglia are most responsive. These cells whose processes are localised in the neurophile where functional synapses are present have high concentrations of octopamine[35,36].

Incubation of the abdominal ganglia of *Aplysia* with octopamine caused a considerable elevation in cyclic AMP[50]. This increase is prevented by the adrenergic blocking agent phentolamine, and by methylsergide. Incubation of the ganglia with octopamine also resulted in an incorporation of P^{32} into a specific protein[51]. The change in phosphoprotein metabolism produced by octopamine and mediated by cyclic AMP seemed to be localised to the neurophile.

Conclusion

Octopamine is highly concentrated in neurones of several invertebrate species. Unlike in mammals, octopaminergic neurones in invertebrates are spatially separated from catecholaminergic neurons. In identified nerve cells of *Aplysia*, however, this amine coexists with other putative neurotransmitters. Octopamine is synthesised in nerves from tyrosine and tyramine and metabolised mainly by monoamine oxidase. When lobster nerves are depolarised, octopamine is liberated by a Ca^{2+}-dependent process. A specific adenylate cyclase is stimulated by octopamine in several invertebrates to activate phosphorylase in the cockroach, induce a light-flash in firefly lantern or inhibit rhythm contractions in locust muscle. All of these observations provide compelling evidence that octopamine is a neurotransmitter in invertebrates.

In mammals octopamine is localised in nerves in peripheral tissues and brain where it seems to coexist with noradrenaline, the catecholamine being present in much higher concentrations. Octopamine is released from nerves together with noradrenaline and it may under certain conditions modify the actions of the adrenergic neurotransmitter. Octopamine is present in unusually high concentrations in certain neurological and hepatic diseases and may have a pathophysiological role.

Haloes from plutonium minerals and fission alphas?

C. H. Holbrow*

W. K. Kellogg Radiation Laboratory, California Institute of Technology, Pasadena, California 91125

The normal alpha decay of naturally occurring ^{244}Pu *can be expected to have produced pleochroic haloes detectable in existing rocks. Several methods of identifying such haloes are described here. Giant haloes might also be produced by the* α *particles that occasionally accompany the spontaneous fission of* ^{244}Pu. *It is plausible to speculate that in ideal circumstances such gaint haloes might be as large as 100* μm, *and that the X rays recently induced from central inclusions of giant haloes and identified as L rays of* $Z = 126$ *might instead have been K X rays from Te fission fragments.*

BECAUSE of its relatively short half life of 82.8 Myr, ^{244}Pu is present only in small amounts in the contemporary Earth. Mass spectrometry of meteorites, however, shows that at the time the Earth formed the ratio of $^{244}Pu/^{238}U$ was about 0.014 (refs 1 and 2). Consequently, for a period in the Earth's history there was sufficient ^{244}Pu present to affect the economy of fissionable materials and to form minerals. Isotopes which are products of the fission of ^{244}Pu have been identified in meteorites and the Earth[3-4], and work has begun on the mineral chemistry of plutonium[5]. It would be interesting to know the enrichments, fractionations, crystallisations and mineral formations of which plutonium is capable in geochemical processes. In the past such minerals may have been concentrated sufficiently to produce normal and anomalously large pleochroic haloes. Identification and study of these haloes might contribute to more accurate estimates of the concentration and the nature of plutonium minerals at different times in the Earth's history.

*Permanent address: Department of Physics and Astronomy, Colgate University, Hamilton, New York 13346.

Pleochroic haloes are spherical shells of coloration usually about 40 μm thick surrounding small grains of radioactive mineral. They commonly occur in pegmatites around grains of minerals such as sphene, apatite, zircon and monazite containing uranium and thorium. Haloes should also have formed around grains that have in the past contained sufficient amounts of plutonium minerals. Although haloes occur in several different types of rock, they have been studied mostly in biotite mica largely for reasons of experimental convenience[6–10].

Haloes generated by 10^{10} to 10^{14} atoms of ^{244}Pu would only rarely be distinguishable visually from haloes generated by ^{238}U or ^{232}Th. But plutonium haloes might be distinguishable by mass spectrometric detection of residual ^{244}Pu, its descendant ^{236}U, or by the presence of characteristic fission fragments in the central inclusions.

An interesting possibility is that some haloes around inclusions containing more than 10^{15} atoms of ^{244}Pu might be larger than uranium and thorium haloes. For every 3.2×10^5 decay α particles with energies around 5 MeV, an inclusion of ^{244}Pu will produce one α particle accompanying a spontaneous fission. More than half of these spontaneous fission α particles will have energy greater than 15 MeV and might produce shells of coloration with thicknesses as great as 100 μm.

The possible existence of plutonium haloes is interesting not only as further evidence of the presence and activity of a mineralogy of primordial ^{244}Pu in geological processes. The subject has interest because it may be possible to identify as ^{244}Pu haloes the 'giant haloes' reported by Gentry[10]. Such an identification might provide a basis for an alternative interpretation of the data from which Gentry *et al.*[11] deduced the existence of elements $Z = 116$, 124, 126 and 127—the so-called superheavy elements.

Normal haloes

Halo coloration behaves like the photographic process. There is a threshold of exposure below which no colouring occurs; there is a region in which optical density of the mica increases approximately linearly with exposure; above certain exposure levels there is saturation, and coloration remains constant. Finally, very intense exposures will produce complicated bleaching and reversal. Deutsch[7–9] studied naturally occurring uranium and thorium haloes in various biotite micas and also artificially induced coloration in these micas with α particles from radon. The coloration is triggered by sufficient ionisation density, but the mechanism is not known. They concluded that a fluence (time integrated flux) of about 10^{13} α particles per cm^2 is required to initiate coloration in the laboratory. They also found that natural fluences must be four to seven times greater than artificial ones to make the same effect in a given mica, and that different micas may differ widely in sensitivity[7–9].

Since the fluence must exceed a threshold for coloration to occur, no halo will form beyond the range of the most energetic α particle. Also, if the fluence drops below $\sim 10^{13}$ α particles per cm^2 there may not be sufficient ionisation to colour the halo. Consequently, the size of the halo is limited by the range of the α particles or by inverse square dissipation of the fluence below the threshold, whichever happens first.

Under the assumption that the fluence threshold in nature is 4×10^{13} α particles per cm^2, the minimum number of α particles that will colour a halo out to 18 μm from an inclusion small compared with the halo size is 1.6×10^9. This number of α particles would be produced by the decay of 5.4×10^8 nuclei of ^{244}Pu, and if they occupy 10% of the volume of the inclusion, 1 μm is the characteristic dimension of the smallest inclusion for which the size of its halo is determined by the range of α particles rather than by the inverse square law. In Fig. 1 such haloes correspond to inclusions with initial amounts of ^{244}Pu above the horizontal line labelled 'threshold of formation of visible haloes'.

Can such haloes be present in existing rocks? Can more than 5×10^8 atoms of plutonium have been concentrated into mineral grains 1 μm in diameter or larger? The likelihood of such an occurrence depends on the extent of geochemical concentration of plutonium at different geological times, and on the abundance of ^{244}Pu at the time of the formation of the mineral grains.

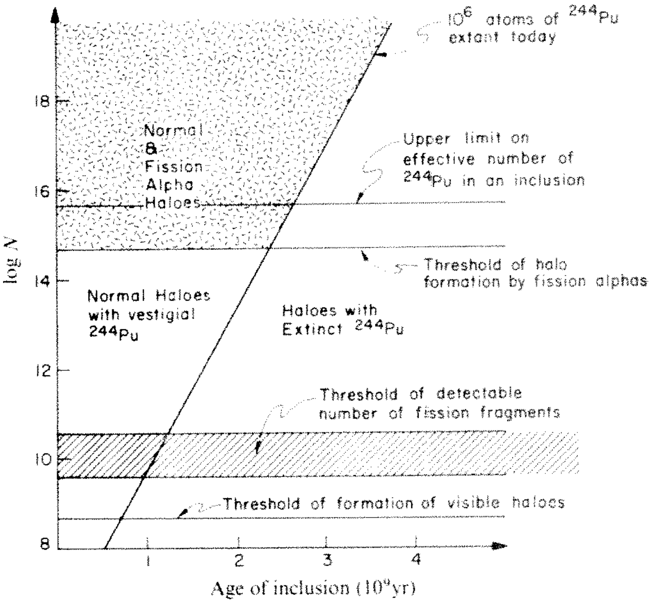

Fig. 1 Relationship of number of ^{244}Pu atoms in a mineral inclusion to the age of the inclusion. The diagonal line corresponds to 10^6 atoms of ^{244}Pu at present extant in the inclusion. The other features of the graph are discussed in the text. N is the number of ^{244}Pu atoms in inclusion at the time of formation.

Ores and minerals of most elements can be found somewhere in nature with enrichments of at least 10^6–10^8 times their average abundance in the Earth. Very pure grains of minerals and, in some cases, the elements themselves, can occur within such ores. The frequency of occurrence of the enriched ores and grains depends on the elemental abundance and the particular chemistry of the minerals. Hoffman *et al.*[12] examined some ore rich in bastnaesite, (Ce,La)FCO$_3$, from Mountain Pass, California, in which cerium is some 10^6 times more abundant than its average in the Earth. In 8.5 kg of the bastnaesite, they found 2×10^7 atoms of ^{244}Pu which they estimate is an enrichment of 2×10^8 over the average amount present in the Earth.

Moreover, bastnaesite may not be the best mineral in which to look for the maximum concentration. Considerably greater concentrations of plutonium probably occur in monazite. One may expect plutonium to concentrate approximately as thorium because the most stable oxidation state of the two chemicals is four, and in this they differ from all other lanthanides and actinides. But thorium is only 0.39% of the Mountain Pass bastnaesite[13] while it occurs as up to 28% of some monazites[14]. (Monazites from Mountain Pass are about 3% thorium.) Furthermore, monazite is a phosphate mineral, and during formation of phosphates of uranium, thorium and plutonium, the fractionation of plutonium is favoured by a factor of two to three (ref. 5).

The abundance of ^{244}Pu drops by 10^6 every 1.65×10^9 yr. Thus, pleochroic haloes will be produced by plutonium far enough back in geological history that the combination of concentrating processes and abundances suffices to produce grains 1 µm in diameter, or larger, containing 5.4×10^8 or more atoms of ^{244}Pu. Whether this occurred in rocks young enough to be part of the Earth's crust today needs to be determined experimentally.

If, when examined in thin sections, samples exhibited haloes with sharp rings and had only one radioactive element, Th, U or Pu, in the centre, they could be distinguished easily. Ideally the three α particles emitted as a ^{244}Pu nucleus decays to ^{232}Th would produce rings of coloration in biotite at about 14.2, 14.6 and 17.8 µm from the surface of the inclusion. Among the bands of colour that uranium would produce would be two at 15.3 and 19.9 µm. Two of thorium's several colour bands would occur at 12.4 and 20 µm. Unfortunately, inclusions can be expected to contain all three elements. Furthermore, the rings are not sharp except under rare ideal circumstances and are usually seen as bands or even discs of colour. Colour bands produced by plutonium will normally be difficult to distinguish from those from uranium. If no uranium were present, it might be possible to recognise a combination plutonium–thorium halo. It might be possible with such a combination to reproduce the characteristics of the X haloes mentioned by Gentry[6].

A more certain identification of plutonium haloes would be the mass spectrometric detection of vestigial ^{244}Pu, its descendant ^{236}U or fission fragments in a halo inclusion. Detection of plutonium with a mass spectrometer requires the presence in the inclusion of about 10^6 atoms. Their presence will depend upon the age of the inclusion and the original amount present. The diagonal line in Fig. 1 corresponds to inclusions containing 10^6 atoms of ^{244}Pu today. Therefore, points in the stippled region represent inclusions which should still have detectable amounts of ^{244}Pu. For example, an inclusion formed 1.4×10^9 yr ago must have contained 10^{11} atoms of ^{244}Pu in order to contain 10^6 atoms today. Points to the right of the diagonal line represent extinct plutonium haloes that would not now contain enough ^{244}Pu to distinguish them from thorium haloes.

Uranium 236 is formed in the decay chain of ^{244}Pu and has a half life of 2.4×10^7 yr. In transient equilibrium the ratio ^{236}U/^{244}Pu will be 0.41. Measurement of ^{236}U would suggest the presence of a plutonium halo.

Another distinctive feature of ^{244}Pu that might permit unambiguous identification of plutonium haloes is its relatively short half life for spontaneous fission. For ^{244}Pu the fission half life is 6.6×10^{10} yr (ref. 15), much less than the $\sim 10^{16}$ yr for ^{238}U, $\sim 10^{17}$ yr for ^{235}U and the $> 10^{21}$ yr for ^{232}Th (ref. 16). Consequently, for every 800 normal α-particle decays there will be a spontaneous fission producing two fragments.

The characteristic asymmetric mass and charge distributions of these fragments might serve to identify the halo as a plutonium halo. Of course, in such a distribution any given mass constitutes at most 7% of the total number of fragments, and if the level of detection by mass spectrometry is 10^6 atoms (about the best possible and it varies widely with the element), there will have to be a total of 10^7 fragments present to make the most abundant fragment isotopes detectable. Thus, about 4×10^9 atoms of ^{244}Pu is the smallest amount that will produce a detectable number of fission fragments. At least another factor of 10 is needed before quantitative measurements are reliable. Therefore, inclusions originally formed containing more than 4×10^{10} atoms of ^{244}Pu should contain enough remnant fission fragments to indicate the earlier presence of ^{244}Pu. The threshold for detection of fission fragments in an inclusion is indicated in Fig. 1 by the horizontal cross-hatched band.

Fission fragments have the advantage of indicating the nature of the halo whether the ^{244}Pu in the inclusion is extinct or not. Of course, the haloes may have been subject to the vagaries of physical and chemical action that remove fission fragments or in some other way vitiate their usefulness as identifiers. One of the most abundant fragments is xenon, but it is especially easily removed because it is a gas.

Anomalously large haloes

The fission of ^{244}Pu could lead to the production of haloes larger than those commonly observed. In about one out of 400 fissions an energetic α particle may be expected to be emitted[16]. In the spontaneous fission of ^{252}Cf, in the induced fission of ^{240}Pu and in all other cases of fission studied these α particles have a roughly Gaussian distribution of energies from 0 to 30 MeV with a peak around 16 MeV (refs 16–19). Because about 0.6 of the emitted α particles have energy greater than 15 MeV and a 15-MeV α particle has a range of $\sim$ 100 µm in biotite, it would seem possible to generate haloes as large as 100 µm or even larger, certainly much bigger than the normal size of 40 µm.

The production of large plutonium haloes, however, is by no means as probable as the production of normal plutonium haloes. To generate a number of fission alphas to produce a fluence of $\sim 10^{13}$ α particles per cm^2 at a distance of 100 µm from the surface of an inclusion requires an inclusion so large that self-absorption becomes a serious problem.

A simple model illustrates the difficulty. Consider a 100-µm diameter spherical inclusion of a pure crystal of 'plutonite', a hypothetical mineral of plutonium phosphate of density 7.5 g cm^{-3} and molecular weight 339. The Bragg–Kleeman rule predicts that a 15-MeV α particle will have a range of 79 µm in this mineral. Self-absorption in the inclusion will be important.

A simple numerical integration of this model taking self-absorption into account and assuming that the emitted fluence of α particles has a Gaussian energy distribution with a peak at 16.4 MeV and FWHM = 10.8 MeV, yields a fluence of 10^{13} α particles per cm^2 at 50 µm from the surface and 1.9×10^{12} α particles per cm^2 at 100 µm. Both of these numbers are smaller than the 4×10^{13} α particles per cm^2 assumed above as necessary to initiate coloration of a halo. Making the inclusion larger or smaller does not eliminate the problem.

Nevertheless, the possibility of anomalously large haloes still needs consideration chiefly because the threshold of coloration is poorly defined. Our knowledge of the threshold is based on experiments which assumed reciprocity between intensity and duration of exposure and used much higher rates of exposure than occur around haloes in nature. Yet reciprocity is known to fail in the coloration processes[6].

The possible failure of reciprocity is interesting in two respects. Unlike normal haloes which are terminated by the limits of the ranges of the alphas emitted from the inclusion, haloes produced by α particles from spontaneous fission would be limited by the inverse square law. Consequently, the volume 'outside' the halo would be subject to an appreciable α-particle fluence over periods of geological time. There have been no laboratory investigations of circumstances like these and it is conceivable that coloration might occur at fluences much below the nominal threshold.

We recognise that these inclusions and their immediate environment would be subject to strenuous conditions very different from those under which the laboratory determinations of threshold were made. The plutonium mineral would in the course of the lifetime of a halo convert itself into a thorium mineral. Also inside and around the inclusion there would be a large fluence of α particles from the normal mode of decay. The inclusion in the model described above would contain 7×10^{15} atoms of ^{244}Pu which would emit 21×10^{15} α particles with energies from 4.5 to 5.2 MeV. This is a fluence of 5×10^{20} α particles per cm^2 at 18 µm from the surface. These α particles would deposit more than 15,000 J in and around the crystal, which would consequently be metamictised, undergoing changes of density and varying degrees of recrystallisation. The amount of helium generated would be large, as can be appreciated by realising that if it did not diffuse away it would produce a pressure more than 600 atm at room temperature in the 68-µm radius volume of the inclusion and halo.

Furthermore, there would be 14×10^{15} electrons emitted from the two stages of beta decay in the normal decay chain of ^{244}Pu. With energies from 0 to 2 MeV these electrons would extend several hundred μm out from the inclusion and would deposit about 500 J in the spherical volume 150 μm in radius centred on the inclusion. Although this is about 1,000 times more energy per unit volume than is deposited by a threshold fluences of 4×10^{13} α particles per cm^2, it is unlikely that the β particles produce coloration by themselves because there is no evidence that similar intensities of β rays outside large inclusions rich in Th or U have produced coloration[6]. A large inclusion rich in ^{244}Pu, however, has a unique combination of an appreciable α particle fluence along with a large β-particle fluence. It is possible that the β particles might activate the mica and lower the coloration threshold for the α particles.

The foregoing considerations suggest that a variation in the threshold for coloration by large amounts from values based on laboratory experiments is definitely possible.

Giant haloes

There is an important reason for pressing to its limits the possibility of ^{244}Pu as a source of large haloes. Such haloes have been observed, but no adequate explanation of them exists. Figure 2 shows the relationship between distribution of haloes and their size, as observed by Gentry[10]. The sharp peak at 37–43 μm is attributed to normal uranium and thorium haloes. The peak at 50–58 μm has been attributed to the 10.6-MeV α particle from ^{212}Po* which has a branching ratio of 1 : 5,500 in the usual thorium decay chain[10]. (As can be seen, this peak appears too high for such a small branching ratio.) The larger haloes are unexplained.

The possibility of producing large haloes depends on the ratio of the partial half life T_1 for emitting long-range α particles during spontaneous fission to the overall half life T_0 of the nuclide. It is helpful to relate this ratio to our model mineral inclusion and the nominal threshold fluence φ required to produce a halo out to a distance r_0 from the surface of the assumed spherical inclusion of density ρ, molecular weight A, and radius r. A useful inequality between T_1 and T_0 follows from the fact that the ratio of the number of radioactive nuclei in the inclusion to the number of long-range α particles passing through a surface a distance r_0 from the inclusion must be greater than or equal to the ratio T_1/T_0, that is

$$(4/3\pi r^3 \rho N_a)/(A 4\pi (r + r_0)^2 \varphi) \quad R \geqslant T_1/T_0$$

where N_a is the Avogadro constant. The 'registration factor' R has been introduced to take into account enhanced ionising efficiency, absorptive losses, different concentrations of plutonium, or deviations of actual from nominal threshold. Let $a_0 = (r + r_0)/r$, then

$$T_1 a_0^2 (a_0 - 1)/R \leqslant T_0 \rho N_a r_0/(3A\varphi)$$

is an inequality which must be satisfied in order to produce giant haloes by α particles accompanying fission.

In terms of our hypothetical plutonite inclusion with $r = 50$ μm, $r_0 = 100$ μm and a threshold fluence of 4×10^{13}

$$T_1 \, 18/R \leqslant 1.1 \times 10^6 T_0$$

For plutonium $T_1/T_0 = 32 \times 10^4$, so in 'plutonite' a registration factor of 5.2 is needed to satisfy the inequality. The numerical calculation referred to above gives $R = 0.25$. Thus to meet the conditions of the inequality, the registration factor must be increased by a factor of about 20.

It is easy although not altogether convincing to increase R. The uncertainty in the threshold is probably a factor of at least 40. It is only necessary to believe that a fluence of 10^{12} α particles per cm^2 over geological time would produce colour in a region adjacent to one undergoing coloration and in the presence of a large fluence of electrons. In the absence of any information about the mechanism of colour formation in haloes, this is at least a possible assumption. In addition, the peak in the Bragg ionisation curve folded into the inverse square decrease in ionisation is, at the end of a 100-μm track, 30% higher than at the minimum on the track. With about half the nominal fluence it would be possible to achieve coloration at the ends of tracks although some intermediate parts along the tracks would not be coloured. Or again, metamictisation or recrystallisation might lower the density sufficiently to increase the range by 20% and thus the fluence at r_0 by as much as 40%. Together these factors could produce an R of 16.

It is necessary to recognise that only pure 'plutonite' has been discussed here. Most mineral inclusions are not pure. Mixtures of plutonite with other substances to lower the registration factor by factors of two, three or more are likely. This dilution of plutonium might have been offset by preferential fractionation of plutonium such as was mentioned above[5]. It is therefore appropriate to modify our model inclusion by assuming that it is only 50% plutonite. Under this assumption the registration factor for the model inclusion will be $R = 0.13$; optimally, for this model, R might equal 8.

Therefore, it seems likely there could be haloes of 50–60 μm size, and it seems conceivable that optimum conditions could result occasionally in giant haloes of up to 100 μm around an inclusion containing ^{244}Pu. Such a sequence of probabilities is consistent with the distribution of halo sizes shown in Fig. 2.

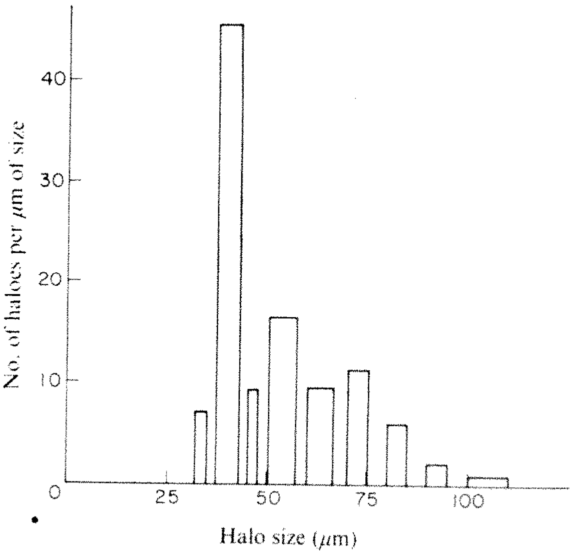

Fig. 2 Distribution of haloes by size. Size is measured from the nearest surface of the inclusion to the outer edge of the halo. These data are adapted from ref. 10.

It should be quite straightforward to determine whether a giant halo is due to ^{244}Pu. The size of the halo will be directly related to the size of the inclusion. The largest haloes should occur only around inclusions with dimensions of 50–100 μm; the smaller the inclusion, the smaller the halo. The short half-life of ^{244}Pu suggests that the substantial concentration of ^{244}Pu required to make a giant halo would have been more likely long ago, so the rock containing giant haloes should be old. Giant plutonium haloes should also have quantities of fission fragments in and around the central inclusion which could easily be detected by mass spectrometry and even by X-ray spectrometry. (Our model plutonite inclusion and halo would contain about 10^{13} fragments.) The fragments are 800 times as abundant as the α particles emitted in fission. There might also be detectable amounts of ^{244}Pu in the inclusion, but if the minimum number of nuclei needed to produce a fission α particle halo is 10^{15}, Fig. 1 shows that the rocks in which such haloes occur must be younger than 2.5×10^9 yr if plutonium is to be detectable.

Because of the vigorous thermal, physical and chemical history of the inclusion, it is likely that most etchable fission tracks in the vicinity of the inclusion would have been annealed out.

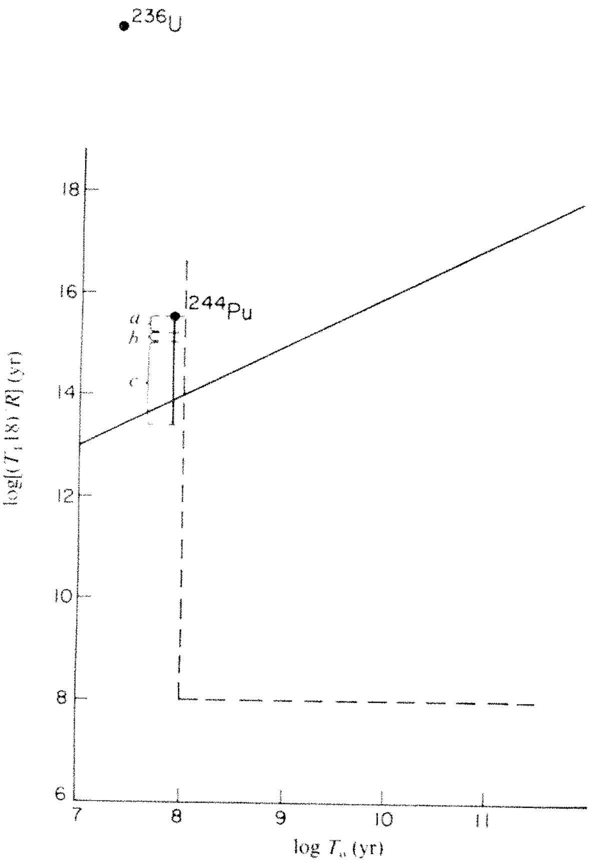

Fig. 3 Relation of α particle-fission half lives and overall half-lives that will permit production of giant haloes by fission alphas. The diagonal line is drawn assuming a threshold fluence of 4×10^{13} α particles cm^{-2}. Possible corrections to the location of ^{244}Pu are *a*, Bragg ionisation, *b*, changes in density and range, and *c*, lowering of the coloration threshold. At present no isotopes are known with values in the preferred region below the diagonal line and above and to the right of the dashed lines. ^{244}Pu is the closest.

The graph in Fig. 3 plots $T_1 a_0{}^2(a_0 - 1)/R$ against T_0. (R is a function of a_0, so a_0 cannot be varied independently of R.) For a nuclide to produce giant haloes by fission α particles, its half lives must define a point in the region below the diagonal line defined by the inequality, and above and to the right of lines corresponding to 10^8 yr. These last constraints are not well defined but take into account that if its half life were much shorter than the age of the Earth the likelihood of a nuclide being around long enough to be incorporated into a mineral is small. Plutonium 244 probably represents a lower limit.

Superheavy elements

The possibility of giant haloes from fission α particles is relevant to the suggestion of Gentry *et al.*[11] of the existence of the elements $Z = 126$, 127, 116 and 124, based on the X-ray spectra produced by proton bombardment of the inclusions of several giant haloes. The analysis of their spectra is complicated by the necessity of subtracting a large background from a nearly equal foreground. It seems possible that they may have been studying plutonium haloes and inclusions rich in fission fragments. The very elements they must argue are not contributing to the peaks attributed to superheavy elements are ones expected to be among fission fragments: Te, In, Sb and Xe. Moreover, the intensity of the peak identified as the $L_{\alpha 1}$ of $Z = 126$ is roughly of the right size and energy to be K_α X rays from $\sim 10^{11}$ Te fission fragments, somewhat less than the number to be expected in our model sample.

The association of the peak with $Z = 126$ is most strongly supported by the apparent discrepancy of 173 eV between the observed position of the peak (which is about three channels and 350 eV wide) and the expected position of the centroid of the Te K_α lines. The background, however, is so large that it seems possible that the subtraction procedure might shift the apparent position of the centroid enough to account for the difference.

The uncomfortable stretching of parameters required to form a ^{244}Pu giant halo is not the only alternative to balance against the hypothesis that the superheavy elements exist in their inclusions in quantities of "several hundred picograms" (ref. 11). There is the alternative of attributing giant haloes to an as yet undiscovered isotope or its short-lived descendants. The isotope could of course be a superheavy, but it seems as plausible that a new isotope could be a member of a known atomic species with a half life of $\sim 10^9$ yr and either a fission half life not much greater or a daughter isotope with a short fission half life.

Conclusions

It is reasonable to expect to find in nature pleochroic haloes produced by extinct or nearly extinct minerals of ^{244}Pu. These could be identified visually, by vestigial ^{244}Pu or ^{236}U in the central inclusion, or by the presence of the appropriate fission fragments.

Larger than normal haloes, perhaps up to 100 μm, might arise from the energetic alpha particles that occasionally accompany the spontaneous fission of ^{244}Pu. If the giant haloes observed in nature are not produced by the fission α particles of ^{244}Pu, they might, as Gentry *et al.*[11] suggest, come from elements $Z = 126$, 127, 116 and 124, or they may be caused by the fission α particles of some as yet undiscovered isotope.

To determine the relative probabilities of these phenomena, further study of the chemistry of plutonium pertinent to geological processes and mineral formation is required. Also, the coloration process should be examined, especially in the presence of combinations of fluxes of different radiations.

I thank the members of the Kellogg Radiation Laboratory for assistance, and C. A. Barnes, D. Burnett, T. Tombrello and G. Wasserburg for advice. I thank the US NSF for finance.

Tomato bushy stunt virus at 5.5-Å resolution

The coat of tomato bushy stunt virus is built from protein subunits having rigid domains connected by a flexible hinge. Two states of the hinge are present in the $T = 3$ icosahedral structure. Each subunit has a binding site for RNA on its inner surface.

DESIGN principles of regular viruses were first clarified by Caspar and Klug[1] who showed that quasi-equivalence could reconcile the variability of subunit packing (required to construct a shell of sufficient size) with the specificity of subunit bonding, necessary for self-assembly. The small, spherical RNA viruses pose two important structural questions: how is quasi-equivalent packing of identical protein subunits achieved, and how is the nucleic-acid chain accommodated in the particle? We describe here a 5.5-Å resolution electron-density map of tomato bushy stunt virus (TBSV), and derive some initial answers.

The TBSV particle comprises a single molecule of RNA (MW 1.5×10^6), 180 coat protein subunits (MW 41,000 each) and perhaps one copy of a larger polypeptide[2-4]. The coat protein forms a $T = 3$ icosahedral surface lattice, with prominent dimer clustering at the outside of the particle[5]. This design implies that a single kind of polypeptide chain packs in relation to its neighbours in three slightly different ways (Fig. 1). X-ray crystallography[6,7] has revealed the orientation of local symmetry axes and suggested that the differences between quasi-equivalent contacts is related to RNA-induced perturbations.

The structure has been solved using multiple isomorphous replacement, combined with phase refinement by icosahedral averaging. Problems for data collection due to the large unit cell were solved using a focusing X-ray camera[8], and a strategy for oscillation photography appropriate to the restriction that only one exposure can be obtained per crystal[9]. As in the 5-Å resolution study of the tobacco mosaic virus disk[10], a problem of comparable magnitude, exploitation of the non-crystallographic symmetry[11] has been important for obtaining a good map.

Data collection and phase determination

TBSV crystals, obtained as described before[7], are cubic, space group I23, $a = 383$ Å. Each lattice point of the body-centred cubic cell is occupied by one virus particle, such that the crystallographic point group is the tetrahedral subgroup of the viral icosahedral symmetry.

X-ray intensities were measured by oscillation photography from crystals of the native virus and of two derivatives, $PtCl_6^{2-}$ and Hg^{2+} (Table 1). Coordinates for the $PtCl_6^{2-}$ derivative were available from earlier work, refined in projection to 9 Å (ref. 7). A difference-Fourier *hk*0-projection for the Hg^{2+} derivative at 9 Å, (from a 6° precession photograph), using signs from $PtCl_6^{2-}$, revealed two sets of quasi-equivalent sites (six sites per icosahedral asymmetric unit). One of these corresponds to the CH_3Hg^+ sites used in the 16-Å work[7], and the other to positions near the subunit tips. After conventional refinement, the average figure-of-merit was 0.57 (Table 2). Fivefold molecular averaging was then carried out using recently developed methods[11]. After one cycle of phase refinement the mean figure-of-merit was 0.76 (Table 2). Previous experience suggested that additional cycles were unlikely to improve the map further[7,10]. A second map was computed using the combined phases, icosahedrally averaged[11].

Electron density map

It is convenient to look at the electron density map in sections normal to a crystallographic twofold (arbitrarily chosen as the *Z*-axis). The 16-Å resolution map[7] shows that the quasi-threefold axis is approximately parallel to the nearest strict twofold (Fig. 1), so that quasi-threefold related electron density features appear in almost the same *Z*-sections. The triangle shown in Fig. 1 is thus a useful choice for the icosahedral asymmetric unit, and we chose to contour on acetate sheets a region somewhat larger than this triangle, indicated by the rectangalar outline.

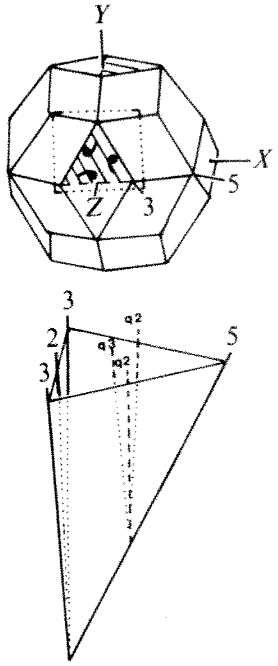

Fig. 1 Orientation of TBSV symmetry axes and choice of icosahedral asymmetric unit. *a*, Rhombic triacontahedron, showing some icosahedral symmetry axes. This figure has icosahedral symmetry, and it is useful for representing a $T = 3$ icosahedral surface lattice. The triangular half-face (shaded) is an asymmetric unit of the surface, that is, this region, replicated by the various symmetry operations, will cover the entire surface. In a $T = 3$ lattice, there is a local threefold axis near the centre of this triangle, relating the three quasi-equivalent subunits in the icosahedral asymmetric unit. Note that *X*, *Y* and *Z* are twofold axes. The rectangle indicates the area of the electron-density map, computed in sections normal to *Z*, chosen for contouring (compare Fig. 2). *b*, An asymmetric unit of volume in a region governed by icosahedral symmetry. This volume, replicated by the various symmetry operations, will fill the rhombic triacontahedron in (*a*); it can be thought of as the domain swept out by the upper shaded triangular half-face in (*a*) on a series of concentric rhombic triacontahedra of continuously increasing radius. Orientations of local (quasi) symmetry axes (denoted by small numbers) are also shown. The quasi-twofold and threefold axes around each fivefold axis intersect it, about 60 Å out from the particle centre.

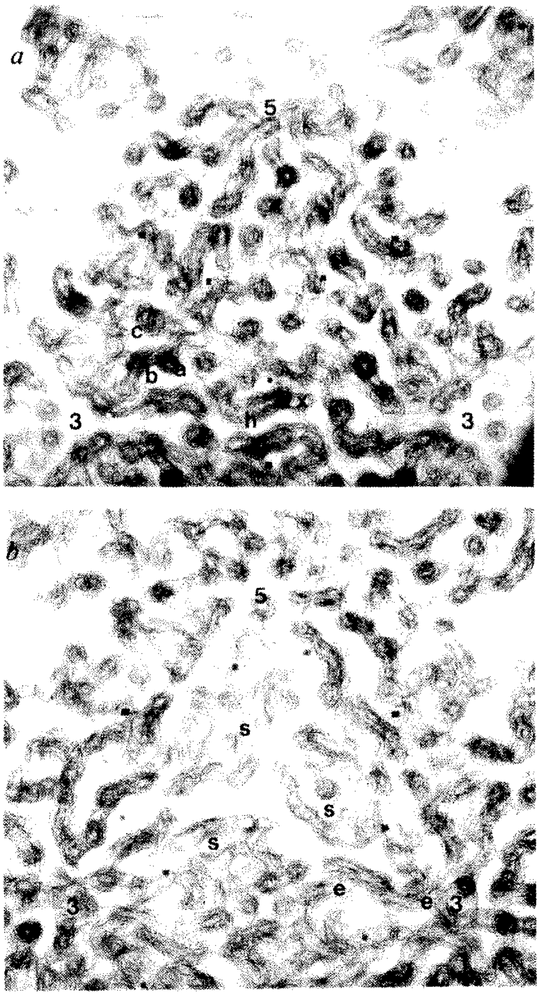

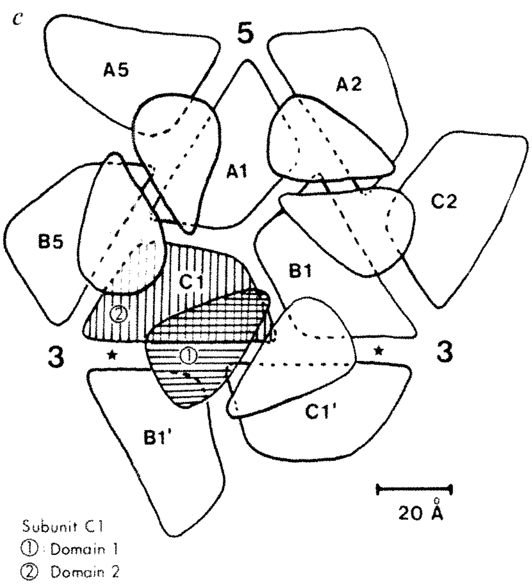

Fig. 2 Views along Z through sections of the TBSV 5.5-Å electron density map. *a*, $Z = 125$–140 Å; *b*, $Z = 110$–125 Å. Figure 1 gives orientation. Some features of secondary structure are indicated by lower-case letters: *X* is the inter-domain connection; *h*, the tangential rod; a, b and c, some radial rods; s, the saddle-like feature; and e, the extra density. The subunit boundaries may be judged by reference to (*c*). *c*, Packing of subunits and domains. A1, B1 and C1 represent subunits packed in one icosahedral asymmetric unit, related to each other by quasi-threefold rotation; A2, . . . , A5, are related to A1 by fivefold rotations; similarly, B1, . . . , B5 and C1, . . . , C5; B1′ is related to B1 by a strict dyad, A2 to B1 and B5 to A1, by quasi-dyads. The domains are indicated in rough outline: barrel-shaped domains 1 protrude outwards from the surface, making only twofold contacts; the more extensive domains 2 make contacts across all adjacent symmetry axes, forming a continuous polyhedral shell. The shading of C1 indicates which domain 1 is associated with the labelled domain 2. Domains 1 for C2, B1′ and A5 are not shown. Stars indicate the interrupted contact ('cleft'), occupied by RNA. The scale is the same for (*a*), (*b*) and (*c*).

Table 1 Statistics of data collection to 5.5 Å

	Native	$PtCl_6^{2-}$	Hg^{2+}
Total fully recorded reflections measured	69,000	75,000	65,000
No. of independent reflections measured	26,700	27,100	26,700
$R_{\text{sym}} = \sum_{h,i} \lvert I_i - \bar{I} \rvert / \sum_h \bar{I}$	0.100	0.133	0.145
Mean isomorphous difference $= \langle \lvert I_{\text{nat}} - I_{\text{der}} \rvert \rangle / \langle I_{\text{der}} \rangle$	—	0.29	0.56

Data were collected by oscillation about [101], the shortest axis in reciprocal space; rotation from 0° to 20° (where 0° corresponds to [101] coincident with the X-ray beam) includes more than 90% of the 29,000 independent reflections to 5.5 Å. The crystals thus always present a rather plate-like aspect to the X-ray beam, which is much smaller than the crystal diameter, so absorption effects are minimised. The oscillation range of a single 20–24-h exposure was 55–65′ of arc. Exposure usually exhausted the crystal lifetime, so that we could not add partially recorded reflections from abutting photographs[12]. Partial reflections, about ⅓ of those recorded, were not included in the data set but the ratios of the measured intensities of some of them to the intensities of corresponding symmetry-related whole spots on the same film, were used to obtain an accurate estimate of crystal orientation and hence an accurate discrimination between fully and partially recorded reflections[9]. Because of the small cross-fire in the focused beam and the small mosaic spread of the crystals, a 10–15′ overlap of adjacent exposures ensured that all reflections were fully recorded on film. Films were densitomered using a PDP-11/20-linked Optronics Photoscan and a modified version of the program SCAN 12 (ref. 13). The output included an integrated intensity and a standard deviation for each reflection, the latter determined from the actual standard deviation of the measured background. The three films in a pack were scaled to each other by the method of Fox and Holmes[14]. The approximately 3,000 fully-recorded reflections were sufficient to generate a Wilson-type plot of ⟨I⟩ against $\sin^2\theta/\lambda^2$, and these plots were used to determine relative scale and temperature factors for each film pack.

The electron-density features within this icosahedral asymmetric unit begin at about $Z = 112$ Å and extend out to $Z = 170$ Å. At $Z \sim 110$ Å there are faint and rather wispy but relatively continuous features. From $Z = 112$–140 Å, the volume is entirely filled with dense features, and at larger values of Z, density is concentrated more and more around the strict and quasi dyads, leaving large gaps in between. The icosahedrally-ordered part of the virus structure can thus be described as a roughly 30-Å thick, compact polyhedral shell, from which 90 protrusions, the dimer-clustered morphological units so clearly seen in electron micrographs, emerge.

Boundaries and domains

Figure 2*a* shows the composite electron density of sections from the central part of the polyhedral shell. Local threefold symmetry is visible in the central part of the asymmetric unit, and there is striking similarity of corresponding parts of quasi-equivalent subunits. Assignment of subunit boundaries was aided by the requirement that symmetry-related density features near an axis must belong to different subunits, even though they may seem weakly connected. A good illustration of the clarity of most boundaries is the gap running more or less along the lower edge of the icosahedral asymmetric unit (connecting the strict threefolds) in Fig. 2*a*. The quasi-equivalent boundaries, not as pronounced in this view, show up equally well if viewed along the local dyad.

The most outstanding characteristic of the subunit is that it falls into two very distinct, globular domains (Fig. 3). The smaller of these (domain 1) forms half of one of the dimer-clustered protrusions; the larger (domain 2) forms part of the polyhedral shell. Domain 2 has a rather distinct, saddle-like feature just against its innermost surface, which we describe in the next section. The two domains are connected at only one place by a narrow

Table 2 Phase determination

$R_c = 0.55$, $R = 0.53$, r.m.s. f_c/r.m.s. $E = 1.9$, mean ΔF/mean $F = 0.26$						

Z, occupancy in electrons, on experimental absolute scale[7]; B, heavy-atom 'temperature factor'; R, $\Sigma||\Delta F_{obs}|-|\Delta F_{calc}||/\Sigma|\Delta F_{obs}|$, all reflections; R_c (Cullis R factor), R for centric reflections; E, lack of closure at best phase; f_c, heavy-atom structure factor; r.m.s., root-mean square.

Statistics of molecular averaging up phase refinement.

Figures of merit: initial (DIR), 0.57; final (combined), 0.76.

Comparison of calculated and observed structure factors:

$R = \langle||F_{obs}|-|F_{calc}||\rangle/\langle|F_{obs}|\rangle = 0.37$.

Mean phase difference $= \langle|\alpha_{calc}-\alpha_{DIR}|\rangle = 47°$.

Mean phase change after combination $= \langle|\alpha_{final}-\alpha_{DIR}|\rangle = 25°$.

Alternate rounds of phasing and icosahedrally-constrained least-squares refinement[7,15] used starting coordinates obtained as described in the text. Coordinates and occupancies for both derivatives were refined in projection, first at 9 Å then at 5.5 Å, and finally in three dimensions against a set of approximately 3,500 reflections representing a random sample of resolution and intensity ranges, selected with the criterion that the precision of heavy-atom intensity differences meet a pre-determined minimum. After refinement in projection, self and cross-difference maps gave no evidence for additional sites, a conclusion confirmed in three dimensions. Site names correspond to the subunit to which they were subsequently seen to bind (compare Fig. 2*c*), and only one icosahedral asymmetric unit of sites is given. The quoted values of R_c and so on, refer to the 3,500 well-measured reflections used for the refinement. For icosahedral phase refinement, an initial map, computed on a 1.1-Å grid for accurate interpolation[11], was averaged about the icosahedral fivefold axes to determine the molecular envelope; density not part of the particle to which these axes refer is smeared out by this procedure, enhancing the boundary contrast. The final envelope for an entire virus particle is a rhombic triacontahedron (Fig. 1) with roughly cylindrical 'pillars' at each twofold and quasi-twofold position, where subunit tips protrude[7]. Averaging and setting all density outside this envelope to zero yielded a symmetrised map (2.2-Å grid), from which structure factors were computed. The agreement between observed and calculated amplitudes is tabulated: most of this residual comes from the scatter of the figure-of-merit around its mean value in resolution shells[11]. Calculated and DIR phases were combined using the Sim formula[16].

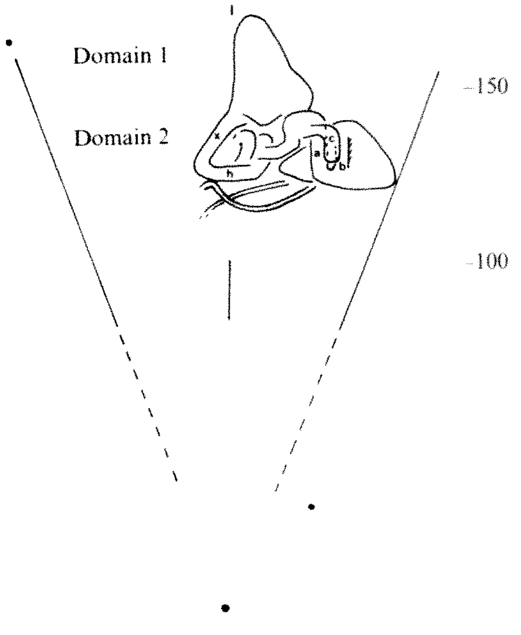
region of strong electron density: each domain thus appears to contain one terminus of the polypeptide chain.

Domain 1 is about 30 × 30 × 25 Å in overall dimensions. It consists of two approximately parallel layers, oriented such that one layer forms an extended and tight dimer contact with domain 1 of the twofold (or quasi-twofold) related subunit. The general distribution of electron density in this domain resembles very strongly the β-barrel structures, also found dimer-clustered, in immunoglobulin fragments[17,18] and in superoxide dismutase[19]. The outer layer of the barrel is markedly curved; the inner appears quite flat, especially in the contact region. The strand directions in each layer cannot be established with certainty in a 5.5-Å map, but there is definite indication of a radial rather than tangential course. The outer layer of the barrel is markedly curved; the inner seems quite flat, especially in the contact region. The strand directions in described below.

The connection of domains 1 and 2 is well defined and occurs at the point marked with a cross in Figs 2*a* and 3. Domain 2 itself is considerably more complex than domain 1, both in its internal structure and in its interactions with adjacent subunits. Nevertheless, its boundaries appear rather well determined, with one major ambiguity (see below). In tracing a boundary, we used the symmetry criteria described earlier and assumed that the domain is a reasonably compact globular unit. Figure 2*c* shows schematically the relation of domains 1 and 2 and the nearest-neighbour packing in the protein shell.

Domain 2 has a number of rodlike features indicative of α-helices (these are absent in domain 1). These rods are oriented more or less radially with one important exception, which we refer to as the tangential rod (h, in Fig. 2*a*). As seen in Figs 2*a* and 3, one end of this rod connects with the feature that forms the junction between the two domains. The tangential rod is 15 Å long (2–3 turns of α-helix) and located close to the dyad, such that the distance between twofold-related helical axes is 10 Å. Each rod is tilted slightly out of the plane normal to the dyad, and we have chosen the enantiomorph such that the tilted rods have a left-handed relationship. This packing is appropriate for right-handed α-helices[10,21]. Closely-packed, radially-oriented rods in domain 2 show the same relative tilt, and the twist of the outer wall in the domain 1 β-barrel is also consistent with this choice. The three most prominent radially-directed rods (a,b,c in Fig. 2*a*) seem to be in direct contact. Their lengths correspond to 2–3 turns. Rods a and b are tightly packed, whereas rod c is somewhat farther away. The principal ambiguity in boundary tracing, mentioned above, concerns the assignment of c and some connected density to subunit C1 (Fig. 2*c*). The alternative assignment of c to A1 leads to

Fig. 3 Schematic representation of the electron density in one subunit, viewed normal to the adjacent dyad and looking toward that dyad from the quasi-threefold. If the drawing is taken to represent C1 in Fig. 2*c*, then the direction of view is downwards in the plane of that figure. The lobe at the outside of the subunit (Z = 140–170 Å) is the β-barrel of domain 1; the cross indicates its connection to the more extensively α-helical domain 2; the 'saddle' lies beneath domain 2, and a tentative interpretation in terms of two stretches of RNA backbone is shown in the diagram.



a more extended domain 2, but the choice is arbitrary. In the pentamer (or hexamer) contact regions near the bottom of domain 2, the density has a layer-like character, suggestive of β-sheet. Rods a and b are packed partly against this sheet-like feature. There are a number of shorter pieces of rodlike density, less clearly α-helices. One of these occurs close to the local threefold axis: the three such symmetry-related rods appear to form a sort of rudimentary, left-handed, three-stranded coiled-coil[21].

We estimated the volume occupied by all the strong features of one subunit as $51{,}000 \pm 6{,}000$ Å^3, where the upper and lower limits correspond to generous and restricted estimates of surrounding side chain, Fourier cutoff and so on. If all this volume were protein, the corresponding MW would be $39{,}000 \pm 5{,}000$ (taking $\bar{v} = 0.74\ \mathrm{cm^3\ g^{-1}}$). Twelve nucleotides, our upper estimate for RNA in the saddle feature, occupy about 3,400 Å^3 (taking $\bar{v} = 0.51\ \mathrm{cm^3\ g^{-1}}$). We can thus account for most of the protein subunit, although some 10% of the chain could be outside strong density in the present map.

Nucleic acid

A significant problem in interpreting the TBSV electron-density map has been to establish criteria for recognising RNA. Strength of the density alone proved insufficient: the features described below are among the strongest in the map but no stronger than the α-helices. This is not surprising because partial occupancy of polynucleotide binding sites and other sorts of static disorder would diminish the corresponding density. A general picture of the nucleic acid might be one of ordered regions of backbone, bound to protein, interspersed with more disordered regions at smaller radii. The overall appearance of the map at about 110 Å from the particle centre is consistent with this view: strong features trail off towards the centre in little streamers of density. The distribution of this streaky density suggests that the polynucleotide chain may enter or leave a binding region in more than one way, but the strength of the beaded features to which they join indicates a definite conformation in the binding site.

A striking aspect of the map is the complicated and cross-connected texture of features between 110 and 120 Å, in contrast to the rather clear sheet-like or rod-like density of domains 1 and 2. In this region, each icosahedral asymmetric unit shows three very similar, though not precisely identical, saddle-shaped features, about 30 × 20 × 10 Å in extent (s in Fig. 2*b*). Each of these saddles forms the innermost density associated with one protein subunit. In addition, there is a set of strong features with no quasi-equivalent counterpart extending from near the strict twofold toward the strict threefold axes; we refer to this as extra density (e in Fig. 2*b*). Since the protein subunits are identical and since RNA is the only other significant component, this extra density is likely to represent part of the nucleic acid chain. Inspection of a 5.5-Å resolution map of yeast-phenylalanyl tRNA (computed as an F_{cal}, α_{calc} map by A. Jack, MRC Laboaratory of Molecular Biology, Cambridge) shows that the sugar phosphate backbone has a quite characteristic appearance: a continuous stretch of density with barely resolved maxima spaced at distances of 6–7 Å, at or near the positions of phosphates, giving it a beaded aspect. Both the extra density and certain parts of the edges of the saddles have just this 6–7-Å beading. Moreover, the saddle lying beneath subunit C is connected to the extra density at several points, with the 6–7-Å periodicity continuing from one to the other. We therefore conclude that a significant part of the density between 110 and 120 Å represents polynuceotide chain.

The saddle features form rather distinct lobes of density just against the bottom of domain 2. We followed possible RNA backbone configurations in this region, although, in view of the ambiguities involved, such a tracing is rather speculative at this resolution. We believe that we can recognise two pieces of RNA backbone (Fig. 3). One of these emerges from the particle interior and passes near the strict or quasi-twofold; the second forms the outer rim of the saddle. We detected 10–12 possible phosphates. Density between these chains could in part be nucleotide bases, and the backbones are so oriented that they could be joined by two or three base pairs in the A-RNA geometry.

No simple description would seem to summarise protein-RNA contacts. The structure of domain 2 shows that several portions of the polypeptide chain, separated in the amino acid sequence, must come together to form the shallow pocket in which the saddle feature lies. Stretches of α-helix, as well as a region that may be β-sheet, are involved.

States of the protein subunit

The clarity of the electron density map has facilitated quantitative analysis of subunit similarities. The coat protein assumes two clearly different conformational states, depending on whether it is near a local or a true dyad in the $T = 3$ surface lattice. The individual domains 1 and 2 are essentially invariant, and a hinge between the rigid domains relates the two subunit conformations.

Corresponding well defined electron density maxima could easily be recognised in all three quasi-equivalent subunits and their superposition determined after appropriate rotation and translation. Referring to Fig. 2*c*, subunits A and B superpose very well, whereas A (or B) and C do not. Taken separately, however, domains 1 and 2 of A (or B) can be superposed with their analogues in C as well as A and B can be matched to each other. This implies that the relative orientation of domains 1 and 2 in C is different from their relative orientation in A or in B, but that individual domains are nearly invariant. The hinge between domains is

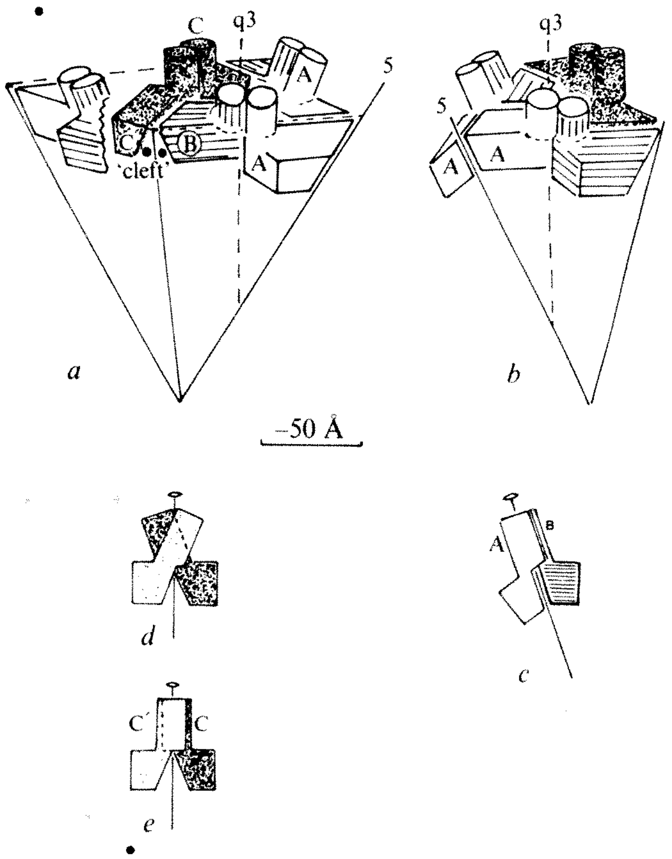


Fig. 4 Packing diagrams, showing subunits and relative orientation of the two domains. *a*, View similar to Fig. 1*b*, with a second icosahedral asymmetric unit replicated by the strict twofold axis. Each subunit is represented by a cylinder (domain 1) on a block-like base (domain 2). The three quasi-equivalent subunits are shown: white (A), hatched (B) and stippled (C). *b*, View of an icosahedral asymmetric unit, rotated 120° with respect to the view in (*a*). Considering just the domain 2 contacts, note that the A–A contact about the fivefold axis and the B–A contact across the quasi-dyad are quite tight, whereas the B–C′ and C–C′ contacts about the quasi-sixfold and strict twofold axes are opened up to produce a cleft. The difference in the angle of contact across quasi (A–B) and strict (C–C′) dyads requires a change in the angle between domains 1 and 2 to preserve the dimer pairing of domains 1. This is shown in (*c*–*e*): the A–B contact (quasi-dyad) is depicted in (*c*). If the contact between the domains 2 were altered, without a relative reorientation of domains 1 and 2 in each subunit, the C–C′ contact (strict dyad) would appear as in (*d*). In fact, there is rotation by approximately 20° about a hinge between domains 1 and 2, producing the sort of contact shown in (*e*).

located just above the end of the horizontal α-helix (Fig. 3). The hinge rotation axis is approximately parallel to the axis of the tangential rod, and the angle of rotation is about 20 (for C, relative to A or B). There are small, though significant, differences between A and B, but the hinge position is clearly the same for both.

The inter-subunit contacts of the hinged protein are represented in Figs 2*c* and 4, which show how the hinge leads to quasi-equivalent subunit bonding. Domains 1 have large and essentially identical contacts across both local and strict twofold axes. Domains 2 are likewise in extensive contact around the local threefold axis, which, for these domains, approximates well to an exact triad. Schematically, the polyhedral shell formed by all the domains 2 can be represented by 60 wedge-like trimers in continuous contact across local dyads but with only their outer edges in contact across strict dyads (Fig. 4). This produces a cleft connecting strict threefold (quasi-sixfold) axes. The quasi-sixfold relationship is thus very inexact: domains 2 of C1 and B5 in Fig. 2*c* are related essentially as A1 and A2, whereas the analogous contact between B1′ and C1 (star in Fig. 2*c*) is largely broken by the cleft. This is in fact the only place where contacts are not basically the same for all three quasi-equivalent subunits. It is the hinge between domains 2 and 1 of subunit C that permits the cleft to open (Fig. 4*e*); without it, TBSV protein could form only a simple $T = 1$ icosahedral shell. Since 'extra' electron density features appear in the cleft, but not in the tight contacts between C1 and B5 or A1 and A2, RNA may play a significant role in regulating assembly of correct-sized, $T = 3$ particles. RNA-free, $T = 1$ structures have indeed been observed in studies of reassembly of the related turnip crinkle virus[23].

Domains and hinges

The generalisation that large polypeptide chains will fold into smaller, compact domains has gained considerable strength from the several proteins solved thus far with subunit molecular weights greater than 30,000 (refs 24–26). The two domains of TBSV protein have approximate molecular weights of 15,000 and 25,000; in the scheme of Levitt and Chothia[27] they seem to be members of class II (all β) and III ($\alpha + \beta$), respectively.

The TBSV subunit is not the first example of a protein with flexibly-linked domains. The immunoglobulins are the classic case of such a structure[17], and the relation between light chains in the Mcg Bence–Jones dimer[18] is precisely analogous to the situation in TBSV: one of the chains in this dimer (the chain with a 'heavy-chain-like' configuration) bends at a hinge point, in order to conserve strong inter-molecular contacts. This type of structure could lead to controlled polymorphism in assembly.

The presence of RNA in the cleft at the C1/B1′ interface seems to dictate the nature of inter-molecular contact and hence the choice of a $T = 1$ or $T = 3$ design. Since the angle of the contact is determined by the hinge angle, binding of ligands to residues in the hinge region, or at the domain 1/domain 2 interface, could likewise influence the mode of association. In general, a subunit with flexibly-connected rigid domains can be a useful element for controlled switching between distinct states of a macro-molecular assembly. Work on a 2.8-Å resolution map of TBSV is underway.

We thank James Crawford for the SCAN 12 oscillation film scanning program, A. Jack for programs and a tRNA map, D. L. D. Caspar for advice, W. N. Lipscomb for use of an Optronics scanner and P.D.P. 11/20, Howard Bailey for technical assistance, Athena Andriadis for aid in data processing and the Harvard Chemistry Department for computing facilities including a remote terminal to the Columbia University IBM 360/91. The work was supported by a grant from the NCI. S.C.H. acknowledges a USPHS Research Career Development Award and F.K.W. a fellowship from the Swiss National Fund.

Far infrared observations of IRC + 10216

THE detection of infrared radiation in the 1.2–20 μm band from IRC + 10216 was first reported by Becklin *et al.*[1]. Toombs *et al.*[2] determined its angular size by lunar occultations at 2.2, 3.5, 4.8 and 10 μm, and deduced that the source is a late-type carbon star surrounded by a dust shell with two components: a bright, optically thick central component with a characteristic diameter and temperature of 0.4″ and 600 K, respectively, and an outer component of diameter 2″ and a temperature around 375 K. The longest-wavelength ground-based observations were made by Low, Rieke and Armstrong[3] at 34 μm, and the only other far infrared measurements are those of Campbell *et al.*[4]. We present here measurements of IRC + 10216 at 100 μm made with the 91-cm telescope of the NASA G. P. Kuiper Airborne Infrared Observatory[5].

The infrared photometer consists of a gallium-doped germanium (Ge:Ga) photoconductive detector with a Mosfet pre-amplifier and load resistor, all of which were cooled to liquid helium temperature. Fabry optics were used to reduce the background radiation on the detector, and a 4-mm aperture was used to define a 0.9′ circular field of view. The instrumental passband was defined by cold filters (crystal quartz and Yoshinaga filters) at the field aperture. The spectral response of the detector–filter combination shown in Fig. 1*a*, was measured by using a Perkin–Elmer grating spectrometer and normalised to a Golay detector.

The Bent Cassegrain mode was used with the infrared photometer mounted in the aircraft cabin. Modulation and background calculations were achieved with an oscillating secondary mirror operated at 30 and 100 Hz. The half-power beamwidth was 0.9′ and the separation between modulated beams was 2′.

Owing to mechanical difficulties with the aircraft, only one flight was made on March 9, 1976. Mars was observed for calibration

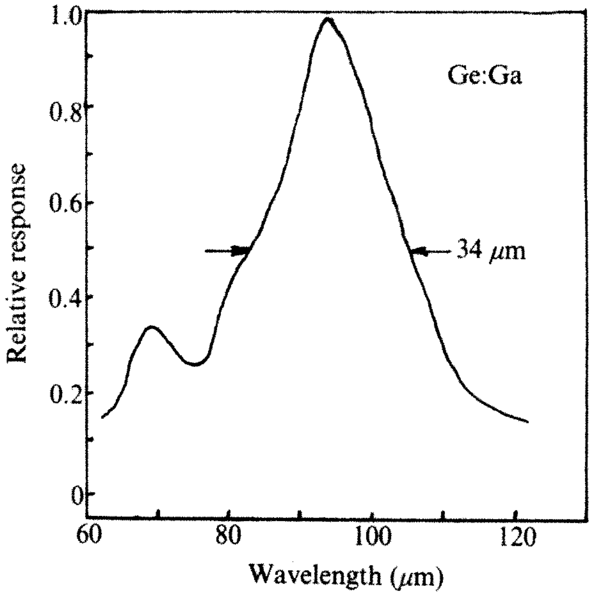

Fig. 1 *a*, Spectral response of Ge:Ga detector;

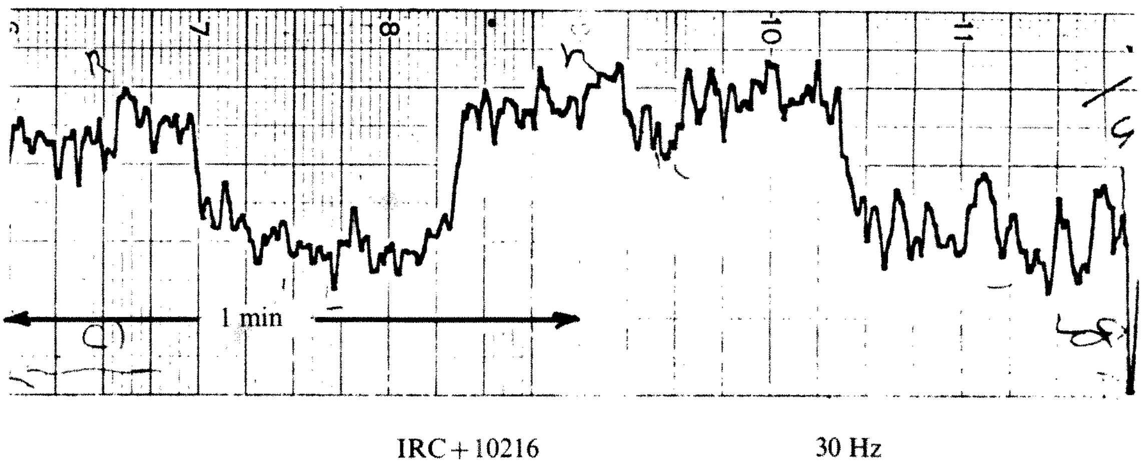
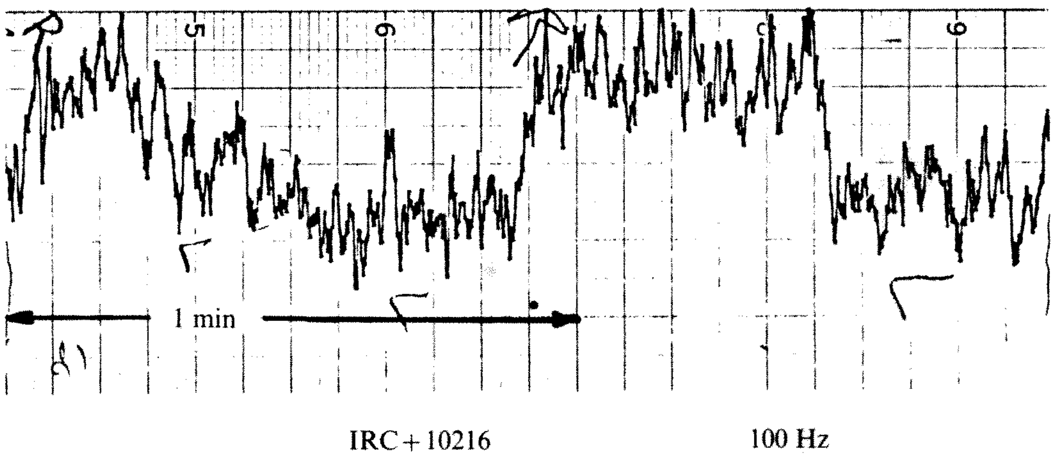


b, signal from IRC + 10216 at 30 Hz;



c, signal from IRC + 10216 at 100 Hz.

purposes for 5 min and IRC + 10216 for 30 min. Figure 1*b* and *c* shows the signals obtained from IRC + 10216 at modulation frequencies of 30 and 100 Hz; the two levels are produced by pointing the telescope so as to place the source in alternate beams. The apparent signal-to-noise ratio for both measurements was 6:1 but because of the wider recording bandwidth, the 100-Hz data are in fact less noisy when normalised to unit bandwidth. The flux level for IRC + 10216 was obtained by assuming a brightness temperature of 200 K for Mars, whose semi-diameter at the time of observation was 39.9″. Our 100-μm flux measurements of IRC + 10216 as shown in Table 1 agree with the measurements of Campbell *et al.*[4]. A unique aspect of this measurement is the use of

Table 1 100 μm flux measurement of IRC + 10216

2.4-µm mapping of the galactic central region

OBSERVATION of the diffuse galactic radiation at near infrared wavelengths where the interstellar extinction becomes comparatively small could be an effective way of investigating the galactic structure especially in the central region of the Galaxy. We report here observation of the diffuse galactic radiation at 2.4 µm in the central region of the Galaxy between $l = 350°$ and 30° using a balloon-borne telescope with a resolution of 1°. The central bulge of the Galaxy, and the very flat and narrow disk components were clearly demonstrated. A strong interstellar extinction concentrated in the galactic plane in the central region of the Galaxy was observed.

Our first observation by a balloon-borne telescope with wide spectral response (1.5–2.5 µm) was subject to unexpected temporal and spatial irregularities of the OH airglow emission[1]. For near infrared observation of the diffuse light at balloon altitudes we thus limited the wavelength range to between 2.35 and 2.45 µm; a unique band gap of the OH emission bands.

The successive observations were made on June 16, 1975 and May 31, 1976 by a 20-cm (f/1.25) balloon-borne telescope with two 5×5-mm² PbS detectors cooled by liquid nitrogen, each with a 1° square field of view, separated by 3.2° in elevation. The filters, which were also cooled, had an effective wavelength $\lambda_e = 2.4$ µm and a bandwidth $\Delta\lambda = 0.08$ µm.

A malfunction of the chopping motor in the flight of 1975 limited the intensity profile across the galactic plane at $l = 6°$. During the flight on May 31, 1976, we scanned the extended area along the galactic plane between $l = 350°$ and 30° within latitudes of $[b] \leq 10°$ in such a way that the elevation angle was stepped up by 0.9° after each strip scan of 30° width in azimuth.

The direction of the telescope was assigned to celestial coordinates with the aid of a geomagnetic aspectometer for the azimuth sensor and an elevation meter with a potentiometer. Definite detections of several bright IRC stars facilitated a check on the accuracy of the position determination, estimated to be ±0.3° throughout the observation.

The absolute responsivities of the detectors were calibrated by observing α Sco ($m_K = -3.87$) (ref. 2) and also monitored by an artificial calibration light during the flight. The contribution of nearby infrared objects, a single or a group of IRC stars, was subtracted by referring to *K*-magnitudes in the infrared catalogues[3,4].

The two detectors yielded independent values for the brightness distribution, and the consistency between these was satisfactory. The brightness values were synthesised into a map (Fig. 1). The data beyond $l = 27°$ may be less reliable because of a fault arising in the transmitter system, so the map has been limited within $l = 27°$. Our map tends to be smoothly linked to that presented by Hayakawa *et al.*[5].

The marked concentration of the surface brightness toward the galactic centre clearly implies that the central bulge or the spheroidal stellar distribution of our Galaxy has been detected. This constitutes the first demonstration of the deep inner structure of our Galaxy. The apparent shape of the central bulge must be subject to the interstellar extinction which should be highly concentrated in a narrow zone along the galactic plane. This is clearly indicated by the fact that the highest contours close to the galactic centre are prolonged not along the galactic equator, but perpendicular to it. The 2.4-µm brightness at the galactic centre is $1.6 \pm 0.03 \times 10^{-9}$ W cm^{-2} sr^{-1}.

Figure 2 shows the 2.4-µm brightness distribution along the galactic equator, the 2.6-mm CO line intensity[6] and the 100-µm brightness[7]. The near infrared profile seems to consist of two components, the central spheroidal structure and the flat disk component. Flatness beyond $l = 10°$ is remarkable, extending to the sudden decline near $l = 30°$, which was found by Hayakawa *et al.*[5]. This would imply a strong concentration of infrared sources in the 5-kpc ring as discovered from the CO observations[8]. Thinness of the disk component (4° in FWHM) is also prominent.

The concentration of the spheroidal component toward the galactic centre is much less steep compared with that observed in M31 in infrared[9,10], and in visual brightness distributions[11]. If the intrinsic brightness distribution of the central region of our Galaxy is the same as that of M31, the difference could be attributed to obscuration by a dense dust layer lying in the central region of the Galaxy. This dust layer extends mainly within $b = \pm 1°$, with a slight concentration towards the galactic centre. The total amount of the extinction in direction to the galactic centre is about 2.4 mag at 2.4 µm, corresponding to $A = 30$ mag, if we assume the general wavelength dependence of the interstellar extinction. It is almost compatible to the value obtained by Becklin and

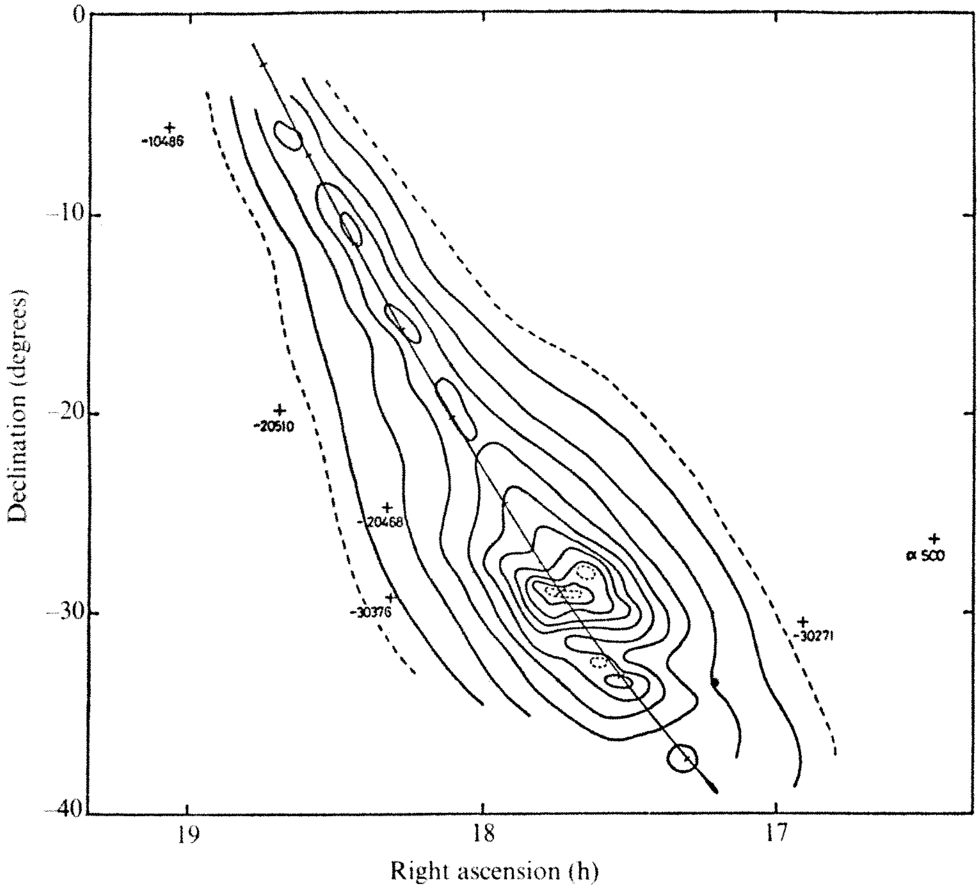

Fig. 1 2.4-μm map of the galactic diffuse light. Unit of the contour is 1.6×10^{-10} W cm^{-2} μm^{-1} sr^{-1}, dashed contours indicate half interval. Crosses indicate the positions of IRC stars used for the position calibration.

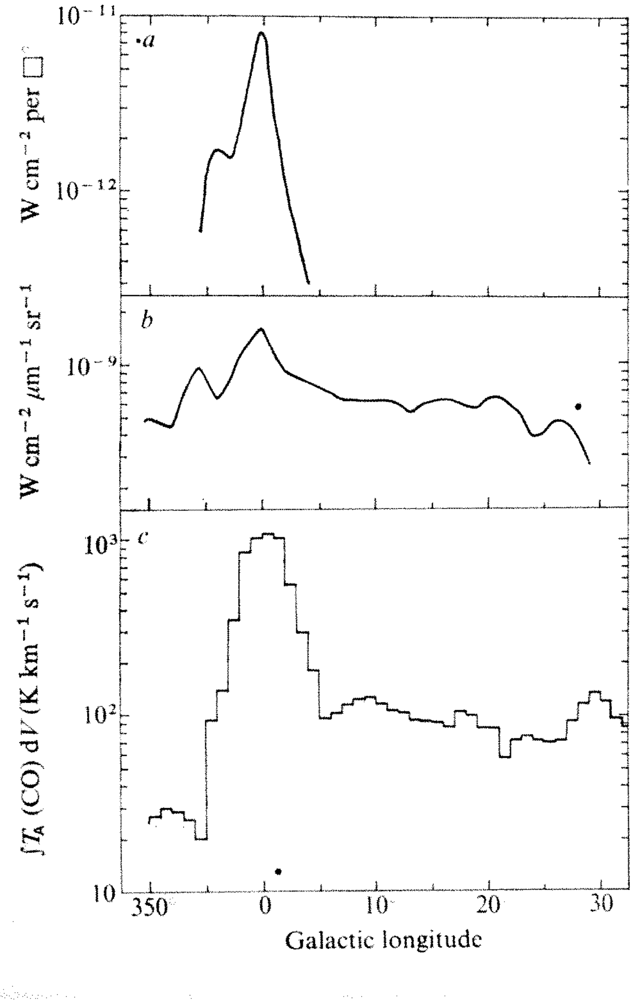
Fig. 2 *b*, Longitudinal dependence of the 2.4-μm intensity along the galactic equator. Those of *a*, the 100-μm intensity, and *c*, the CO intensity ($J = 1 \rightarrow 0$) are shown for comparison.



Neugebauer[12]. About one third of the extinction is attributed to the dust layer in central region of the Galaxy, that is, within $l = \pm 2°$. This dust layer corresponds well to that detected as the extended far infrared source by Hoffmann *et al.*[13] and Soifer and Houck[7], and may be related to the CO molecular clouds concentrated in the galactic centre.

It is noticeable that there is an asymmetry between positive and negative sides of the galactic longitude. A dip near $l = 357°$ may correspond to the subsidiary peak in the 100-μm profile. A peak near $l = 354°$ is also interesting. Open clusters NGC 6383 and 6405 (M 6) locate at the same position but seem to be insensitive to the 2.4-μm brightness. Similar features have been found in the balloon observation made by the infrared group of Nagoya University (T. Matsumoto, personal communication).

Whether these features are caused by variation in local interstellar obscuration or by some hidden objects should be clarified by further investigation.

We thank the staff of the Sanriku Balloon Centre for assistance; also Professor H. Hasegawa and other members of our infrared group for their encouragements.

Infrared profile of central region of our Galaxy at 2.47 μm

SEVERAL investigators have described the features around the galactic centre in some infrared wavelength regions[1-3]. Their results demonstrate the conspicuous peak and several humps around it. These observations, however, are confined to a rather small region mainly because of the terrestrial background radiation. So the overall feature of the central bulge of our Galaxy could not be derived. Studies of the central bulge have been carried out only with the aid of the distribution of RR Lyrae variables through the 'galactic window'[4], but the distribution does not necessarily represent that of general stars which are responsible for the galactic structure. On the contrary, near infrared observation reveals the structure of the central bulge more directly, because the main constituents of the bulge are probably late-type stars which radiate their energy effectively in the infrared region, as inferred from external galaxies. Much weaker interstellar extinction in the infrared region also enables us to observe the whole central bulge through thick interstellar dust clouds. The surface brightness at 2.4 μm in the range of $75° > l > 23°$, $|b| < 20°$ was attained by our previous balloon experiment[5,6]. We have now attempted further similar observations aiming mainly to derive the surface brightness of the central bulge of our Galaxy.

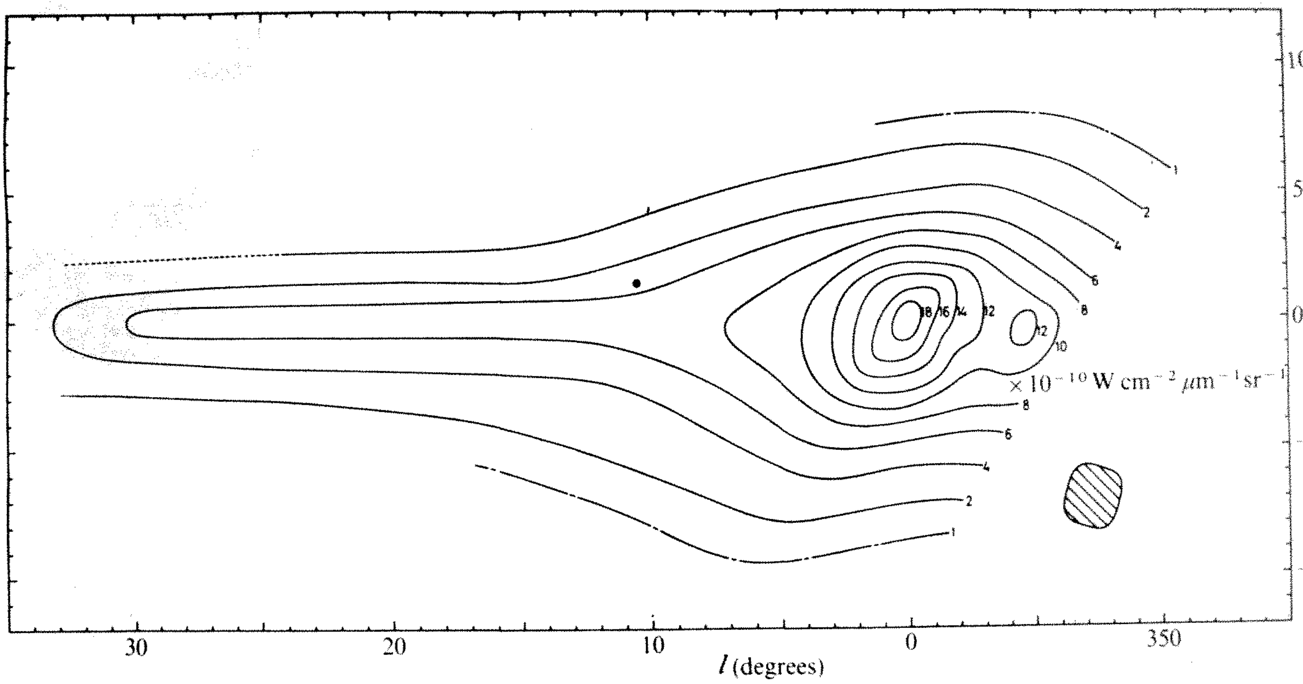

Fig. 1 Isophoto of the observed surface brightness of our Galaxy. The shaded area (bottom right) indicates the field of view used (HMBW).

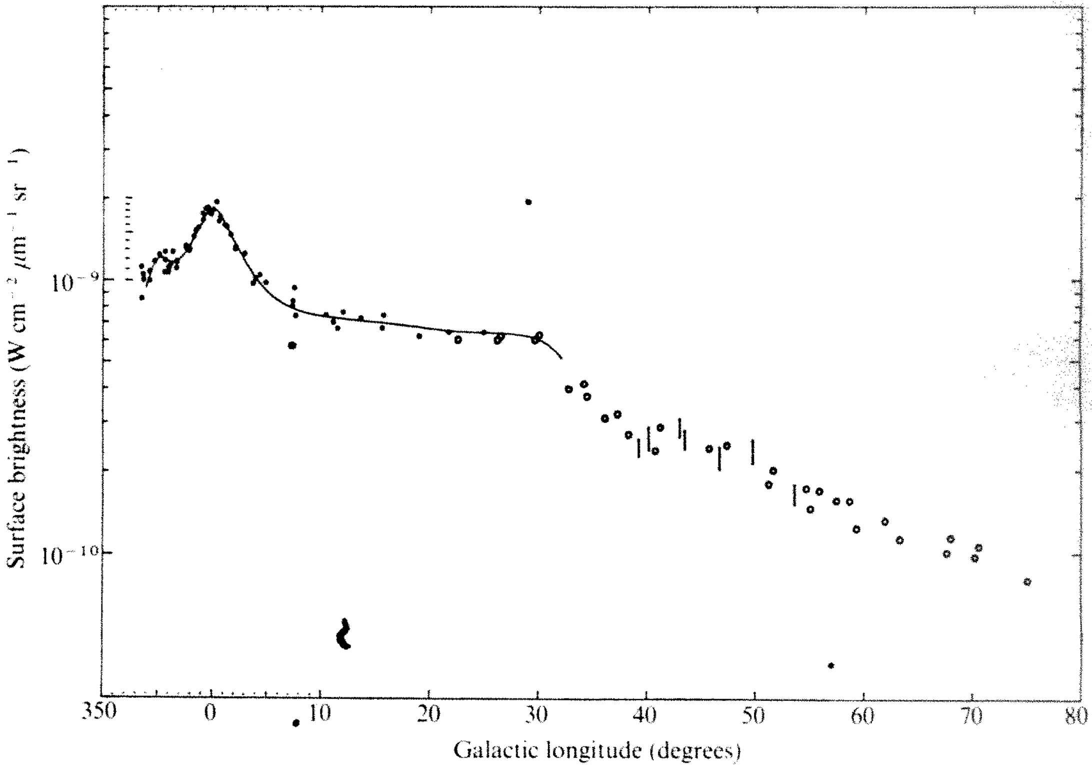

Fig. 2 Longitude dependence of 2.4-μm surface brightness on the galactic plane. Newly obtained data are shown by filled circles while open circles and bars represent the previously observed data[5,6]. The solid line is drawn according to the isophoto.

The balloon-borne infrared telescope was similar to that used for the previous flight. It consisted of a silicon combination lens system (D = 10 cm, F = 1.0) in front of which an interference filter (λ = 2.4 μm, $\Delta\lambda$ = 0.1 μm) was attached, and an array of four lead sulphide detectors installed at the focal plane, each of which generated the field of view of 2° × 2°. The whole system was cooled by liquid nitrogen to reduce the thermal background radiation and improve the detector sensitivity.

The instrument on board a balloon was launched at 1850 JST on May 30, 1976 from Sanriku Balloon Center of the Institute of Space and Aeronautical Science, University of Tokyo.

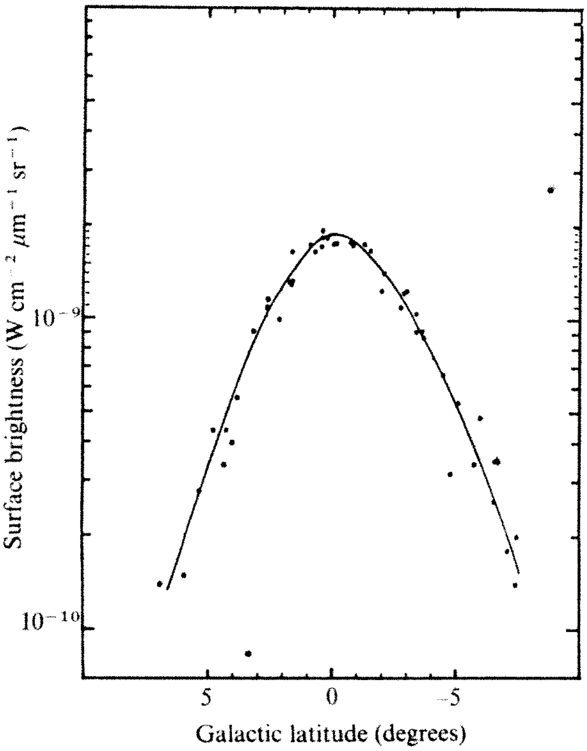
The whole system functioned as expected during the flight and a celestial region of $35° \geq l \geq -7°$, $|b| < 15°$ was covered by 72 scans. These scan paths were derived from the output of the magnetometer and confirmed by the transit of α Sco across the field of view. The observation of α Sco also provided an absolute calibration. The flux 1.38×10^{-12} W cm^{-2} μm^{-1} of α Sco at 2.4 μm was provided by the balloon observation on the previous night[7]. The responsiveness of the detector systems was checked by lighting a calibration source.

The infrared surface brightness thus obtained is shown in the form of an isophoto in Fig. 1. The scan paths are rather concentrated into the range of $-10° < l < 10°$, so that the contour lines in that region are more accurate than in the rest. The contours beyond l = 30° are drawn with reference to previous data. The longitude dependence at b = 0° and latitude dependence at l = 0° are shown in Figs 2 and 3, respectively. The present result agrees well with our previous one between l = 20° and 25°.

At a glance the isophoto shows that the galactic radiation at 2.4μm consists of two components: disk component and bulge component. The surface brightness and width of the plane are nearly constant in the region $10° < l < 30°$ with the value of 6.5×10^{-10} W cm^{-2} μm^{-1} sr^{-1} and 4.5° (f.w.h.m.) respectively.

The bulge component extends in the region $l < 5°$ which corresponds to 1 kpc from the centre. If we exclude the hump at l = 355.5°, b = −0.5° and absorbing lane from centre to l = 357.5°, b = −2.5°, the bulge component is almost symmetrical with respect to the galactic centre.

Fig. 3 Latitude dependence of 2.4-μm surface brightness at l = 0°.



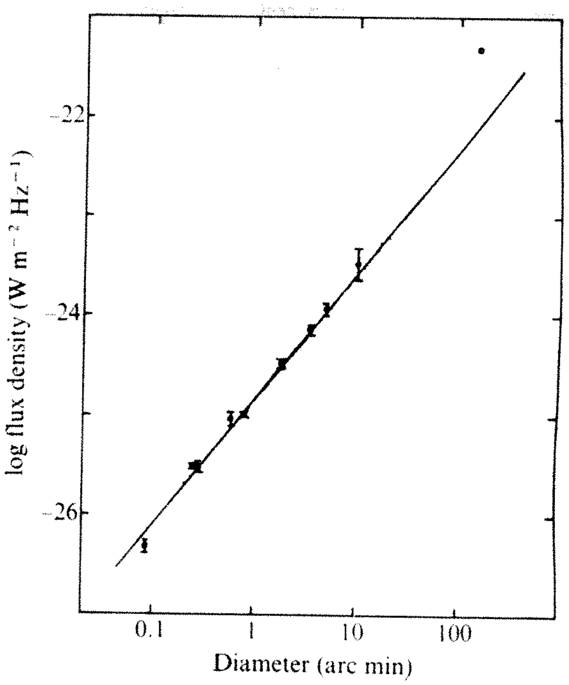


Fig. 4 The relation between flux density of the galactic centre and aperture diameter employed. Filled circles and straight line are taken from ref. 1. An open circle at upper right represents our value.

The flux of the galactic centre of $(1.9 \pm 0.1) \times 10^{-9}$ W cm^{-2} μm^{-1} sr^{-1} is compared with ground-based observations at 2.2μm[1] in Fig. 4. Our value is rather larger than that extrapolated from the small aperture, since our value contains the disk component and the large aperture results in smaller interstellar extinction because of strong concentration of the absorbing matter on the galactic plane.

The contour lines within 2 arc deg from the centre in Fig. 1 are elongated in the direction perpendicular to the galactic equator, and in the outer region the lines are elongated parallel to the galactic plane. The former can be attributed to the interstellar absorption, and the latter probably reflects the property of the central bulge.

The hump at l = 355.5°, b = −0.5° in Fig. 1 is considered to be an extended source, since there are no corresponding bright stars at 2.2 μm around the position of the hump[8]. The open cluster NGC 6383, which is located at the almost same position, cannot contribute to the 2.4-μm surface brightness. A radio source which may correspond to the hump is not also found in this region. It is uncertain at the present time, however, whether the hump is related to the structure of the central bulge.

We thank the staff of Sanriku Balloon Center for their kind support.

Disappearance of puddle water during the night with growth of ice needles and its reappearance during the day

A PUDDLE appears in a dip in the ground after a fall of rain or snow. It becomes covered with an ice sheet during cold nights in the winter in the rural area of the northern part of the Kanto district in Japan. The ice sheet has a characteristic shape. It is not flat but dished and usually an air space is found under thin ice sheets without puddle water. Furthermore, an abundance of ice needles grow on the soil surrounding the puddle. These phenomena in puddles in winter seem to be general in the Kanto district. This report describes observations made on some puddles located at the side of the road in the Kanto district during February 1976 to clarify the process of formation of the dished-out ice sheet, the air space under the ice sheet, and the disappearance and appearance of puddle water.

Photographs of the various states of puddle water obtained on February 7–8 are shown in Fig. 1*a-f*. In the daytime the puddles were not covered with an ice sheet (Fig. 1*a*) though they were covered with ice sheets early in the morning before the increase in air temperature (Fig. 1*b*).

Stripe patterns were found in the ice sheet. Under the ice sheet the puddle water was replaced by air (Fig. 1*c*). A cross section of the ice sheet showed the difference of ice thickness with position (Fig. 1*d*). The stripes observed on the ice sheet are due to the difference in ice thickness.

Abundant ice needles 3–5 cm long were observed on the soil surrounding the puddle (Fig. 1*e*). Furthermore, melting of the ice needles and an increase in puddle water under the ice sheet were observed in the morning with the increase in solar radiation.

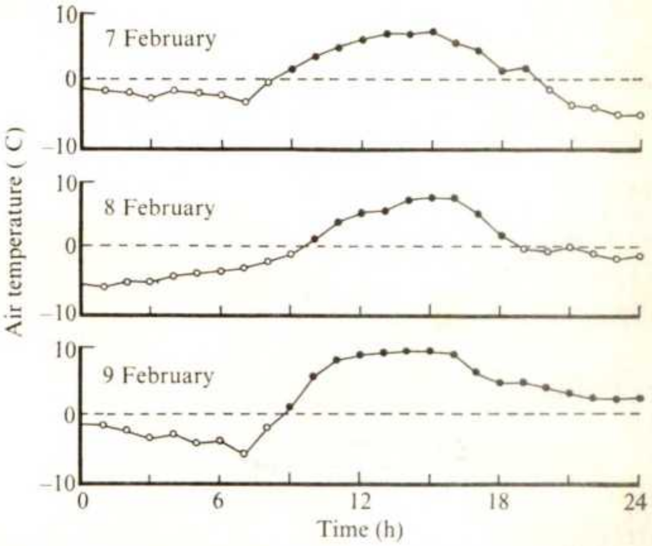

Fig. 2 Air temperature variation about 300 m from observation area.

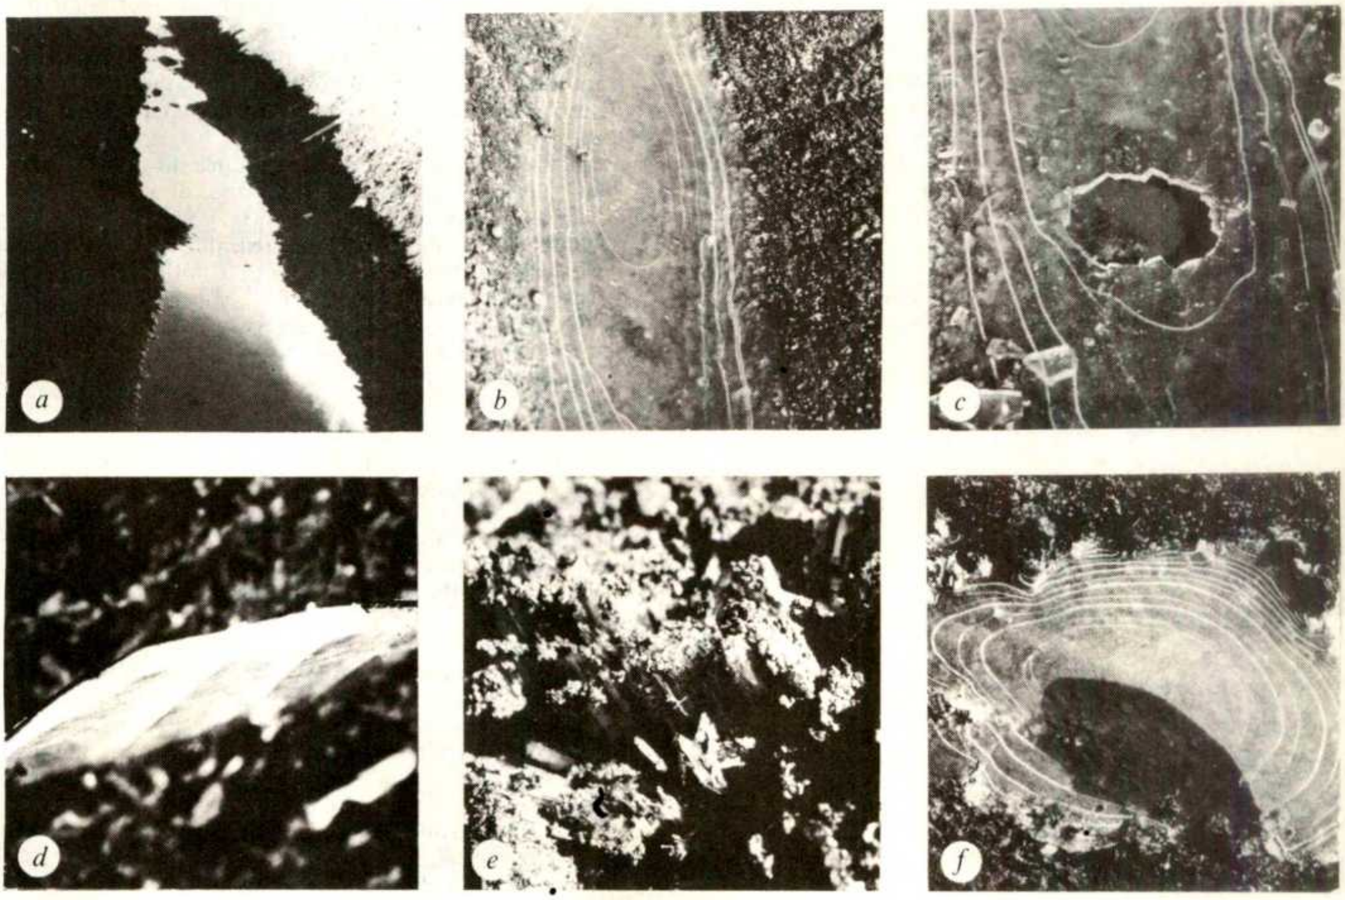
The air temperature data obtained at the Tateno Aerological Observatory about 300 m from the observed puddles on February 7–9, 1976 showed the cycle of air temperature above 0 °C from 0900 to 1900 and below 0 °C from 2000 to 0800 (Fig. 2).

These observations suggest that the following events occur. The growth of ice needles around the puddle is due to the supply of water from the puddle followed by the

Fig. 1 Photographs of puddle water at various times of day.



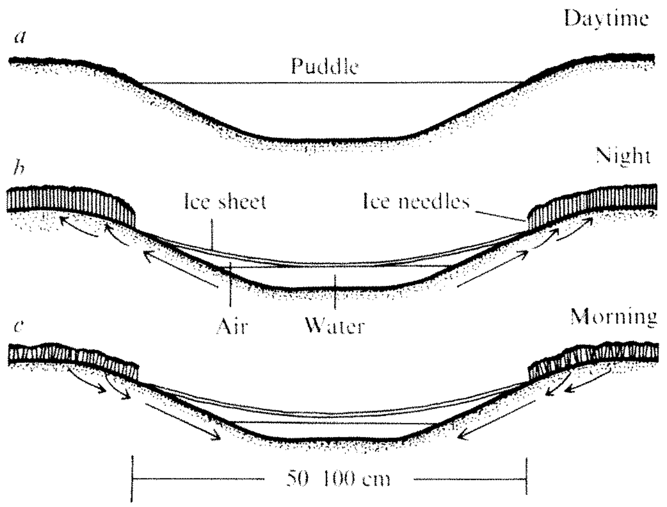


Fig. 3 Air space formation beneath puddle ice sheet.

decrease of puddle water. The decrease of puddle water results in the gradual lowering of the level of formation of the ice sheet which occurs on the surface of puddle water. This is the reason for the formation of the dished ice sheet. And then, with the continuation of the growth of ice needles, the puddle water separates from the ice sheet to form an air space (Fig. 3). The irregularity of the growth of ice needles controlled by the delicate balance of meteorological conditions of air and soil[1-7] may be the cause of the striped patterns of the ice sheet. With the increase of solar radiation in the morning, the ice needles and ice sheet melt and water returns to the puddle.

After the melting of the ice needles and ice sheet, the puddle water regains its previous daytime shape.

The puddles formed at the side of road after a fall of rain or snow in winter repeat this process with the evaporation of puddle water. The area of water evaporation from the surface of puddle water is extended by the penetration of the water into the soil surrounding the puddle. This results in more rapid disappearance of puddle water from the dip in the ground. The periods of existence of the puddles which we observed were about 10 days.

I thank I. Tsuchiya for discussions and Tateno Aerological Observatory for the air temperature data.

Measurement of forces of molecular attraction of crossed fibres as a function of width of air gap

DERJAGUIN and Abrikosova[1] were the first to measure molecular forces as a function of the distance between macro-objects, using negative feedback. The results coincided, within the limits of experimental error, with the conclusions of the theory of retarded molecular forces (which was subsequently developed by Lifshits[2,3]). In the earlier research work[1], as in a number of subsequent experiments, the width of an air gap was measured by optical methods (using the interference of light). The research work was therefore limited to transparent bodies. Moreover, test bodies had to possess a sufficiently large radius of curvature. The latter condition meant that the quality of the surfaces had to meet stringent requirements; it was also difficult to ensure the absence of dust particles in the gap between interacting bodies with large radius of curvature. As a result, only in two cases[4,5], owing to the use of molecular-smooth surfaces of mica, did researchers succeed in measuring, not only the retarded, but also non-retarded molecular forces.

In the present work, we have used fibres of small radius (about 150–500 μm) crossed at right angles. With a view to presetting the gap, instead of measuring it directly (including that between opaque bodies), we preset the displacement of one of those bodies relative to the position of the contact with another fixed body. (The contact we assumed to be that position of fibres, which corresponds to the contact interaction force $F = 0$). To this end, a movable fibre was attached to the frame of a photoelectric galvanometer and another fibre was fixed.

The light ray reflected by the galvanometer mirror impinged on two photoresistances. When the instrument was operating normally as a galvanometer, the equilibrium position of the frame corresponded to the equality of illumination of those photoresistances. In the case of a deviation from the equilibrium, current I_1 passed through the diagonal of the bridge circuit, and a part of current I_1, current I_2 through the galvanometer frame. Owing to the negative feedback, the current I_2 reset the frame in its equilibrium state. In addition to the two photoresistances, the bridge circuit comprised two constant resistances S_1 and S_2. When the frame was in equilibrium, $I_1 = 0$.

The instrument was remodelled by replacing the constant resistances S_1 and S_2 by the variable ones, to measure the forces of interaction of fibres. To this end, multistage magazines of resistances were used. By varying S_1 and S_2, one could vary the illumination ratio of the photo-resistances, corresponding to $I_1 = 0$, and, hence, the equilibrium position of the frame. The readings S_1 and S_2 were converted into the values of displacements of the movable thread by the preliminary graduation. The currents I_1 and I_2 were measured by microammeters.

Each equilibrium position of the movable thread was preset by the values of S_1 and S_2; in the absence of a force applied to the thread this corresponded to $I_1 = 0$.

When the interaction forces appeared, this equilibrium state was violated. An electric current $I_1 \neq 0$ flowed through the diagonal of the bridge circuit. To compensate for it, an independent controllable power source was used, which was additionally cut in the circuit of the galvanometer frame. The value of the current, I_2, was proportional to the forces applied to the thread. The instrument had been previously graduated, to convert the values I_2 into the force value.

Thus, the space position of the moveable fibre, which was read off the contact point of fibres, was determined by the values S_1 and S_2 at $I_1 = 0$. In this case, the force of interaction of the fibres was determined according to the current I_2. Consequently, the circuit applied enabled us, using only one device, to measure both the spacings between the fibres and their interaction forces.

As a result, we have succeeded in presetting the shift of fibres at an accuracy of up to 10 Å. The position of the contact was defined at an accuracy of up to 50 Å. The sensitivity of the instrument to the interaction force was about 10^{-4} to 10^{-5} dyne.

The forces of interaction of quartz, glass, platinum and gold fibres were measured as a function of the shortest distance h between them, within the range of 100–1,000 Å. In the case of dielectrics, a β-radiation source was used to remove electrostatic charges.

The theory of molecular forces[2,3] gives the following relationships for the forces of attraction of cylinders crossed at right angles and having radii R_1 and R_2

$$F_1 = 2\pi B\sqrt{(R_1R_2)}/3h^3 \quad (1)$$

$$F_2 = A\sqrt{(R_1R_2)}/6h^2. \quad (2)$$

Equation (1) corresponds to the case of retarded forces, and equation (2) to that of non-retarded forces. Here A and B are the constants of molecular forces.

To compare the experimental results obtained with fibres of different diameters, it will be more convenient to use the interaction energy u per unit area of the plane-parallel surfaces separated by the same gap h. In accordance with ref. 6,

$$u = \frac{F}{2\pi\sqrt{(R_1R_2)}};\quad u_1 = \frac{B}{3h^3};\quad u_2 = \frac{A}{12\pi h^2} \quad (3)$$

Unlike F, the values u do not depend on the radius of the cylinders that are used to measure the force.

Figure 1 shows the relationships $u(h)$ obtained for quartz and platinum fibres. Each point on the curve represents a result of averaging several experimental values of u with a definite value h. Solid straight lines were plotted by the least squares method (over the entire field of points, but not according to the averaged results), taking into account the square or the cube dependence of u on $1/h$.

Using the same plurality of experimental points as the basis, we were able to determine the exponent n, without having recourse to the relationships (1) and (2) (assuming that $u \sim 1/h^n$). For quartz, the values n were found to be equal to $n_1 = 3.01$ and $n_2 = 2.0$; for platinum, to $n_1 = 3.03-3.23$ and $n_2 = 1.93-2.01$. This agrees well with theory. At $h \lesssim 300$ Å, platinum deviates from the dependence $u \sim h^{-2}$; this is probably attributable to the roughness of the surface of fibres.

From the results represented in Fig. 1, it was easy to determine the values of constants A and B, as well as to evaluate the gap width h_0, at which the non-retarded molecular forces go over into the retarded ones.

Table 1 gives the values of A, B and h_0 for quartz and platinum. The values of A and B obtained agree satisfactorily with the calculated ones[7]. In the case of quartz, those values are close to the measured results obtained by other methods: $A = 6.5 \times 10^{-13}$ erg, $B = (0.66-1.15) \times 10^{-19}$ erg cm (ref. 6). We were the first to obtain the experimental values B for platinum. The values A for platinum were calculated earlier, using the results of experiments made with crossed fibres in electrolyte solutions[8]: $A = (0.8-1.6) \times 10^{-12}$ erg.

Fig. 1. Dependence of the specific energy of the molecular attraction of plane-parallel surfaces, u, on distance h. a, Quartz, $2R_1 = 0.8$ mm, $2R_2 = 1.15$ mm. b, Platinum, $2R_1 = 1$ mm, $2R_2 = 0.3$ mm. c, Platinum, $2R_1 = 2R_2 = 0.3$ mm.

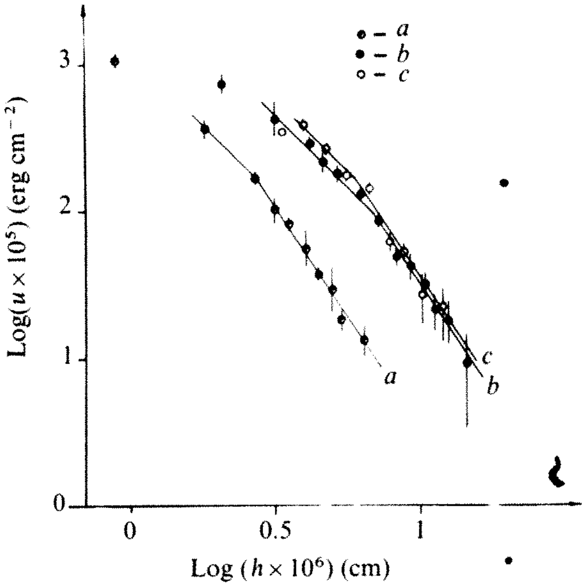

Table 1 Results of measurements of A and B

Material	$A \times 10^{12}$ (erg) Expt	$A \times 10^{12}$ (erg) Theory	$B \times 10^{19}$ (erg cm) Expt	$B \times 10^{19}$ (erg cm) Theory	h_0 (Å)
Fused quartz	0.45	0.8	1.02	0.6	270
Platinum	2.0	—	10.5	13.0	650

Hence, the method thus worked out allowed the molecular forces to be measured as a function of the spacings between the fibres in air at a distance of about 100–1,000 Å between various materials, including these opaque ones. The experimental results agree well with the theory.

Cross relaxation and spin diffusion in the proton NMR of hydrated collagen

PROTON NMR of water is being used extensively to probe the molecular dynamics of water molecules in biological systems such as protein solutions, hydrated macromolecules, cells and tissue. The nuclear magnetic relaxation rates R_1 (spin–lattice) and R_2 (spin–spin) can be analysed in terms of the rotational motions of the water molecules[1–3]. A crucial assumption in this analysis is that the proton relaxation of the water proceeds independently of that of the macromolecules. Kimmich and Noack[4–6] claim that this assumption may be incorrect for proton spin–lattice relaxation because of spin diffusion, but clear evidence of spin diffusion in hydrated biological samples has not been reported. We show here that the proton spin–lattice relaxation behaviour in hydrated collagen is dominated by cross relaxation between the water protons and the macromolecular protons as a result of spin diffusion; the macromolecular spin–lattice relaxation contributes significantly to the water proton R_1.

The proton spin–lattice relaxation of ribbons of reconstituted collagen[7], hydrated with H_2O or D_2O, was studied by pulsed NMR. The spin–lattice relaxation was determined from a comparison of the free induction decay (FID) signal after a (180° – t – 90°) pulse pair with that after a single 90° pulse. The pulse pair yields the partially relaxed magnetisation $M_z(t)$ whereas the single 90° pulse yields the equilibrium magnetisation M_0. The spin–lattice relaxation rate was determined from a logarithmic plot of the reduced magnetisation $m(t) = -(M_z(t)-M_0)/2M_0$ against t.

The FID of hydrated collagen consists of two components (see Fig. 1). Protons in the rigid collagen matrix constitute a

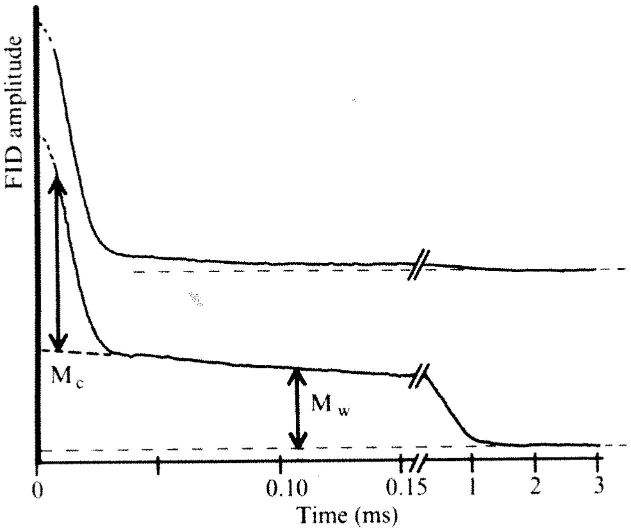

Fig. 1 Proton FID signals in reconstituted collagen, hydrated with 28 g water per 100 g collagen. Lower curve: hydrated with H_2O. Upper curve: hydrated with 95% D_2O. The collagen signal intensity $M_c(t)$ was measured immediately after receiver recovery from the 90° pulse, 10 μs after the beginning of the pulse. The water signal intensity $M_w(t)$ was measured 60, 110 and/or 400 μs after the pulse; the spin–lattice relaxation decay at these times is the same. The collagen fibres were oriented perpendicular to the magnetic field. Measurements were performed at room temperature with a Bruker pulse spectrometer operating at 30 MHz; a Varian V-2708 magnet was used, equipped with a Varian V-3508 flux stabiliser. The 90° pulse length was 1.5 μs. The FID signals were averaged with a combination of a Biomation 802 signal digitiser and a Nicolet 7002 signal averager. Typically 64 or 128 repeated measurements were averaged together.

fast relaxing part ($R_2^* = 60{,}000\ s^{-1}$), and the water protons relax much more slowly ($R_2^* \lesssim 5{,}000\ s^{-1}$). This identification of the two signal components is supported by the observations that the intensity of the water fraction changes in direct proportion to the amount of hydration water and to the isotopic dilution with D_2O, and that the relative intensities of the two fractions correspond to the calculated ratio of collagen protons to water protons (three to seven, respectively, for the sample shown in Fig. 1). No static dipolar splitting of the water signal was apparent, in agreement with other studies of natural collagen under similar conditions[8,9].

The two components of the FID can easily be separated (see Fig. 1) so that we could study the spin–lattice relaxation of the water and of the macromolecular protons separately (Fig. 2). Measurements at different water contents all showed the following characteristics (see Fig. 2): (1) The relaxation rate R_1 of both water and collagen protons is the same if the initial 10 ms of the relaxation decays is ignored. (2) The beginning of the water relaxation decay is clearly concave (curve *c*) and that of collagen is convex (curve *b*). Both relaxation curves are described by a sum of two exponentials. (3) When collagen is hydrated with D_2O, then the relaxation rate of the collagen protons is single-exponential and proceeds at a rate which is much slower than in the presence of H_2O (curve *a*).

Proton NMR relaxation is brought about by magnetic dipolar interactions. Substitution of D_2O for H_2O changes the nuclear dipolar interactions between collagen protons and water nuclear spins. Assuming that the dynamics of hydration are similar for H_2O and D_2O, then the dipolar interaction between a collagen proton and a water proton is of the order of $(\gamma_H/\gamma_D)^2\ (I_H/I_D) \times (I_H+1)/(I_D+1) = 16$ times more effective at inducing nuclear spin transitions than the interaction between a collagen proton and a water deuteron[10]. The large change in R_1 of the collagen protons on substitution of D_2O for H_2O clearly indicates that the macromolecular protons 'feel' the presence of water protons. Consequently, dipolar coupling between water and macromolecular protons must be an important factor in the proton relaxation mechanism in hydrated collagen.

The non-exponentiality of the water relaxation might be ascribed to the presence of two slowly exchanging water fractions. This seems unwarranted, however, as it does not explain the convex curvature in the collagen relaxation, or account for the similar relaxation rates of the two components after the initial 10 ms of decay. We can explain all of our observations by realising that the dipolar coupling between water and collagen protons provides a way for cross relaxation between the water and the collagen protons by the spin diffusion mechanism[10,11].

We will assume that the protons in the water phase as well as in the collagen phase have, at any time, a uniform spin temperature, that is, the longitudinal magnetisation $M_z(t)$ in each phase is uniform. Within the collagen phase spin diffusion among the collagen protons will rapidly establish a common spin temperature, whereas in the water phase this is accomplished by rapid chemical exchange. The water phase may also include exchangeable collagen protons. Let p_w and p_c be the fraction of protons in the water phase and in the collagen phase respectively, with the proton relaxation rates in the absence of cross relaxation denoted by R_{1w} and R_{1c}. It should be noted that R_{1w} comprises the contributions to the water proton relaxation rate which are normally included in theoretical treatments, for example, effects from bound and free fractions of water[1–3]. Whenever a proton of the water phase resides near a collagen proton, the two protons are coupled by the magnetic dipolar interaction and a mutual spin flip can occur[10]. Such a spin flip exchanges spin energy between the two proton phases,

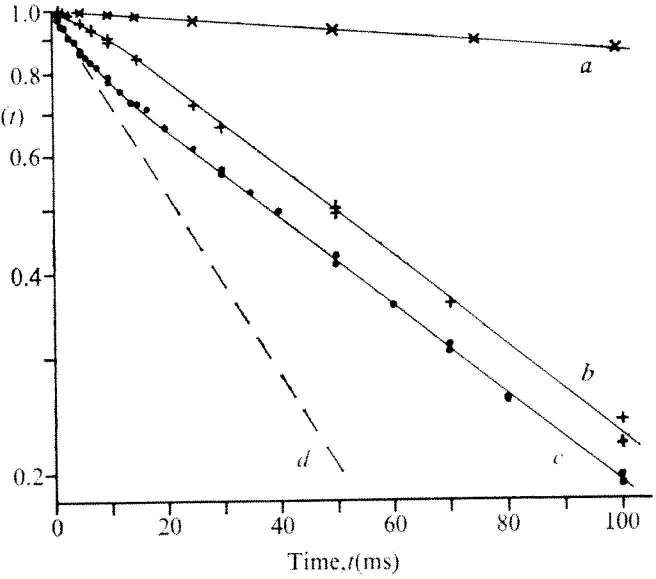

Fig. 2 Proton spin–lattice relaxation decays for the reduced magnetisation $m(t)$ in hydrated reconstituted collagen for the same samples as in Fig. 1. Measurements of $M_z(t)$ and M_o were alternated and the FID signals were averaged into two halves of the memory of the signal averaging system. This alternation ensures very accurate R_1 measurements since slow changes in time of signal gain and/or of field drift affect $M_z(t)$ and M_o in the same way and are compensated. Curve *a*, $m_c(t)$ for the collagen proton signal, hydrated with 95% D_2O (×). Curve *b*, $m_c(t)$ for the collagen proton signal, hydrated with H_2O (+). Curve *c*, $m_w(t)$ for the water proton signal of H_2O (●). A least squares fit of equation (2) to $m_w(t)$ yields the estimates, $R_1^- = 15 \pm 1\ s^{-1}$; $c_w^- = 0.89 \pm 0.01$; $R_1^+ = 160 \pm 15\ s^{-1}$; $c_w^+ = 0.11 \pm 0.01$. Curve *a* gives $R_{1c} = 3 \pm 0.5\ s^{-1}$. With $p_w = 0.3$, equation (3) gives $R_{1w} = 31 \pm 4\ s^{-1}$; $k_c = 40 \pm 10\ s^{-1}$; $k_w = 100 \pm 25\ s^{-1}$; $c_c^- = 1.08 \pm 0.01$; $c_c^+ = -0.08 \pm 0.01$. Solid lines represent the theoretical decays obtained with these values of the parameters. Curve *d* represents the water relaxation decay with a relaxation rate $R_{1w} = 31\ s^{-1}$ as it would occur in the absence of cross relaxation.

leading to cross relaxation between the two phases. Spin diffusion may occur through protons on water molecules that are temporarily bound to the collagen, or through rapidly exchanging collagen protons. Spin diffusion will be effective in particular, if such bound nuclei exchange at a rate which is slow compared to ω_0, the NMR measuring frequency[10,11].

We can introduce a cross relaxation rate k_c, the rate at which magnetisation diffuses from the collagen to the water; k_w is the reverse rate. We can then write a set of modified Bloch equations, similar to those well-known for the case of chemical exchange:

$$\mathrm{d}m_w(t)/\mathrm{d}t = -R_{1w}m_w(t) - k_w m_w(t) + k_w m_c(t) \qquad (1a)$$

$$\mathrm{d}m_c(t)/\mathrm{d}t = -R_{1c}m_c(t) - k_c m_c(t) + k_c m_w(t) \qquad (1b)$$

Unlike the case of chemical exchange, (1) applies only to the z-component of the magnetisation; spin diffusion does not lead to cross relaxation in the transverse magnetisation.

The solution of the set of coupled differential equations (1) predicts that the relaxation in either phase is described by two apparent relaxation rates R_1^+ and R_1^- which are the same for both phases. The complete solution[12] is (the subscript i refers to either of the phases)

$$m_i(t) = c_i^+ \exp(-R_1^+ t) + c_i^- \exp(-R_1^- t) \qquad (2)$$

where

$$R_1^{\pm} = \tfrac{1}{2}(R_{1c} + R_{1w} + k_c + k_w) \pm \tfrac{1}{2}\sqrt{[(R_{1c} - R_{1w} + k_c - k_w)^2 + 4k_c k_w]} \qquad (3a)$$

$$c_i^{\pm} = \pm(R_1^{\mp} - R_{1i})/(R_1^- - R_1^+) \qquad (3b)$$

$$k_w = (p_c/p_w)k_c \qquad (3c)$$

From (3b) follows

$$R_{1i} = c_i^+ R_1^+ + c_i^- R_1^- \qquad (3d)$$

With these expressions all the characteristics of the spin–lattice relaxation can be explained quantitatively.

The two fractions in the relaxation curve of the water signal are clearly resolved, permitting the determination of all the parameters in equation (2). A fit to the data points (see Fig. 2) yields R_1^+, R_1^-, c_w^+ and c_w^-; using these values, R_{1w} is calculated, from equation (3d), to be 31 ± 4 s^{-1}. A similar calculation for the collagen proton signal decay is less accurate, but gives $R_{1c} \approx 3\ \mathrm{s}^{-1}$, which is similar to R_{1c} measured in D_2O. p_c and p_w can be determined from the relative signal intensities in the FID, extrapolated to zero time (Fig. 1), or from the known amounts of protons in the two phases. Within experimental error the two methods give the same values for p_c and p_w.

The parameters that describe the complete relaxation behaviour consistent with equations (3) are given in the legend to Fig. 2. For the cross relaxation rate k_c we obtain an estimate of 40 ± 10 s^{-1} for a hydration of 28 g H_2O per 100 g collagen. We believe that this is the first time that a figure has been given for the proton spin diffusion rate from a protein to the hydration water. Our measurements show that the water phase constitutes the relaxation 'sink' for the collagen proton phase. This result differs with the model of Kimmich and Noack[4–6], who proposed that the water relaxation proceeds via relaxation 'sinks' located with the macromolecular phase.

Usually, water relaxation rates in hydrated biological systems are obtained from plots similar to Fig. 2. It is common practice, however, to ignore, or avoid measurements (because of associated experimental difficulties) during the initial 10 ms of the relaxation decay. It is clear from our analysis that this practice would lead to a measurement of an apparent relaxation rate of water (R_1^- in the present case), which is not necessarily the same as R_{1w}. We find for the hydrated collagen sample in Fig. 2 that $R_{1w} \approx 2R_1^-$. Clearly, cross relaxation can significantly affect water proton spin–lattice relaxation in biological samples. Its importance must be more carefully evaluated before applying molecular dynamical interpretations to apparent water relaxation rates. We are currently measuring cross relaxation effects in other hydrated biological systems and evaluating its consequences for a published analysis[9] of the relaxation behaviour in hydrated collagen.

We thank the US National Institute of Arthritis, Metabolism and Digestive Diseases for a grant and Ethicon Inc. for oriented ribbons of reconstituted steer tendon collagen.

Effect of NO photolysis on NO_y mixing ratios

IT has been suggested that the only significant sink for odd nitrogen in the stratosphere is through transport of HNO_3 to the troposphere[1]. As a result, if NO were to be injected in the middle or lower stratosphere, the change in odd nitrogen, NO_y ($NO_y \equiv NO + NO_2 + HNO_3 + N$), mixing ratio above the height of injection would be nearly constant. The photolysis of nitric oxide, however, and the subsequent reactions of nitrogen atom with nitric oxide act as a sink for odd nitrogens in the upper stratosphere. This mechanism has long been recognised as important to mesospheric chemistry[2,3], and has also been included in many of the stratospheric models[4–7]. Its role in the stratospheric NO_y budget, however, has not been analysed. This paper reports an investigation on the importance of this net NO_y sink by means of a one-dimensional transport-kinetics model[8].

In this model the reactions

$$\mathrm{NO} \xrightarrow{h\nu} \mathrm{N} + \mathrm{O}$$
$$\mathrm{N} + \mathrm{NO} \rightarrow \mathrm{N_2} + \mathrm{O}$$
$$\mathrm{N} + \mathrm{NO_2} \rightarrow \mathrm{N_2O} + \mathrm{O}$$

provide a chemical sink for odd nitrogen in the upper stratosphere. We studied the effect of NO photolysis on NO_y mixing using a parameterisation of NO photolysis as shown by Cieslik and Nicolet[9] and the chemical reactions used by Duewer *et al.*[10]. We found that inclusion of the sink would not result in a constant change in odd nitrogen mixing ratio above the height of a NO_x injection. This sink has a significant effect on model predicted effects of chlorofluoromethanes.

We computed an ambient NO_y mixing ratio and a perturbed NO_y mixing ratio due to an injection of NO at a rate of 2,000 molecules $\mathrm{cm}^{-3}\,\mathrm{s}^{-1}$ in a 1-km thick layer centred at 17 km using our standard chemistry (with the rate constant for $OH + HO_2 \rightarrow H_2O + O_2$ equal to $2 \times 10^{-11}\ \mathrm{cm}^3\,\mathrm{s}^{-1}$). We then repeated the calculation with the rates of the NO photolysis sink set equal to zero.

Both of the above sets of calculations were repeated for the Hunten[11] eddy diffusion profile and for the Crutzen[12] eddy diffusion profile.

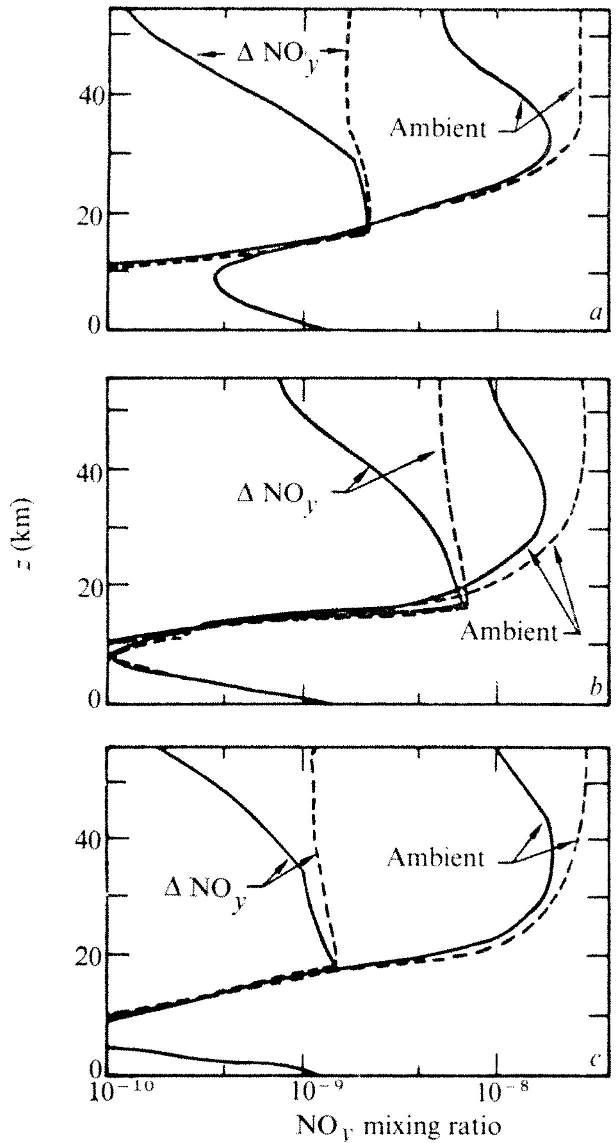

Fig. 1 Plots of computed ambient NO_y mixing ratios (ambient) and changes in NO_y mixing ratio after a 17-km NO_x injection (ΔNO_y) as described in text. ———, normal model; — — —, model with the NO photolysis sink suppressed. *a*, Chang[8] K_z profile; *b*, Hunten[11] K_z profile; *c*, Crutzen[12] K_z profile.

The NO_y mixing ratios resulting from the above calculations are given in Fig. 1. A comparison of the results with and without the NO photolysis sink implies that this sink for NO_y is responsible for both decreasing (NO_y) at all altitudes and for a decrease in NO_y mixing ratio with altitude above about 30 km.

Note that for the perturbed cases the changes in mixing ratio are not constant with altitude even when the photolysis sink (the only chemical sink for NO_y in the model) is removed. This is a result of a change in the net rate of the 'natural' production of NO_y from the reaction

$$N_2O + O(^1D) \rightarrow 2NO$$

This source term changes because the ozone concentration changes. The ozone reduction leads to a decrease in $O(^1D)$ concentrations at high altitudes where the proportional change in solar flux is less than the change in ozone concentration, and an increase in $O(^1D)$ at low altitudes, where the change in solar flux density more than compensates for the change in ozone. The changes in N_2O (because of altered solar flux) are relatively minor. The net change in the production of NO_y from $O(^1D) + N_2O$ in the model with NO photolysis suppressed, is given in Fig. 2 for the three diffusion profiles.

The net changes in ozone column for the above calculations are given in Table 1. For ozone reductions, note that the rate coefficients used in the current calculations are the recommended values from Hampson and Garvin[13], with 2×10^{-11} cm^3 s^{-1} for $OH + HO_2$. Thus, there are numerous minor changes and one major change in the rate coefficients used here compared to those used to generate the CIAP findings[11]. Although omission of the N atom sink for NO_y makes a very substantial difference in the NO_y mixing ratio above 31 km, it causes only a minor increase in the percentage ozone perturbation for NO_x injections. This results because both the ambient and perturbed NO_y mixing ratios are reduced by the sink. The ozone perturbation is more strongly affected for the Hunten profile, which was used in the formula developed by NAS[11], than for the other diffusion profiles considered.

The effect of the N atom reactions on the O_3 response of the model to a ClO_x injection is opposite in sign and larger than their effect on the O_3 response to an NO injection. We find that, when the N atom sink is removed from our model, the stratosphere is substantially less sensitive to chlorofluorocarbons than when it is included. A model that computed a 0.51% reduction in ozone due to chlorofluorocarbons in 1976 using our full chemistry computed only a 0.30% ozone reduction in 1976 when NO photolysis was neglected. This effect occurs because the reaction

$$NO + ClO \rightarrow NO_2 + Cl$$

reduces the efficiency of both the chlorine and NO_x ozone destruction cycles, and the effect of this reaction is especially dependent on the NO_x mixing ratio above 35 km.

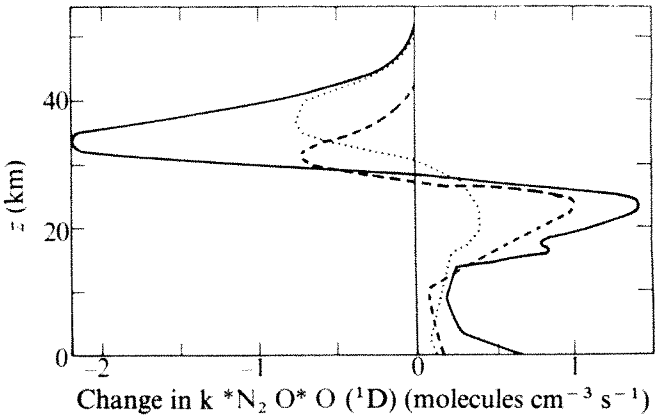

Fig. 2 Change in the odd nitrogen production rate in models with the NO photolysis sink suppressed. ———, Hunten (1974) K_z profile; — — —, Chang[8] K_z profile; ····, Crutzen (1975) K_z profile.

Table 1 Ozone columns (molecules cm^{-2}) and percentage deviations

	K_z (Chang)	K_z (Hunten)	K_z (Crutzen)
Normal, ambient O_3	7.4334×10^{18}	7.4627×10^{18}	7.4437×10^{18}
Normal, 17-km NO source	7.2920×10^{18}	6.9644×10^{18}	7.3459×10^{18}
ΔO_3 (%)	−1.75	−6.68	−1.31
No N atom ambient	7.2752×10^{18}	7.148×10^{18}	7.1165×10^{18}
No N 17-km NO source	7.1467×10^{18}	6.630×10^{18}	7.0195×10^{18}
ΔO_3 (%)	−1.77	−7.25	−1.36

Although models of the effects of NO_x injections on the stratosphere are not very sensitive to the NO photolysis sink for NO_x, inclusion of this sink is quite important for models of the effects of chlorofluorocarbons in the stratosphere. Indeed, the concentration of NO above 35 km is an important and poorly validated quantity in current models.

This work was performed under the auspices of the US Energy Research and Development Administration and was supported in part by the High-Altitude Pollution Program of the Federal Aviation Administration, US Department of Transportation.

Quantitative effects of sediment mixing on stratigraphy and biogeochemistry: a signal theory approach

SEDIMENT mixing by benthic fauna greatly affects the detailed historical record of the environment preserved in the sediments[1]. Mechanical stirring is a major transport mechanism affecting fluxes of solid material and dissolved chemicals between sediments and the water column[2]. Therefore, chemical and microbiological reaction rates in sediments are coupled to the rate at which substrate and product are transported to and from the site of reaction by bioturbation[3]. In order to understand better these processes, models which allow quantitative prediction of sediment mixing effects on inert and reactive sedimentary constituents are desirable.

The complexity of mixing events by benthic infauna has generally resulted in neglect of the environmental effects of mixing. Previous models have described mixing by a parametric 'diffusion coefficient'[4] or 'mixing depth'[5–8], but such models have been applicable only under restricted assumptions of steady-state sedimentation and of constant and invariant mixing.

I have developed a general signal theory based model of bioturbation that does not require assumptions of temporal or spatial steady state, or of constant mixing to an invariant depth (Goreau, unpublished). This method allows calculation of the effect of any series of time-varying mixing events on any time-varying input to the sediment. It thus allows, when we have sufficient knowledge of the mixing history, the recovery of some original input information from sediments that have had their stratigraphic records mixed by bioturbation by comparison of actual profiles with model profiles based on realistic values of the relevant parameters.

As mixing moves material to shallower and deeper depths in sediments, corresponding to past and future inputs, there is no unique age at each depth, but rather a mixture of material of different ages. It is useful to define a 'mixing function' $F(x)$, the depth profile of some unit quantity of inert material that has been introduced to the sediment surface at a discrete time and then been mixed and buried. Figure 1*b* shows the 'mixing functions' that result from the mixing and burial of three separate historical inputs to the sediment. If there were no mixing these would be found at depths X_0, X_1 and X_2. If we consider the profile that would result if some time-varying input was delivered to the sediments in the absence of mixing, $I(x)$ (Fig. 1*a*), then it can be shown that the mixed profile $O(x)$ (Fig. 1*c*) that results from the action of mixing on the input can be calculated as a convolution integral of input $I(x)$ and the mixing function $F(x)$:

$$O(x) = \int_{\infty}^{0} I(x')\,F(x-x')\,\mathrm{d}x' \qquad (1)$$

where x' is a dummy variable and mixing is represented as spatial filtering of the undisturbed input by the mixing function $F(x, x')$. The mixing process acts as a low pass frequency filter, allowing slow changes in input to be recorded in the sediment while attenuating rapid changes. Fine structure of the stratigraphic record is smeared out in a predictable manner, and recent events are recorded deeper in the sediment than they would be in the absence of mixing (Fig. 1*d*). As a result, estimates of sedimentation rates and palaeo-oceanographic changes derived from penetration depths of such recent inputs as the bomb-produced radionuclides ^{14}C and ^{137}Cs are often too high. The true value can be found if $F(x)$ is known.

$F(x)$ can be determined from measurements of $O(x)$, the natural mixed profile of a non-reactive constituent with known inputs, and measured directly when that input is a spike such as thin ash layers, microtektites, or rapid microfossil changes. When $F(x)$ is known at a particular site, it is applicable to other inert inputs, and can be used in conjunction with measured mixed profiles to deconvolve the effects of mixing by inversion of equation (1) to derive the original input history.

A similar mixing function is derived for pore water, $F_w(x)$, the volume of pore water exchanged with overlying seawater per unit area per unit time, as a function of depth (Fig. 1*e*). If the concentration of dissolved constituent with depth is $C(x)$ (Fig. 1*f*), and C_w in seawater, then the flux of the constituent across the sediment–water interface is shown to be

$$\text{Flux (g cm}^{-2}\,\text{s}^{-1}) = \int_{0}^{x_{\max}} F_w(x)\,(C(x) - C_w)\,\mathrm{d}x \qquad (2)$$

When $C(x)$ exceeds C_w the flux will be from sediment to the water column, and when $C(x)$ is less than C_w the net flux will be into the sediments. This expression contrasts with Fickian diffusion terms used to estimate fluxes in previous work[9], since bioturbation is much faster than molecular diffusion. Ions transported across the interface have their source or sink throughout the mixed zone of sediment, and are not just passively driven by diffusion along pore water concentration gradients at the interface, as assumed in diffusive flux calculations. Measured values of $F_w(x)$ may substantially modify estimated sediment–water geochemical fluxes.

Reactive inputs, consumed or produced in sediment, will have different depth profiles than inert inputs. The difference between mixed profiles resulting from similar reactive and conservative inputs is a measure of net consumption or production of inputs with depth. By interpreting carefully controlled laboratory experiments in conjunction with the present approach, I believe it possible to estimate means and ranges of net reaction rates as a function of depth in naturally mixed sediments to obtain quantitative measures of geochemical and microbially mediated reaction rates in sediment. These rates should be quite different from those estimated in the absence of mixing, since redox potential dependent reactions are affected by the rate of oxygen

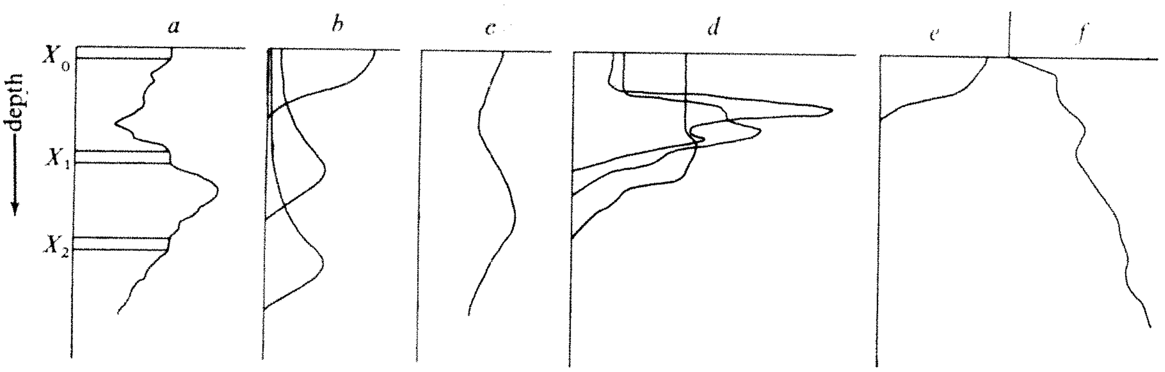

Fig. 1 *a*, An undisturbed time varying sedimentary input, $I(x)$, that would be observed in the complete absence of mixing. *b*, Mixing functions showing the depth profiles caused by the mixing and burial of three successive inputs, $I(x)$, $I(x_1)$ and $I(x_2)$. *c*, $O(x)$, the mixed output obtained by operation of the mixing function on $I(x)$. The mixed output is derived from the time-varying input and mixing function through the finite difference form of equation (1): $O(x) = \Sigma_i I(x_i) F(x, x_i)$. *d*, Calculated effects of uniform mixing to 1, 2 and 4 relative depth units on the fallout inputs of the bomb-produced radionuclide ^{137}Cs. (Increased depth of mixing is seen to push the ^{137}Cs maximum deeper into the sediment and obliterate fine scale information in the mixed profile.) The calculated profiles are similar to those measured by Pennington *et al.*[10]. This choice of mixing functions produces results similar to those of Robbins and Edgington[11]. *e*, $F_w(x)$, the volume of pore water exchanged with overlying water per unit area per unit time, as a function of depth, due to bioturbational mixing of sediment and faunal water pumping. *f*, A typical depth profile of a dissolved nutrient such as ammonia or phosphate in pore water. The flux of the dissolved constituent across the sediment–water interface is given by equation (2).

transport into sediment. Bioturbation affects oxygen fluxes, the Eh microhabitat, and ecological depth zonation of the microfauna that mediate such environmentally important processes as aerobic heterotrophic decomposition, sulphate and nitrate reduction, and ammonia and methane generation.

This work shows that many stratigraphic, geochemical and microbiological problems in recent sediment can be approached through measurable 'mixing functions' characterising the real-world dynamic effect of mixing in a quantitative and predicitively useful manner. Further development of the numerical model with applications to the spatial and frequency response of the historical record, detailed stratigraphic records of bomb-produced radionuclides, the deconvolution of recent pollutant trace-metal sediment profiles, sediment–water fluxes, temporal and spatial variation, and the estimation of sediment geochemical and microbiological reaction rates will be published elsewhere.

I thank Stephen Blake, Demetrios Matsakis, Donald C. Rhoads, Charles Denham, Heinrich Holland, Raymond Siever, Anthony Lasaga and Margaret Goreau for valuable discussions and criticism.

Evidence of major sulphate evaporite deposits in the Proterozoic McArthur Group, Northern Territory, Australia

WE report the occurrence of extensive sulphate evaporite relicts from the McArthur Group (1,600–1,400 Myr old), Northern Territory (16° 30′ S: 135° 30′ E approx), Australia. The McArthur Group comprises a sequence of carbonates, shales, siltstones and sandstones, with a minor volcanic component, of mid-Proterozoic sediments and includes the huge H.Y.C. stratiform Pb–Zn–Ag deposit[1].

Some models for the early evolution of the Earth's hydrosphere[2] postulate that sulphate evaporite minerals were not deposited before late Proterozoic times (~800 Myr ago)[3–7]. However, our work, and other evidence[8–11] indicates that these evaporite minerals do indeed occur in older rocks.

Pseudomorphs after halite and gypsum were first reported from the Group in the 1960s[12–14]. Our present studies show that these and other evaporite relicts are much more widespread and significant than was originally thought. Most of the evaporite relicts are in the form of carbonate pseudomorphs after a variety of morphologies of gypsum and anhydrite crystals, chert pseudomorphs after anhydrite nodules (=the 'botryoidal quartz' of ref. 5), halite casts, and microscopic remnants of original, unaltered sulphate minerals. The characteristics of each of these evaporite relicts are described and their distribution within the McArthur Group is shown in Table 1.

The most abundant evaporite relicts in the McArthur Group are carbonate pseudomorphs after discoidal and euhedral to subhedral gypsum and anhydrite crystals (Fig. 1*a*). The size of the pseudomorphs is variable. The discoidal crystals range in length from less than 1 cm to about 15 cm. They are lensoid in cross section, with length to breadth ratios varying from about 2 : 1 to 15 : 1. The euhedral pseudomorphs are less common than the discoidal ones and range in length from about 5 mm to 3 cm. We have found discoidal pseudomorphs in quartz arenites, and they are very abundant in a number of carbonate lithologies.

In quartz arenites, the pseudomorphs are disseminated and randomly oriented, and they contain numerous small inclusions of quartz and dolomite The distribution of the pseudomorphs in the carbonate rocks, however, varies from a few randomly oriented and disseminated specimens, to whole beds of pseudomorphs (originally mapped as sideritic marbles[12]), ranging from 10 cm to 45 cm thick. In the massive beds, discontinuous wisps of chert characteristically delineate algal mats, domal stromatolites and *Conophyton*. In the carbonate rocks, pseudomorphs cross cut sedimentary features such as bedding and laminated algal mats, suggesting that the original sulphate minerals crystallised in the host sediments during diagenesis. The pseudomorphs may be either single crystals or mosaics of anhedral grains displaying a polygonal texture. The grains vary in diameter from 50 to 100 μm, and are generally larger than the grain size of the host sediment. As well as carbonate, the pseudomorphs frequently contain traces of disseminated pyrite, and occasional blebs of chalcedonic quartz. Electron probe microanalyses of the carbonate minerals show that they are iron-rich phases such as ferroan dolomite, ferroan magnesite (bruenerite) and magnesian siderite (pistomesite), whereas the host carbonate is usually less iron-rich dolomite or magnesite. Some pseudomorphs are compositionally zoned with respect to their iron content. In some of the pseudomorphs, we have observed tiny, highly birefringent inclusions, reaching a maximum size of 10–20 μm, and have identified them as anhydrite, using the petrological microscope. Our identification was confirmed by electron probe microanalysis. Using these techniques, we have also identified nodules of anhydrite averaging 2–3 mm in diameter from a silicified algal mat horizon in a massive pseudomorph bed in the Amelia Dolomite.

The discoidal pseudomorphs are identical in habit with the gypsum which grows interstitially in Recent and ancient sabkha and intertidal environments[15–18]. Both have curved faces and both are frequently flattened in a plane perpendicular to the *c* crystallographic axis. Others, however, have spear shaped or serrated terminations that possibly reflect repeated twinning of the original crystals (Fig. 1*b*). Such forms are also characteristic of anhydrite crystals that are found in Recent and ancient marginal sabkhas[17–19].

Apart from the discoidal and euhedral pseudomorphs described, the McArthur Group also contains acicular carbonate pseudomorphs. These were tentatively identified as being dolomite pseudomorphs after aragonite[20], and were believed to be restricted to the Coxco Dolomite Member of the Teena Dolomite (Table 1). Our studies, however, show that as well as the Coxco Dolomite occurrence, acicular pseudomorphs are also present in the Emmerugga Dolomite. The needles are six-sided, and their interfacial angles are the same as those of gypsum crystals elongated parallel to the *c* crystallographic axis (see Fig. 2). The acicular pseudomorphs vary from 2 to 10 cm in length, and from 1 to 5 mm in diameter, and they occur in radiating clusters. In thin section, the needles are seen to be composed of mosaics of anhedral carbonate grains with an average diameter of 100 μm. The pseudomorphs are zoned, having rims of clear dolomite, with cores of dark dolomite containing abundant fine-grained inclusions of what appear to be clay minerals. The carbonate mineral in the pseudomorphs is ferroan dolomite identical in composition with the host dolomite.

The acicular pseudomorphs are identical in habit to a variety of gypsum forming in shallow brine pools on the sabkhas of the Trucial Coast (D. Kinsman, private communication). According to Kinsman, the root of each cluster is situated at the sediment–water interface. The larger acicular gypsum needles are often hollow and partly filled with fine-grained detritus. We therefore interpret the zoning of the McArthur acicular pseudomorphs to have been formed by similar trapping of fine-grained detritus in once hollow gypsum needles, although they may have been

Table 1 Regional stratigraphy and distribution of evaporites, in the McArthur Group. H, halite casts; LD, euhedral and discoidal gypsum and/or anhydrite pseudomorphs; N, acicular gypsum pseudomorphs; C, cauliflower chert nodules

	Formation	Main lithologies	Thickness (m)	Evaporite pseudomorphs
	Stott Formation	Massive and stromatolitic dolomite; dolomitic shale	750	LD
	Smythe Sandstone	Quartz sandstone; chert conglomerate	0–180	
Batten Sub-group	Looking Glass Formation	Chert; chert breccia; minor dolomite	25–230	
	Stretton Sandstone	Flaggy quartz sandstone	30–245	
	Yalco Formation	Chert; chert breccia; minor dolomite	130	
	Lynott Formation	Dolomitic siltstone; chert; chert breccia; minor dolomite	210–760	LD, C (Donnegan Member)
Umbolooga Sub-group	Reward Dolomite	Dolomite with chert pellets; dolomitic siltstone	50–300	
	Barney Creek Formation	Pyritic, carbonaceous, dolomitic shale; dolomite; dolomite breccia; H.Y.C. deposit	0–490	
	Teena Dolomite	Massive laminated and stromatolitic dolomite	57	H, N (Coxco Dolomite Member)
	Emmerugga Dolomite	Massive laminated and stromatolitic dolomite	300	H, LD, N
	Tooganinie Formation	Stromatolitic dolomite; dolomitic shale; quartz arenite, dolomitic siltstone	800	H, LD
	Tatoola Sandstone	Quartz arenite; dolomitic siltstone	140	LD
	Amelia Dolomite	Laminated and stromatolitic dolomite, massive gypsum pseudomorphs in beds	90–240	H, LD, C
	Mallapunyah Formation	Purple dolomitic siltstone; minor dolomite; quartz arenite	30–750	H, LD, C

formed by a mechanism similar to that suggested by Kastner[21].

'Cauliflower' chert nodules[23] also occur in the McArthur Group, and are particularly abundant in the Mallapunyah Formation, and in the Donnegan Member of the Lynott Formation (Table 1). The nodules are roughly circular in plan and are flattened parallel to the bedding. They vary from about 1 to 100 cm in diameter, and from 1 to 30 cm in height. The upper surfaces of the nodules are irregular and botryoidal (Fig. 1*c*). The lower surfaces are similar but more flattened. The outer surfaces have a well developed mesh-like structure of interlocking chert blades. In thin section three zones can be recognised. The outer zone consists of a mesh of lutecite fibres[22] set in a matrix of brown microcrystalline quartz (Fig. 1*d*). In some cases, the fibres display a distinct, sub-parallel lineation, and they contain highly birefringent inclusions which we have identified as anhydrite. This outer zone grades inwards to a zone of macrocrystalline quartz that contains minor amounts of dolomite and barite. The innermost zone of the nodules consists of coarsely crystalline dolomite and barite, together with trace amounts of fluorite. These nodules are remarkably similar to the chert nodules from the Fort Payne and 'Warsaw' Formations of Tennessee which Chowns and Elkins[23] demonstrated to be replacements of anhydrite nodules identical with those described by Kinsman from the sabkha environments of the Persian Gulf[19].

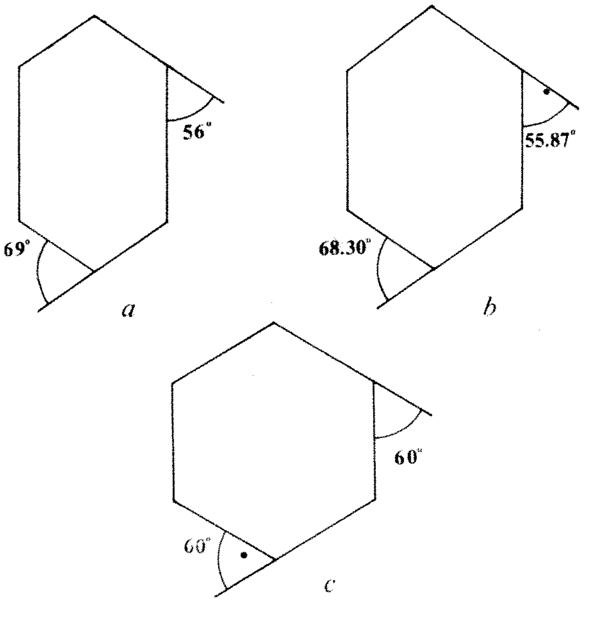

Fig. 2 Interfacial angles of pseudomorphs in radiating clusters (*a*) compared with interfacial angles of gypsum (*b*) and aragonite (*c*).

Pseudomorphs after halite are common throughout the McArthur Group with the highest concentration in red beds and some dolomitic siltstone sequences (Table 1). Brown and Plumb[24] describe the characteristics of the halite casts in the Group, and the present studies have produced little new information. The halite casts which we have seen up to now, all appear to have formed by almost complete evaporation in shallow marine environments, and probably represent ephemeral salt crusts. Pseudomorphs after halite coexisting with either gypsum or anhydrite are extremely rare. This general lack of association of halite and calcium sulphate minerals probably results from the dissolution of previously deposited halite during surface flooding, as it does in Recent marginal sabkhas[17,18].

While we cannot determine precisely the amount of evaporite material because of poor outcrop in the McArthur River area, our studies show that evaporitic sediments occur over an area of at least 5,000 km^2 in the Batten Trough alone[25]. In some sections of the particularly evaporitic formations, for example, the Amelia Dolomite, up to 40% of the measured sections are composed of evaporite relicts. Therefore, not only do our studies show that a variety of evaporite relicts occur in the McArthur Group, but that they occur in vast amounts.

Although our work is still at an early stage, the results obtained so far lead us to several important conclusions. First, we conclude that significant parts of the McArthur Group were deposited in a marginal sabkha environment. Many of the evaporite sequences of the McArthur Group are remarkably similar to the Recent sediments of the Trucial Coast. This resemblance provides the basis for new insights into the sedimentary environments represented in the McArthur Group, the habitats of the microfossils which abound in many of the formations[26–28], and suggest possible physiographic configurations and climatic regimes. Second, the McArthur Group evaporites which are similar to Recent coastal sabkha deposits in terms of chemistry, crystallographic habit etc., are probably the products of brines with essentially the same compositions. Third, the Persian Gulf sabkha model is not applicable to all of the McArthur Group evaporites, some of which appear to have stronger resemblances to the Marion Lake, Yorke Peninsula (South Australia) lacustrine gypsum deposits[29]. Fourthly, our results show conclusively that the giant H.Y.C. stratiform Pb–Zn–Ag deposit at McArthur River is yet another example of the widespread association of stratiform base metal sulphide deposits with sulphate evaporitic sediments[30–32]. The location of the H.Y.C. deposit within a large evaporite bearing basin raises the interesting possibility that this and related deposits formed from metal-rich brines of the kind forming today in evaporite-bearing basins[33], rather than from volcanically derived hydrothermal solutions[34].

Finally, we maintain that the evidence presented here and elsewhere[4] unequivocally shows the widespread occurrence of large volumes of sulphate evaporites in mid-Proterozoic times. The assertion that there was no significant deposition of such evaporites before ~800 Myr ago[2] is manifestly in error. Consequently, the models of crustal, hydrospheric and atmospheric evolution[2] based on this contention require considerable revision and modification.

Discovery of amphibians in the Namurian (Upper Carboniferous) of Fife

CARBONIFEROUS amphibians are very rare as fossils and almost all major finds of British specimens were made in the nineteenth century. Nevertheless, knowledge of Carboniferous tetrapods, both amphibians and reptiles, has expanded considerably in recent years[1,2]. All are from Europe or North America and most are from horizons equivalent to or later than the British Coal Measures (Westphalian and Stephanian, respectively). Far fewer amphibians are known from the Lower Carboniferous and knowledge of the Namurian tetrapod fauna, between the Lower Carboniferous and the Coal Measures, is even more meagre. With the exception of a single incomplete anthracosaur amphibian from the Namurian of the Ruhr, Germany[3], pre-Coal Measure amphibia are known from only three areas (1) West Virginia and south-western Pennsylvania in the United States[4,5]; (2) Nova Scotia, Canada[6], and (3) the Edinburgh area and southern Fife in Scotland[7,8]. In November 1974, however, fossil amphibian and fish remains were discovered at the Dora Opencast Site (area C), south-east of Cowdenbeath, Fife (Fig. 1), in Carboniferous strata of Namurian age. The richly fossiliferous bone bed at Cowdenbeath formed a localised patch in a seatrock (rooty, muddy siltstone), which lies beneath a coal seam below the Lochgelly Blackband Ironstone. The Lochgelly Blackband Ironstone itself has also produced a fauna with amphibian remains in the Dora site, while a few specimens have been recovered from strata up to 6 m lower in the sequence.

All these strata belong to the Limestone Coal Group which forms the lowest subdivision of the Namurian Series (lower Namurian A) in Scotland. In the Dora area this subdivision is about 330 m thick. A measured section (Fig. 2) at the locality indicates the position of the bone bed about 62 m beneath the base of the Index Limestone at the top of the Limestone Coal Group. Currie[9] took the base of the Index Limestone as the junction between the top of the Pendleian (E1) and the base of the Arnsbergian (E2) stages, a conclusion which is supported by Wilson (ref. 10, Fig. 1).

The bone bed was originally exposed as a section some 30 m long, but thanks to the generosity of the Murphy Group, contractors to the National Coal Board, the considerable overburden was removed to expose the upper surface of the bone bed, which dipped gently north-westwards. The bed was cut off by a fault at the south-west end and divided by two small faults into three areas. Three 1.25-inch (31-mm) diameter cores were taken from the surface of the bed to a maximum depth of 5 m, by K. Hall and S. Creany

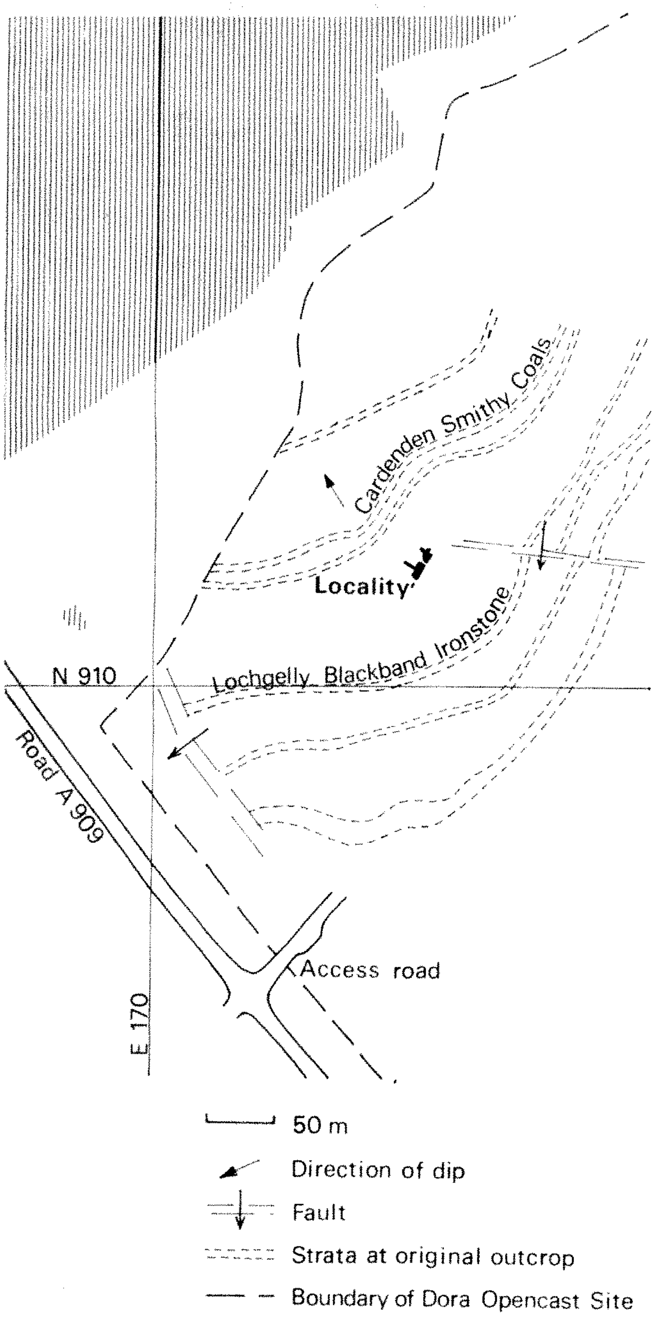

Fig. 1 Position of the fossil amphibian locality in Dora Opencast Coal Site, south-east of Cowdenbeath, Fife (NT 172911). From National Coal Board Opencast Executive Scottish Region, Drawing No. 01/6028.

of the Organic Geochemistry Unit, University of Newcastle upon Tyne. After gridding into 0.33-mm squares to preserve relationships between associated remains, the richest part of the bone bed was collected by hand. This material, together with transects extending outside the richly fossiliferous area, is stored in the University of Newcastle upon Tyne, in the Royal Scottish Museum and by S. P. Wood. After a delay from October to December 1975 to facilitate collection, opencast operations have removed all the surrounding and underlying strata.

Several specimens have already been developed from the bone bed. Many of these are isolated skeletal elements of sharks and of representatives of all the major groups of bony fish known from the Carboniferous. These include acanthodians, actinopterygians, dipnoans (lungfish) and crossopterygians, the group from which the tetrapods are agreed to have descended. The acanthodian fish *Gyracanthus* is by far the commonest form, represented in nearly

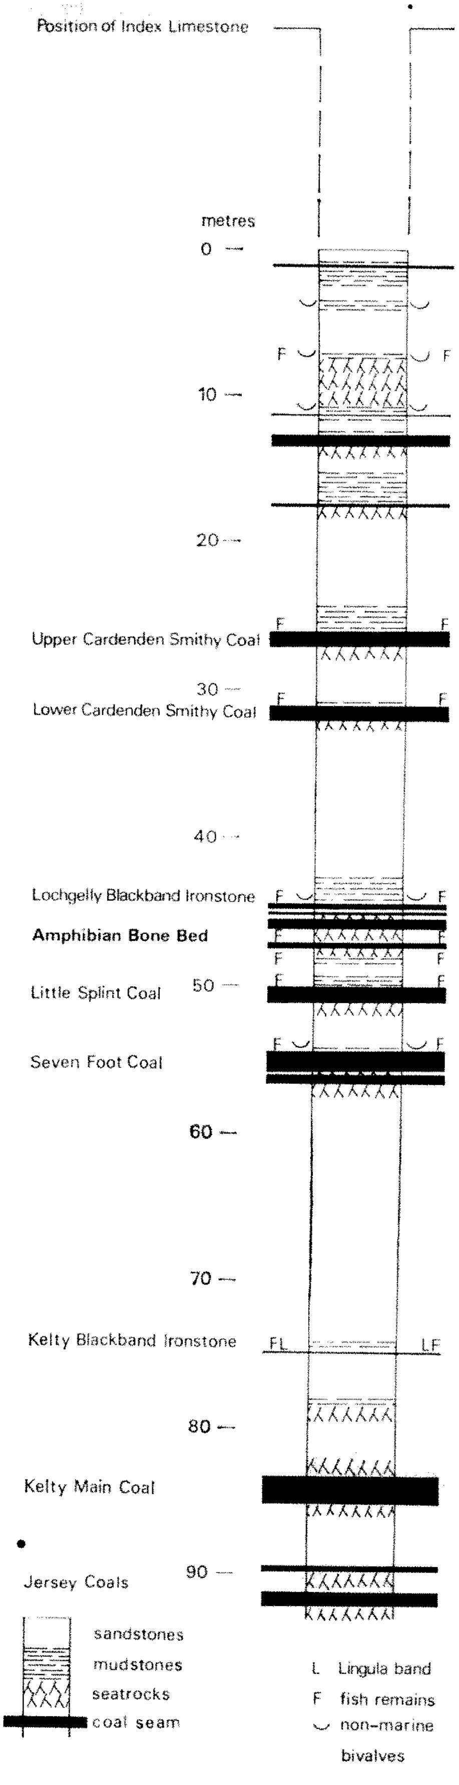

Fig. 2 Composite measured section in Dora Opencast Site (NCB), areas *C* and *D* (Institute of Geological Sciences registered numbers NT 19 SE/534 and 537).

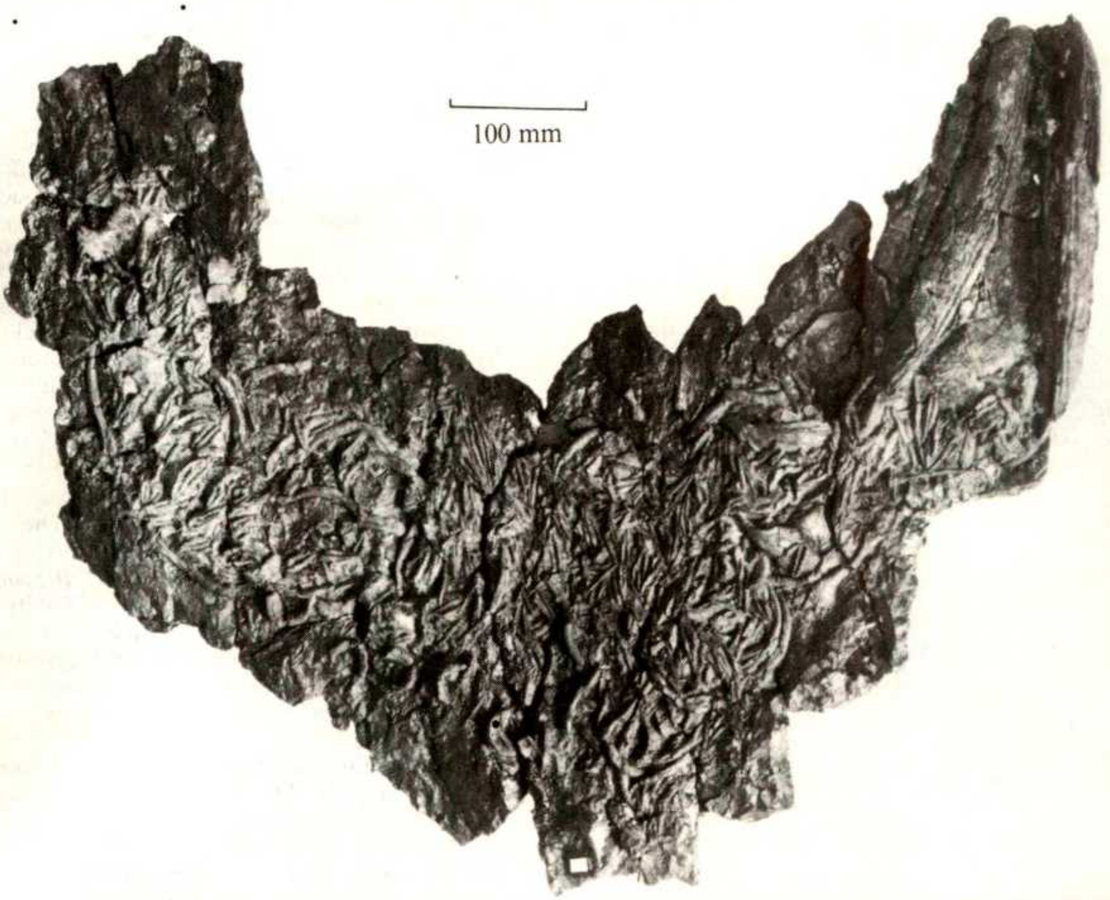

Fig. 3 Skeleton of a new anthracosaur amphibian (BM(NH)R 10,000) in ventral view.

every 0.33-m block of matrix by at least one spine, whereas the actinopterygians are represented only by a single specimen showing palaeoniscid scales. The skull bones of rhizodontiform crossopterygians will give important information on this poorly known group. The fish fauna of the Lochgelly Blackband Ironstone appears to be similar to that of the bone bed but includes six determinable actinopterygian species.

The amphibian specimens include representatives of all three major Palaeozoic groups, the Anthracosauria, Temnospondyli and Lepospondyli. By far the most important specimen so far developed is the almost complete but tail-less specimen of a new crocodile-like anthracosaur amphibian, now registered in the British Museum (Natural History) (Fig. 3). Skull remains of a second anthracosaur are probably to be referred to a primitive Lower Carboniferous species, *Eoherpeton watsoni* Panchen[2] and a third anthracosaur, as yet undescribed, is represented by the skull table and interorbital region (Fig. 4). Temnospondyls include a jaw ramus of the aberrant loxommatid *Spathicephalus mirus* Watson[7], previously known only from a similar horizon at Loanhead near Edinburgh, and appendicular bones probably to be referred to the primitive long-bodied Colosteidae[2]. The small lepospondyl amphibia are represented by isolated postcranial remains.

The Carboniferous was the period of the first major adaptive radiation of tetrapod vertebrates and the earliest reptile known is from the early Coal Measures (Westphalian B) of Nova Scotia[11]. The Cowdenbeath find could extend reptile history down into the Namurian. It also has the potential to vastly increase knowledge of the early Carboniferous fauna beyond the small number of species and individuals from other early Carboniferous sites. Furthermore, the Namurian fauna is particularly important in forging the evolutionary link between the few primitive amphibia known from the Lower Carboniferous and the more advanced and diverse fauna of the Coal Measures.

Study of the Cowdenbeath collection is in progress at the Royal Scottish Museum and, supported by a grant from NERC, in the University of Newcastle upon Tyne. We thank Dr F. J. Matheson and Mr D. J. Harley, National Coal Board, Opencast Executive, for permission to collect and Messrs A. P. Duffy and K. D. Smith of the Murphy Group

Earliest known *Hipparion* from Holarctica

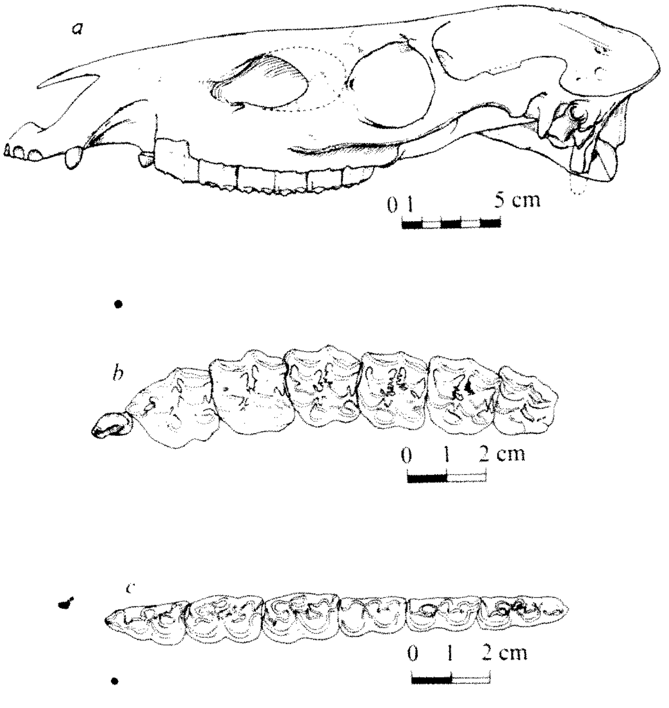
The three-toed horse *Hipparion* was ubiquitous in terrestrial mammalian faunas throughout Holarctica during parts of the Miocene. This report describes *Hipparion* from the early Barstovian Fleming Formation of the Texas Gulf Coastal Plain. These specimens are assigned to *Hipparion* because of dental characters such as the diagnostic presence of isolated protocones in the upper molars. This *Hipparion* is also characterised by a well-developed and anteriorly-rimmed preorbital fossa similar to the condition seen in some Old World forms. Because of this earliest known occurrence, the widely used *Hipparion* datum concept should be restricted to some palaeogeographically finite area in the Old World.

We prefer the designation '*Hipparion*' in the broad sense because we contend that, in common usage, it represents a 'form genus' consisting of Miocene–Pliocene horses with isolated protocones in the upper molars and tridactyl feet, that is, *Hipparion* is not used in the strict taxonomic sense. Because of its great abundance both geologically and geographically, this horse has played a significant role in the biochronology of this time interval, with Eurasian Neogene mammalian assemblages often being termed *Hipparion* faunas. The first appearance of *Hipparion* has been used as a geologically synchronous time plane, also termed 'datum', much in the same way as microfossils have been used in marine sequences. Based on a combination of different geochronological techniques, the *Hipparion* datum has been determined to be 12.5 Myr in the western Old World[1,2], 12.8±1.03 Myr in northwestern Africa[3], and 12–9 Myr in Sub-Saharan Africa[4]. In the well known mammal-bearing Siwalik sequence of the Sub-Himalayan region, the *Hipparion* datum is above the base of the Nagri Sandstone and *Hipparion* is common in the middle Siwaliks[5–7]. Precise determinations for this datum are not available. *Hipparion* is also abundant from parts of the Nearctic Miocene. Until now, the first occurrence of this horse in the New World has been thought to be of early Clarendonian age.

In the collection at the American Museum of Natural History, New York, are several skulls and dentitions of *Hipparion* from Trinity River Pit 1, early Barstovian age (medial Miocene), Fleming Formation, San Jacinto County, Texas Gulf Coastal Plain (Fig. 1). There is no direct geochronological control for this locality. Based on correlation to other early Barstovian assemblages with radiometric age determinations, the Trinity River Pit 1 seems to be significantly older than the Old World localities in which *Hipparion* first occurs, that is of the order of approximately 15 Myr (ref. 8). These specimens belong to a distinctive group of *Hipparion*, also represented in the Old World, that have a well-developed and anteriorly-rimmed preorbital fossa. A detailed discussion of the taxonomic significance of preorbital fossae in *Hipparion* is the subject of another report[9]. The dentition is brachyodont relative to other *Hipparion*. The upper molars are characterised by the distinctive *Hipparion* isolated protocone, which in the sample from Trinity River Pit 1 is rounded in cross section. The plications on the fossette borders are simple relative to other *Hipparion*. The lower cheek teeth have separated metaconids and metastylids and either deep externomedial valleys (ectoflexids) or weak pli-caballinids.

It is generally accepted that *Hipparion* arose in the New World during the Miocene from some species of *Merychippus* and subsequently dispersed to the Old World[10,11]. The *Hipparion* from the early Barstovian of Texas represents the earliest-known member of this group. It is primitive in several aspects, including small size, rounded protocone, and brachyodonty, and advanced in the development of the diagnostic anteriorly-rimmed preorbital fossa, which is also found in later representatives of this group[9]. In younger Clarendonian sediments of the New World,

Fig. 1 Earliest known *Hipparion*, from Trinity River Pit 1, Fleming Formation, early Barstovian, San Jacinto County, Texas Gulf Coastal Plain. *a*, F:AM 73940, skull that shows preorbital fossa. *b*, F:AM 73940, left upper cheek teeth. *c*, F:AM 73940, left lower cheek teeth. F:AM is the abbreviation for; Frick: American Mammals, The American Museum of Natural History.



Hipparion is represented by a few morphologically distinct groups that can be characterised by differences in the development of preorbital fossae, and, to a lesser extent, differences in dental patterns. In the Neogene of the Old World, *Hipparion* first appears at the base of the Vallesian, which represents in part the same time interval as the Clarendonian of the New World[2]. The presence of *Hipparion* in the Old World seems to represent dispersal from the New World. Based on characters of the dentition, it has been argued that *Hipparion* in the Vallesian of the Old World was monophyletically represented by one species, *H. primigenium*. It has also been hypothesised that *Hipparion* underwent an adaptive radiation during Vallesian and later time that resulted in the multitude of species described in the literature[12]. But, based on differences in preorbital fossae in Holarctic *Hipparion* we suggest that clearly differentiated forms of *Hipparion* were already in existence in the New World by Clarendonian time, and dispersal to the Old World could have been polyphyletic with the presence of several forms during Vallesian and later time.

Some early workers used the first appearance of *Hipparion* in Holarctica as the herald of the Pliocene[13,14]. With the advent of more recent biostratigraphic and geochronologic interpretations, this hypothesis is no longer considered valid by most workers[1,2]. Although the *Hipparion* datum does not correspond to the Mio-Pliocene boundary, it is still used as a geologically synchronous event for purposes of correlation in the western Old World. The presence of *Hipparion* in early Barstovian sediments of the New World is significantly older than the first appearance of *Hipparion* in the Vallesian of the western Old World. The question now arises, to what palaeogeographic extent should the *Hipparion* datum be restricted in order to retain its usefulness as a geologically synchronous event? Much evidence has been presented to demonstrate the usefulness of the *Hipparion* datum in the western Old World and Africa. Precise geochronological studies are needed to determine when and what form(s) of *Hipparion* first appeared in the eastern Old World. If the first appearance of *Hipparion* is not a geologically synchronous event throughout the Old World, or if it represents dispersal of several forms, then it would not be necessary to reject the *Hipparion* datum concept, but it would have to be restricted to some palaeogeographically finite area.

We thank Dr Richard H. Tedford and Mrs S. Marie Skinner for encouragement. B.J.M. conducted some of this research during tenure of a faculty fellowship in the Department of Geological Sciences at Columbia University.

Tail autotomy, functional conflicts and their resolution by a salamander

IF an organ serves several functions, two or more of these may conflict at times in their contribution to the immediate fitness of the organism. Among lower invertebrates the tail is commonly used as a defence against predators but it has other functions such as fat storage, locomotion, respiration and courtship. Experiments have shown that tail loss can depress reproductive output in lizards[1,2], but this has not been reported for natural populations. Data reported here suggest that loss of the tail frequently depresses reproductive output in natural populations of the plethodontid salamander *Batrachoseps attenuatus*, which is widespread in California. The dual use of the tail for energy storage and for protection may increase the adaptive flexibility of the salamander for coping with an unpredictable environment.

B. attenuatus has a tail which may reach twice the trunk length. It commonly represents 50% of the biomass of mature animals, and can provide proteins and lipids for maintenance, reproduction and continued growth in trunk length. During the dry summer months *B. attenuatus* retreats underground and does little or no feeding[3]. At this time females produce eggs and males come into full breeding conditions (large premaxillary teeth develop and neck muscles enlarge). During the dry season, the mean tail volume of mature individuals has decreased by 29%. Thus the tail is presumably an important energy source for maintenance and reproduction during this period.

Tail autotomy seems to be an adaptation for escaping from predators. It has been associated with attacks from snake predators in the laboratory (my unpublished results and personal communications from S. Arnold). Although autotomy may be associated with intraspecific competition, I have seen no evidence for this during experiments on competition for burrow sites. The tail of *B. attenuatus* can drop off at any segment; it is then regenerated at apparently a constant rate until it approaches its full length[4]. Estimates of annual tail breakage in populations in or near Berkeley, California, range from 28 to 48% (data to be published elsewhere). For only half the time, however, does a salamander lose more than 30% of its tail. Size and sex classes do not differ significantly in the frequency of observed tail breaks.

Three lines of evidence suggest that tail autotomy inhibits reproduction in natural populations of this salamander. First, mature individuals, both males and females, which fail to breed during one season have significantly shorter tails than do breeding individuals of similar trunk length (Table 1). Both males and females typically reproduce annually in the San Francisco Bay area; the percentage not breeding ranged from 0 to 18% per year for the populations included in my study. Since most of these non-breeding individuals (65% compared with 17% of breeding individuals) had incompletely regenerated tails (estimated as less than 75% the length of unbroken or fully regenerated tails), autotomy, subsequent regeneration or both are interpreted as major depressants of reproductive output in these populations.

Second, maturity may be delayed as a consequence of tail autotomy. In all but one comparison, immature animals, similar to breeding individuals in trunk length and presumably age, had significantly shorter tails (Table 1) due to incomplete regeneration (25% compared with 3% of breeding individuals).

Third, field evidence suggests that tail autotomy not only inhibits reproduction but also reduces the amount of reproductive output for individuals which do reproduce.

Table 1 Comparison of relative tail length between breeding and nonbreeding salamanders of similar trunk length

	Redwood forest		Conifer woodland		Eucalyptus woodland	
	Females	Males	Females	Males	Females	Males
Not breeding, immature	− 1.8 (23)	− 5.7 (26)	− 7.7 (20)	− 1.4 (11)	—	—
Breeding	1.8 (12)	− 0.5 (14)	− 0.6 (22)	1.2 (19)	—	—
Probability	0.12	0.03	0.0015	0.07		
Not breeding, mature	− 9.2 (13)	−12.8 (21)	−23.2 (6)	−18.3 (1)	−26.1 (1)	−23.8 (4)
Breeding	− 2.1 (22)	− 4.4 (25)	− 5.2 (14)	−16.5 (3)	− 5.2 (4)	− 8.8 (4)
Probability	0.02	0.0004	0.0003	0.94	0.0001	0.135

Values are the means of the deviations (mm) of observed tail lengths from the expected unbroken tail length, calculated from the linear regression of tail length on trunk length for individuals that had unbroken or fully regenerated tails. These regressions were based on samples collected in the same habitats at different times than the samples used in this analysis. Only breeding individuals that were within 1 mm of the trunk length of nonbreeding individuals in the same collection were used. Data for each habitat are pooled from samples collected over several years. Numbers in parentheses are sample sizes. Student's *t* test was used to determine the significance of the differences; probabilities are for a two-tailed test.

In all but one case, tail length showed a significant positive partial correlation with an index of reproductive effort (the number of ovarian eggs of gravid females and the extent to which the neck muscles are enlarged in males, expressed as the ratio of neck width to head width) when trunk length is constant (Table 2).

The inhibitory influence of tail loss on reproductive output may derive simply from loss of considerable energy reserves available in the long tail or from use of remaining energy reserves, such as those in abdominal fat bodies or in the tail remnant, to regenerate the tail during the dry season instead of reproducing. Hendrickson[4] concluded on the basis of recaptures of marked animals that regeneration occurs during both the wet and dry seasons. To test the possibility that tail regeneration during the dry season depresses reproductive output I collected 57 salamanders before the dry season (early May) and removed the whole tail from 27 of them; the rest served as controls. The salamanders were maintained, unfed, on a natural photoperiod at 13 °C until September, at which time they were killed and examined for tail regeneration and reproductive condition. (Forty salamanders, which had been collected on a different day than the others, died shortly after the start of the experiment, probably from heat stress when collected[5].)

Table 2 Partial correlation coefficients of trunk length and tail length with an index of reproductive effort

	Redwood forest	Conifer woodland	Eucalyptus woodland
Females			
Sample size	42	78	46
$r_{\mathrm{SVL,RI.TL}}$	0.53 ($P < 0.001$)	0.64 ($P < 0.001$)	0.77 ($P < 0.001$)
$r_{\mathrm{TL,RI.SVL}}$	0.36 ($P < 0.05$)	0.34 ($P < 0.01$)	0.55 ($P < 0.001$)
Males			
Sample size	28	34	
$r_{\mathrm{SVL,RI.TL}}$	0.40 ($P < 0.05$)	0.53 ($P < 0.01$)	
$r_{\mathrm{TL,RI.SVL}}$	0.22 ($P = 0.32$)	0.55 ($P < 0.01$)	

Both tail length and the index of reproductive effort are a linear function of trunk length. Calculations include only actively breeding individuals. SVL, trunk length; TL, tail length; RI, reproductive index (see text for explanation).

Clearly the salamanders regenerate the tail at some expense of reproduction. All experimental animals ($n=9$) regenerated their tails at an average rate of 2.6 mm per month. All but one of them failed to become fully reproductive; all controls ($n=6$) became reproductive ($P=0.001$, Fisher's exact test).

Thus, field observations and one experiment suggest that autotomy of the tail depresses reproductive output, at least in part, because the regeneration is taking place when energy reserves are needed for reproduction. I conclude that the use of the tail for defence has functional priority over its use to supply energy for reproduction. An explanation for this priority is that the environment has selected for longevity in *B. attenuatus* at the expense of reproduction when the two selective pressures are in conflict[6]. The environment is unpredictable to this salamander with respect to both the length of the dry season and the amount of rain during the wet season. Variability in rainfall produces variability in the amount of energy an adult can store for reproducton during the dry season. After a wet season with half the normal rainfall (1971–72), females in two habitats had 6% and 11% fewer eggs ($P=0.12$ and 0.0002, respectively, one-tailed *t* test) than after a wetter than normal season (1972–73). Variability in the length of the dry season is thought to produce variability in mortality, particularly in juvenile mortality[6]. Averaging ten times the weight of first year juveniles, adults have a metabolic advantage in surviving prolonged periods without food, and thus survival is more certain for them than for juveniles. Both variability in the production of young and uncertainty in their survival are predicted to favour increased longevity at the expense of reproduction[7].

It is not surprising that tail regeneration (and therefore defence) has priority over reproduction, for such priority is theoretically expected when selection favours longevity. It is more perplexing that the salamander does not use some other structure for either energy storage or predator defence. Although separate systems may have been 'evolutionarily available' to species, the dual use of the tail may be adaptive in that it can increase the responses of the salamander in allocating energy for reproductive and somatic functions. A specialised defence system, such as a toxin, costs the salamander a certain amount of energy that is then irrevocably tied up in the system. In contrast, by using a structure for defence that can also be used to accumulate required energy reserves, the salamander can draw on these reserves for reproduction if they are not

We're old hands at new labelled compounds

We make about 70 new labelled compounds a year—covering all aspects of research. It's a long-standing, but very essential, development programme. We rely on our customers, our technical representatives and our own scientists, to tell us which compounds are needed for new scientific investigations.

Our current catalogue lists our labelled compounds but goes to press before new products are in production. We try to let customers know what's new—by advertising, mailing and representative calls. But if you still haven't heard the news, please write or 'phone for our new catalogue supplement. You may want to discuss your own ideas on new labelled compounds, and we'll be very happy to consider them. Meanwhile, we'd like you to consider ours.

Circle No. 05 on Reader Enquiry Form.

NATO ADVANCED STUDY INSTITUTES 1977

The purpose of the Advanced Study Institutes (ASI) Programme, one of the main activities of the NATO Science Committee, is to disseminate advanced scientific knowledge and to allow formation of contacts among scientists from different countries. ASIs are intended to be meetings where a small faculty of internationally known experts teaches a carefully defined subject in a coherent lecture programme. Generally, between 50 to 100 scientists are admitted and take an active part in the meeting.

The Advanced Study Institutes listed below, sponsored or co-sponsored by NATO, are organised under the entire responsibility of the director of the institute or his organising committee. Those scientists with adequate background and interest who wish to participate in one of the institutes should **apply direct to the director** of the particular institute. It should be noted that location, dates and deadlines for application for the institutes might be subject to change and it is therefore recommended that contact be made with the appropriate director well in advance of the dates indicated.

A limited number of small grants are available to defray part of the expenses of deserving participants. These grants can only be obtained through application to the ASI director.

THE NATO ASI SERIES

The Scientific Affairs Division of NATO provides the directors of Advanced Study Institutes with an efficient vehicle for publication so that a wider dissemination of the scientific knowledge developed during the courses can be achieved.

An agreement was reached with four internationally known scientific publishing houses to publish the proceedings of the Advanced Study Institutes in a uniform "NATO ASI Series", divided into five sub-series according to the main scientific areas. The virtue of this series is that the publications are available generally a few months after the institutes are held, and that a high quality of publication in book form is guaranteed. For further information about the volumes in your particular field of interest please contact the Publisher.

Coral-snake pattern recognition and stimulus generalisation by naive great kiskadees (Aves: Tyrannidae)

THE neotropical coral-snake complex with its contrasting ringed patterns includes true coral snakes, for example, the highly venomous elapid genus *Micrurus*, and many colubrids that are either less strongly venomous or non-venomous[1]. Whether or not this complex involves Batesian and/or Müllerian mimicry has been widely debated[2–8]. Wickler[1] suggested that if mimicry depends on predator learning, true coral snakes are too deadly to be models; rather, they are mimics of the less dangerous colubrids of the complex (Mertensian mimicry). He also claimed that there was no evidence that any predator could recognise a coral snake innately[1]. I have shown that Costa Rican turquoise-browed motmots (*Emomota superciliosa*) need no learning to show strong aversion to a pattern of wide yellow and narrow red rings[6]; this I have interpreted as an innate recognition of a generalised coral-snake pattern. No Costa Rican member of the coral-snake complex has wider yellow than red rings, however, so I had no proof that the motmots were not simply showing an aversion to a general aposematic pattern. I present here evidence that another avian predator needs no learning to avoid not only a pattern of wide yellow and red rings, but also the most common local *Micrurus* pattern of red, yellow and black rings.

The great kiskadee (*Pitangus sulphuratus*) occurs in open and semi-open habitats from southern United States (Texas) to south Argentina. It regularly eats small reptiles[5], and *Micrurus* and many other members of the complex occur over much of its range. These snakes could be dangerous to kiskadees. *Micrurus* in particular may lie partly concealed in leaf litter during the day, often with its head under leaves. A kiskadee attacking the exposed portion of such a snake would be in danger of being bitten, especially if that portion did not include the head. As kiskadees lack heavy protecting scutes on their legs, such a bite could well prove fatal.

Six young kiskadees from three broods aged 12–20 d were removed in May 1976 from their nests in north-western Costa Rica and raised in the laboratory in 91 × 46 × 46-cm hardware cloth cages. Two cages each held two birds; the other two held one each. Experiments in these cages were begun when the kiskadees were old enough to catch their own prey, that is, 45 d. In each experiment a wooden dowel model 6 cm long and 1 cm in diameter was placed on the cage floor and the number and location of the birds' pecks was recorded for 5 min. Models were painted with non-toxic tempera colours in the following five patterns: white with narrow green rings; yellow with narrow red rings; yellow with narrow red stripes; 'coral-snake' rings (wide red, narrow yellow, wide black, narrow yellow); and coral-snake stripes. Two models were made for each pattern: a 'solid' model completely covered with the pattern, and an 'end-third' model having only one end painted, the other two thirds being plain wood (Fig. 1). With the exception mentioned below, all birds received the patterns in the above order.

Each kiskadee had previously attacked solid models of plain white, green, red, yellow and black without hesitation. Of the five patterns on solid models, two were completely avoided, two readily attacked, and one attacked with great caution (Table 1). Although no kiskadee approached either the yellow and red ring or the coral-snake ring model, the responses to the two differed. Only two birds gave mild alarm calls to the former; the same two plus at least two more gave high intensity alarm calls (like those given by a captured bird) to the latter. Their response to the white and green ring model (the first pattern any bird received) shows that they did not fear ring patterns in general. Nor did they hesitate to attack the yellow and red stripe model, which has a relative proportion of yellow and red identical to that of the ring pattern. Unexpectedly, although all six birds approached the solid coral-snake stripe model, all showed great hesitation, and the four birds that finally did attack did so by darting forward with spread wings and contour feathers tightly in.

With the end-third models, the birds directed most of their pecks to the painted third of the white and green ring, the yellow and red stripe, and the coral-snake stripe models, but gave a significant response to the end farthest away from both the yellow and red ring and the coral-snake ring models (Table 1). Kiskadees thus consistently avoid the coral-snake ring and the yellow and red ring patterns, but hesitate to attack the coral-snake stripe pattern only when it covers the entire model.

This aversion to the two ring patterns seems to require no learning. Kiskadees have covered nests, and the three youngest birds barely had their eyes open when they were taken, so it is unlikely that they perceived any patterns in the dim light within their nest before their capture.

Coppinger[9] found that naive passerines of three species gave alarm calls and active escape behaviour to a large variety of novel stimuli, the degree of rejection depending on the amount of stimulus change and the birds' previous experience. The order in which the kiskadees received the

Fig. 1 Models used in the experiments. *a*, Solid forms. *b*, End-third forms. The basic patterns were: 1, white and green (or yellow and red) rings; 2, yellow and red stripes; 3, coral snake rings, and 4, coral snake stripes. The three sections of the end-third models were recorded as p, m and u.

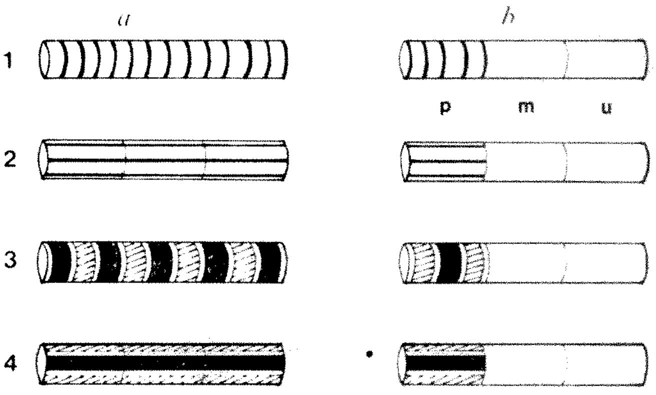

Table 1 Kiskadees' pecks to the ten models

Pattern	Pecks at solid models	Pecks at end-third models				
		% at each area				
		p	m	u	Total pecks	χ^{2}*
White and green ring	59	100	—	—	51	p
Yellow and red ring	—	17.86	—	82.14	28	u
Yellow and red stripe	44	100	—	—	45	p
Coral-snake ring	—	11.11	—	88.89	9	u
Coral-snake stripe	7	100	—	—	23	p

*p indicates a response to the painted third at $P<0.01$; u indicates a response to the unpainted end at $P<0.05$.

models was designed to test for such novelty effects. The first pattern given was the white and green ring, which all birds attacked without hesitation: neither fear of patterns themselves nor fear of rings can thus be attributed to novelty. Because the three oldest birds had received the coral-snake ring model before the coral-snake stripe model, however, their hesitation to attack the latter might have been due to their earlier experience. The three youngest birds were therefore given the stripes before the rings. They responded in a manner similar to that of the older birds (Table 1), showing that this hesitation was not caused by previous experience.

The kiskadees' avoidance of the two ring patterns thus seems to be innate. It is unlikely that two separate innate aversions are involved; their stronger rejection of the coral-snake models, both rings and stripes, suggests that great kiskadees have an innate aversion to the coral-snake pattern, yet will generalise to avoid a pattern of wide yellow and narrow red rings.

Pattern generalisation by predators is essential for the functioning and evolution of both Batesian and Mullerian mimicry[1,10]. If mimics evolve by microevolution, broad stimulus generalisation by local predators is necessary to give selective advantage to early divergent phenotypes just beginning to approach the model in pattern. For predators that have learned to avoid a pattern, such generalisation is well documented[11-12]. My results show that generalisation can also occur with an innate aversion. In the presence of such predators, classical Batesion or Müllerian mimics can theoretically evolve even when the model is lethal; furthermore, for Batesian mimics, the model need not be numerically more abundant than the mimic[13]. If innate recognition and generalisation of the coral snake pattern is a common phenomenon, the Mertensian mimicry hypothesis is unnecessary to explain the evolution and maintenance of the coral snake mimicry complex.

I thank John H. Vandermeer and F. Gary Stiles for comments on the manuscript, and Sigma Xi for a grant.

Divergent taste responsiveness to fruit of the tree *Antidesma bunius*

GENETIC divergence of taste responsiveness was first demonstrated for phenylthiocarbamide (PTC)[1], the inability to taste PTC bitter being described as an inherited Mendelian recessive character, and ability to taste PTC bitter as dominant[2]. This hypothesis has largely been confirmed[3,4] although occasional incomplete penetrance of the 'taster' gene has been reported. Recently, eight people were served with a pie made from antidesma berries, and two people complained that the pie was extremely bitter and inedible. The other six people, however, found the pie pleasant tasting, enjoyably edible and sweet. This incident prompted us to survey taste responsivness to antidesma. We found that all subjects who tasted antidesma as bitter found PTC not bitter, whereas no subject who tasted PTC as bitter found antidesma bitter.

Fresh berries from the tree *Antidesma bunius* were pressed and an aqueous extract derived. The extract was stored at 4 °C. A saturated solution of PTC (Baker) was also prepared. For the test each solution was placed into a 60-ml dark-coloured glass-dropper bottle fitted with a glass dropper.

The subjects were 170 volunteers (88 males) from the greater Washington DC area, aged 7–89 yr. The group included eight blacks, two orientals and 160 Caucasians of diverse national origin. To test taste responsiveness one drop of antidesma extract and PTC was placed successively on the tongue and the subject was requested to taste it. Each subject was also asked whether the drop tasted salty, bitter, sweet or sour and to judge the intensity of its saltiness, sweetness, sourness or bitterness on a scale from 1–100 based on previous taste experience[5]. The antidesma extract was always given first and was followed by the PTC within 5 min. Age and sex of each subject were noted as was the presence of ichthyosis. A modified form of the Ishihara colour plates[6] was shown to each subject in a standard manner in order to identify the presence of colour blindness.

Responders to antidesma extract and to PTC were defined as subjects who described the respective solutions as bitter; non-responders were defined as those who described it either as tasteless or another taste quality. Intensity responses were calculated as the median and the mean responses of the taste responders or non-responders for each respective group.

Responders to antidesma extract comprised approximately 15% of the subjects tested, non-responders, 85% (Table 1); responders to PTC comprised approximately 68% of the group tested, non-responders, 32% (Table 1). There was no relationship in responsiveness to either antidesma or PTC with age, sex, race, national origin, colour blindness or ichthyosis. Most antidesma responders judged antidesma as bitter, the mean response being about 39% as bitter as the bitterest substance ever tasted. Most PTC responders judged PTC as about twice as bitter as the antidesma responders judged antidesma, the mean responsiveness being approximately 82%. Among the 145 non-responders to antidesma, 67 stated that it was slightly sour, 39% that it was sweet,

Table 1 Comparison of PTC and antidesma responders and non-responders

	Responders	Non-responders
PTC		
Subjects	115	55
Sex	57 males; 69 females	31 males; 22 females
Mean age (yr, range)	44 (9–78)	41 (7–89)
Mean response intensity (%, range)	81.6 (5–100)	1.5 (0–30)
Median response intensity (%)	100	0
Median response quality (response, no.)	Bitter (115)	Tasteless (47)
Mean response frequency (%)	67.6	32.4
Antidesma		
Subjects	25	145
Sex	16 males; 9 females	71 males; 83 females
Mean age (yr, range)	43 (7–89)	42 (9–78)
Mean response intensity (%, range)	39 (5–100)	24 (0–100)
Median response intensity (%)	20	12
Median response quality (response, no.)	Bitter (25)	Sour (67)
Mean response frequency (%)	14.7	85.3

29 stated that it was salty and 10 could not designate any specific taste quality.

Among the 25 responders to antidesma there were no responders to PTC and, conversely, among the 115 responders to PTC there were no antidesma responders.

Three families in which antidesma responsiveness was identified were studied. In each family the father was the index subject identified. In one family, the wife and each of the six children (three girls, three boys) were antidesma non-responders. In another family, the wife and two children (one girl, one boy) were antidesma non-responders. In the last family, the wife, paternal mother and father and three children (one girl, two boys) were studied; the paternal father and one son, an addition to the father previously identified, were antidesma responders. Among the latter two families there were no genetic markers to characterise the antidesma responders with respect to red blood cell group, type, phenotype, Rh factor or plasma Xga. One family in which both husband and wife were PTC non-responders was studied; both were antidesma non-responders and both of their children (one boy, one girl) were PTC and antidesma non-responders.

Although taste divergence for antidesma extract has not been described before, the percentage of subjects in whom taste responsiveness to PTC was found in this survey agrees closely with those of previous investigators[7,8] as do the response characteristics of the subjects studied[9]. The active substance responsible for the taste responsiveness of the antidesma extract has not been identified although it is water soluble and heat stable. The genetics by which taste divergence to antidesma is determined is unclear, although it seems to occur among PTC non-responders comprising about half of this group. This suggests that the bitter response to antidesma among PTC non-responders bears some relationship to those factors which determine PTC taste responsiveness either on a functional or genetic level.

The divergence of taste responsiveness to antidesma raises several questions. First, antidesma fruit, unlike PTC, has been used as food by natives in South-East Asia and Florida for many years and has been eaten in pies, jams and sauces or as raw fruit. Divergent tastes to this food raises the question of the presence of other substances which may appear in the diet in which individual differences in taste perception and hence, preference, may occur. Although bitter tasting substances are not usually preferred as food or drink, preferences of the majority may exert significant influence on food practises. Thus, the number of substances to which divergent taste responses may occur and how much they may influence food and drink preference and intake are unknown. Second, these data raise the question of whether preferences for some food and drink may be determined, in part, by genetic factors. Third, individual taste responsiveness to various naturally occurring substances may serve as useful markers to individual differences, not only to food and drink preferences, but also to drug responsiveness[12] and sex differences[13]. Lastly, divergent taste responsiveness to antidesma and PTC as contrasted with the more usual uniform bitter taste responsiveness to most alkaloids[14], may be useful in the study of the psychophysical and biochemical characteristics of bitterness.

We thank Mrs Catherine Sweeney of the Kampong Coconut Grove, Florida for antidesma berries. Mrs Mary McGinness of NIH tested for XgA phenotype.

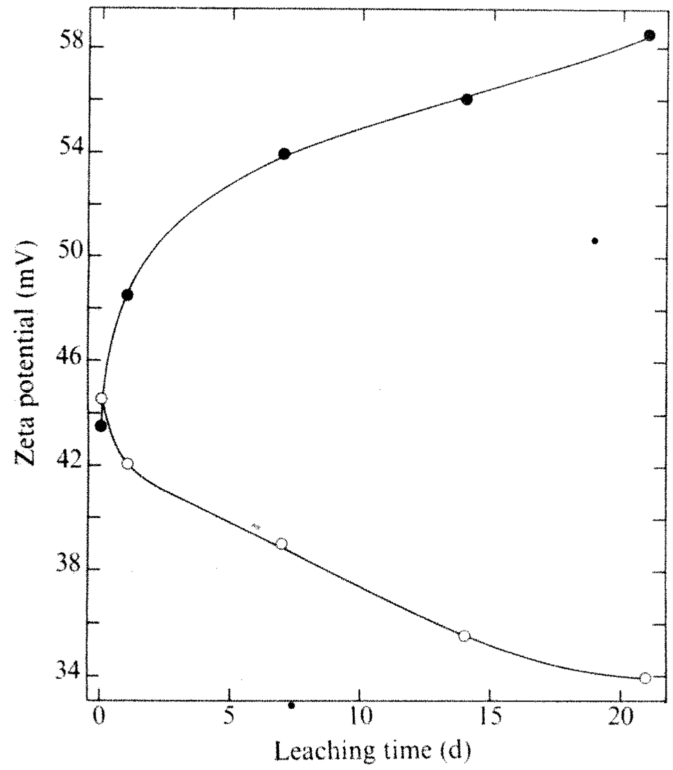
Surface charge and asbestos toxicity

Asbestos is a serious occupational and environmental hazard because of its fibrogenic and carcinogenic actions on the lung. Asbestos fibres exist in various physical forms, all of which are toxic. It is not known, however, which form is the most hazardous or which fibre property is the most important for inducing the toxic effects. It is thus important to examine relationships between the structure of the fibres and their biological activity. We have investigated the relationship between the surface charge and the haemolytic activity (ability to rupture the erythrocyte membrane) of asbestos. We report here that different forms of asbestos can be activated or inactivated by surface charge alterations.

Asbestos fibres are divided into two classes, chrysotiles and amphiboles, on the basis of their crystal structure[1,2]. Chrysotiles are characterised by hollow cylindrical fibres formed by spiralling a double sheet of silica and brucite ($Mg(OH)_2$) with the brucite on the outer surface. Amphiboles are characterised by fibres formed by stacking double silica chains back-to-back with a layer of hydrated cations in between. Owing to their dissimilar crystal structure and chemical composition, the two classes also differ in their physicochemical properties. These differences are reflected in short-term *in vitro* effects, chrysotiles being more cytotoxic to macrophages[1,3,4] and more haemolytic[1,5–7] than amphiboles. For long-term *in vivo* toxicity, however, there is no clear specificity in the fibrogenic and the carcinogenic activities of the two classes[1,8–11]. This paradox of short-term and long-term asbestos toxicity has not been resolved, but factors such as surface charge[12–17] and dimensions[11,18,19] of the fibres, deposition and retention of the fibres in the lung[19,20], coating[21] and dissolution[22] of the fibres by lung secretions, and susceptibility of the fibres to phagocytosis[1,8] may be significant. We have suggested that the haemolytic activity of asbestos is principally determined by the absolute magnitude of the surface charge that the fibres acquire in solution[23]. For chrysotiles the surface charge is associated with structural magnesium atoms which are known to be leached from the fibre surface *in vivo*[22], suggesting that progressive shifts in absolute surface charge could account for the discrepancy in short-term and long-term asbestos toxicity. We report here the effect of leaching on the surface charge and the haemolytic activity of representative samples of both classes of asbestos.

Surface charge, represented by the zeta potential[24], and haemolytic activity were measured for two asbestos reference samples of the International Union against Cancer (UICC) (ref. 25)—chrysotile A and the amphibole crocidolite. The fibres were leached as 0.5% (w/v) suspensions in Tyrode's (physiological buffer) solution, 0.01 M HCl or 0.1 M HCl. On each day of a leaching period, the fibres were centrifuged (3,090*g*, 20 min) and the leachate was siphoned and replaced. The HCl leachings were for 1 d. The electrophoretic mobilities of fibres incubated for 2 h as 0.01% (w/v) distilled-water suspensions were measured using a microelectrophoresis instrument (Zeta-Meter). From these data, zeta potentials were approximated using the Helmholtz-Smoluchowski equation[24] which is generally considered to apply for cylindrical particles placed axially to the electric field. For the haemolysis tests, fibre samples of equal surface area (20 mg crocidolite, 7.7 mg chrysotile A) were incubated for 1 h in 2 ml of Tyrode's solution; 2 ml of a 1.5% (v/v) Tyrode's-solution suspension (*p*H 7.4) of washed sheep erythrocytes was then added. The mixtures were inverted twice every 10 min for 1 h at 23 °C. The optical densities were measured at 541 nm after centrifugation (495*g*, 20 min).

Fig. 1 Zeta potential in absolute units (*Z*) at *p*H 7.4 for asbestos fibres leached with Tyrode's solution. ○, UICC chrysotile A; ●, UICC crocidolite.



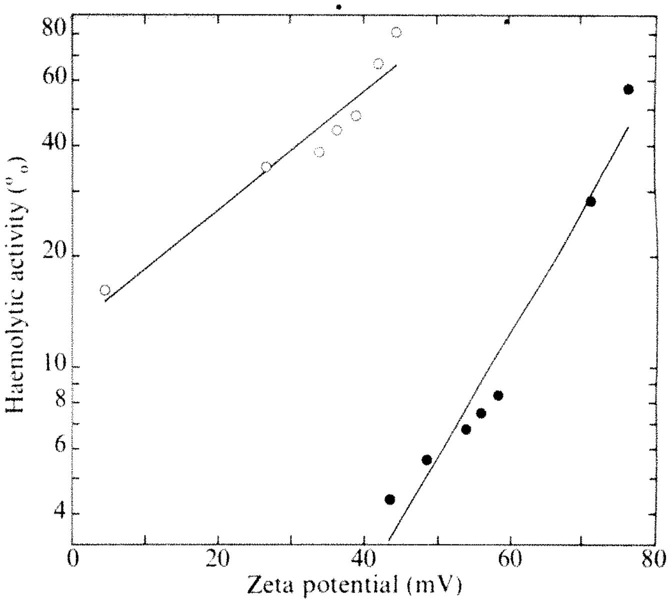


Fig. 2 Correlation between zeta potential in absolute units (*Z*) and haemolytic activity for leached asbestos fibres. ○, UICC chrysotile A (*r* = 0.96); ●, UICC crocidolite (*r* = 0.97).

Zeta potentials at *p*H 7.4 for the two types of unleached asbestos were similar in absolute magnitude, but opposite in polarity: +44.5 mV for chrysotile A and −43.5 mV for crocidolite. On leaching, the absolute magnitude of the zeta potential (*Z*) decreased for chrysotile A, and increased for crocidolite. The rate of change in *Z* at *p*H 7.4 for chrysotile A and crocidolite leached with Tyrode's solution is shown in Fig. 1. After a sharp change in *Z* during the first 5 d, the variation became nearly linear and at 21 d the *Z* values for chrysotile A and crocidolite were 34.0 and 58.5 mV, respectively. For both chrysotile A and crocidolite, there was a proportional shift in haemolytic activity as *Z* changed on leaching. Data for fibres leached with HCl and Tyrode's solution (Fig. 2) show the highly significant ($P<0.01$) correlation between *Z* and haemolytic activity for the two types of asbestos.

These results confirm the importance of surface charge to haemolytic activity and show that fibre dissolution can markedly alter the magnitude of surface charge and hence, activate or inactivate the fibres. The positively charged chrysotile was initially more active than the negatively charged amphibole. Leaching of the fibres caused the absolute magnitude of surface charge and the corresponding haemolytic activity of the chrysotile to decrease progressively and that of the amphibole to increase progressively. With continuous leaching *in vivo*, surface charge could be altered so that the biological activities of chrysotiles and amphiboles converged. This phenomenon could explain why the two classes of asbestos fibres, although different in their short-term *in vitro* effects, are not clearly different in their long-term toxicities.

We thank Professor D. W. Fuerstenau for advice and use of the Zeta Meter, and the USPHS for a grant.

Suppressor cells in experimental trypanosomiasis

HUMAN and experimental forms of African trypanosomiasis are characterised by a profound suppression of immunological responsiveness. Suppression of both humoral and cell-mediated responses has been observed. *Trypanosoma gambiense* infections in man reduce antibody responses to *Salmonella typhi* (H antigen) and skin reactivity to purified protein derivative, *Candida* and dinitrochlorobenzene[1]. *T. brucei* infections in mice cause marked suppression of antibody[2] and splenic plaque-forming cell[3,4] responses to sheep red blood cells (SRBC), and in rabbits suppress the development of experimental allergic neuritis[5]. The mechanism underlying this inhibition of immunocompetent cell function has not been elucidated. We have examined the DNA synthetic responses of spleen cells from *T. brucei*-infected mice to concanavalin A (con A) and phytohaemagglutinin (PHA) (both T-cell mitogens), *Escherichia coli* lipopolysaccharide (LPS, a B-cell mitogen) and allogeneic cells, and the ability of these cells to influence the responses of normal cells. We present evidence suggesting that suppressor cells[6,7] are involved in the immunological hyporesponsiveness observed in this disease.

Infection of CBA/CaJ mice with S 42 strain *T. brucei* produced a progressive and uniformly fatal infection (Fig. 1). After the inoculation of 10^4 trypanosomes (all infections were initiated by the intraperitoneal inoculation of 10^4 trypanosomes derived from stabilate[8] material) parasites were detected in the peripheral blood by day 3 and increased rapidly until day 6. Parasite levels then regressed until day 8 or 9, after which they increased steadily and proved fatal in 30–35 d.

DNA synthetic responses of spleen cells from infected mice to con A, PHA and LPS were suppressed as early as day 3 of infection (Fig. 1) and the suppression increased as the infection progressed. The degree of suppression

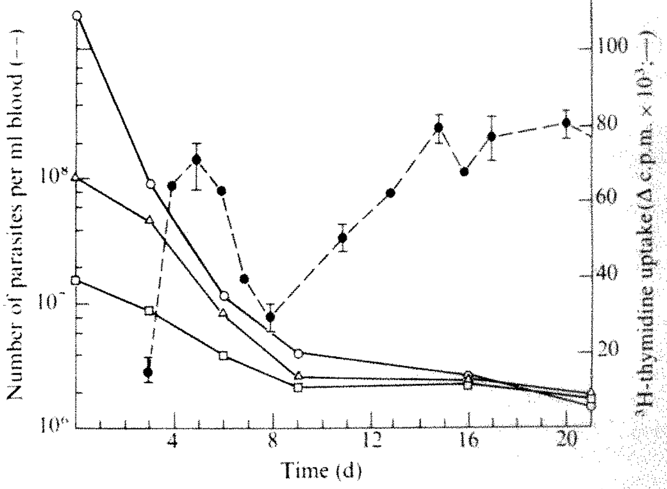

Fig. 1 Mean parasitaemia (●) ± 1s.e. and mean DNA synthetic responses to con A (○), PHA (□) and LPS (△) of spleen cells of CBA/CaJ mice infected with S 42 *T. brucei*. Standard errors were < 5% in all cases. Mean parasitaemia was estimated from haemocytometer counts made on the peripheral blood of six mice. DNA synthesis was measured by Williams[9] method. Viable spleen cells (5×10^5) were cultured in 0.1 ml RPMI 1640 containing 5% foetal calf serum (Gibco) with optimal concentrations of mitogens. Con A (Calbiochem) was used at a final concentration of 2 µg ml^{-1}, PHA (Difco) at 0.31 µl ml^{-1} and LPS (LPS 055:B5, Difco) at 50 µg ml^{-1}. All cultures were set up in flat-bottomed tissue culture plates (Linbro) and were incubated for 72 h at 37 °C in a humidified atmosphere of 5% CO_2 in air. Cultures were pulsed with 1 µCi ^{3}H-thymidine (New England Nuclear, specific activity 5 Ci mmol^{-1}) 16 h before collection. At each stage of infection, spleen cells were pooled from groups of three mice and cultures were set up in triplicate. Results are expressed as mean c.p.m. in stimulated cultures minus mean c.p.m. in unstimulated cultures (Δ c.p.m.).

observed did not always seem to be directly proportional to blood parasitaemia. The ability of spleen cells from infected CBA/CaJ mice to respond to allogeneic (BALB/c) spleen cells in a mixed lymphocyte reaction was also significantly inhibited (data not shown).

As recent work[10,11] has implicated suppressor cells with adherent properties in a comparable situation—the reduced immunological reactivity obtained in animals treated systemically with large doses of protein antigen—we examined the possibility that the nonspecific suppression in *T. brucei*-infected mice was mediated by an analogous mechanism.

Initially, we examined the effect of adding various number (6×10^4, 1.25×10^5, 2.5×10^5, 5×10^5 and 7.5×10^5) of spleen cells from infected mice (at day 12 of infection) or normal mice to cultures of normal spleen cells (5×10^5) stimulated with con A, PHA, or LPS. Spleen cells from infected mice caused consistent, dose-dependent, suppression of the mitogen-induced DNA synthetic responses of the normal cells. Addition of normal spleen cells caused no significant suppression except at the highest cell concentration and this was probably due to 'crowding' effects. Spleen cells from infected mice also caused significant suppression of one-way mixed lymphocyte reactions between normal CBA/CaJ and mitomycin C-treated BALB/c spleen cells. The degree to which the DNA synthetic response of normal cells to con A, PHA, LPS and allogeneic cells was suppressed at a $1(2.5 \times 10^5)$: $2(5 \times 10^5)$ ratio of infected to normal cells is shown in Fig. 2. The ability of 2.5×10^5 spleen cells from infected CBA/CaJ mice to suppress the responses of 5×10^5 normal spleen cells increased as the infection progressed. We found that the con A-induced DNA synthetic response was reduced to 50% of the normal response by day 6 cells, to 19% by day 12 cells and to 11% by day 20 cells.

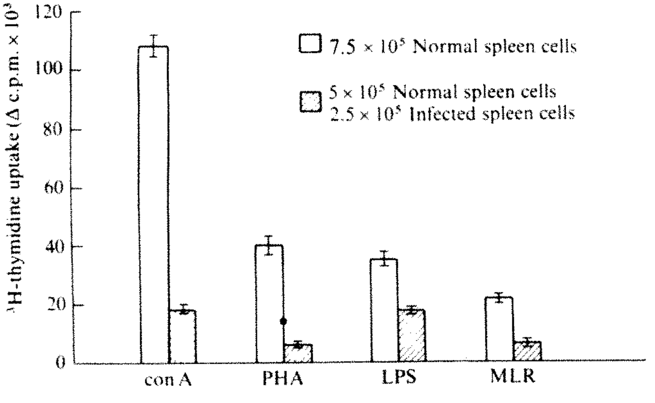
We next examined the effect of depleting *T. brucei* spleen cells of glass-wool-adherent cells. DNA synthetic responses of whole and nonadherent spleen cells from normal and infected mice to con A, PHA and LPS are shown in Fig. 3. Depletion of glass-wool-adherent cells caused a more substantial increase in the response of *T.brucei* spleen cells than of normal cells to PHA and LPS; the response to con A was improved, but to a lesser extent by this procedure. We have also found that glass-wool-adherent cells from infected mice consistently suppressed mitogen-induced responses of normal spleen cells 25–30% more than the unfractionated population; peritoneal macrophages from infected mice had no effect. Hence the suppressor cell seemed to have adherent properties but was distinct from the peritoneal macrophage.

It seemed possible, however, that some of the suppression observed was a direct inhibitory effect of trypanosomes present in spleen cell suspensions from infected mice—at day 12 of infection, the spleen cell to trypanosome ratio was approximately 30 : 1. To investigate this possibility we separated trypanosomes from the peripheral blood of infected mice[13] and added trypanosomes (4×10^3–2×10^5) to cultures of normal spleen cells (5×10^5) which were then stimulated with con A or LPS: these numbers of trypanosomes caused no suppression, indicating that the suppression in our cell mixture experiments was mediated primarily by a cell. This was substantiated by the observation that glass-wool-adherent cells, although more suppressive, were contaminated by 1/10 the number of trypanosomes present in the whole spleen cell population. In more recent experiments we have observed that very large numbers of trypanosomes (6×10^5 or more) suppress mitogen-induced responses of normal cells. The possibility that this suppression is also due to the induction of suppressor cell activity cannot be excluded.

Although the cell mixture and glass wool fractionation experiments clearly implicate a splenic cell in the suppression, it is possible that the presence of some trypanosome antigen in culture may augment the suppression observed. Gershon, Gery and Waksman[10] found that the reduced responsiveness to PHA *in vitro* of spleen cells from animals immunised with SRBC, bovine γ-globulin and bovine serum albumin was further suppressed by the addition of the immunising antigen to the cultures.

To characterise further the cell responsible for suppression in this system, we compared the growth of the parasite in normal and congenitally athymic (nude) BALB/c mice and tested the spleen cells of these mice for suppressor activity. Parasitaemias were generally lower in nude mice than in normal controls (Fig. 4*a*). Although spleen cells from infected BALB/c mice caused significant suppression of mitogen responses, spleen cells from infected nude mice at the same stage of infection (day 11) failed to suppress the mitogen-induced DNA synthetic responses of normal cell (Fig. 4*b*), indicating that the suppressor in the spleens of *T.brucei*-infected mice was either a T cell or was dependent on T-cell influence for its generation. Treatment of spleen cells from infected mice with an anti-Thy-1 antiserum and complement, however failed to remove their suppressive effect. There

Fig. 2 Effect of spleen cells from *T. brucei*-infected CBA/CaJ mice on con A,PHA,LPS and allogeneic-cell-induced DNA synthetic responses ± 1 s.e. of normal spleen cells. Mixed lymphocyte reactions (MLR) were initiated using 2.5×10^5 CBA/CaJ spleen cells and 2.5×10^5 mitomycin C-treated BALB/c spleen cells. Spleen cells (10^7 per ml) were treated with mitomycin C (30 μg ml^{-1}, Sigma) at 37 °C for 30 min. Culture conditions were as described previously. Cultures were pulsed with 1 μCi ^{3}H-thymidine 16 h before collection.



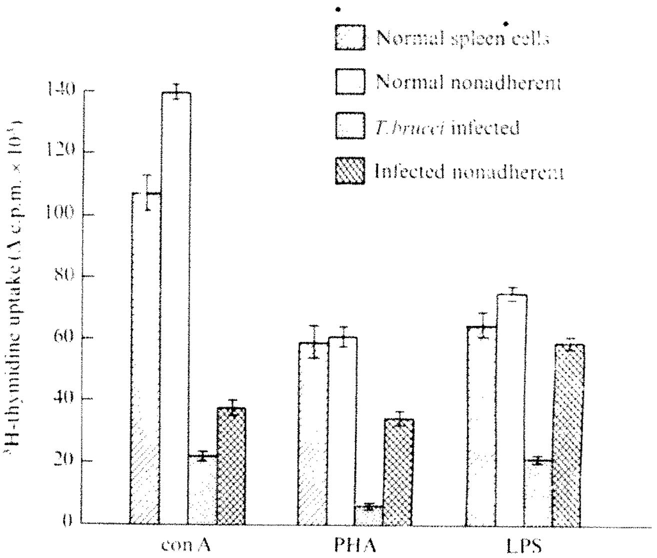


Fig. 3 DNA synthetic responses to con A,PHA and LPS (± 1 s.e.) of whole and nonadherent spleen cells from normal and *T. brucei*-infected CBA/CaJ mice. Spleen cells were pooled from four normal and four infected (day 7 of infection) mice. Adherent cells were removed on glass wool columns using the method of Folch, Yoshinaga and Waksman[12].

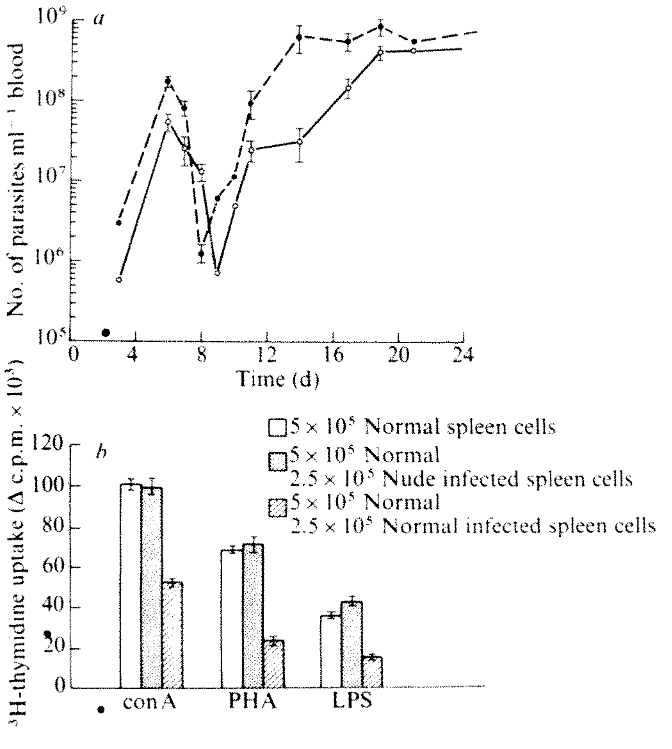
Fig. 4 Mean parasitaemias (± 1 s.e.) in normal (●) and nude (○) BALB/c mice infected with S 42 *T. brucei* (*a*) and the effect of spleen cells from these mice on con A, PHA and LPS-induced DNA synthetic responses of normal BALB/c spleen cells (*b*).



have been reports of suppressor T-cells which seem to express only small amounts of Thy-1 on their surface and are therefore difficult to lyse with anti-Thy-1 antisera[14]. Hence in spite of its insensitivity to the concentration of anti-Thy-1 antiserum which we used we cannot exclude the possibility that the suppressor in our system is a T cell.

We have also observed that unfractionated or T-cell-enriched (on nylon wool columns) spleen cells from infected mice cause marked suppression of the plaque-forming colony response of normal spleen cells to SRBC *in vitro* (unpublished results of D. D. Eardley and A.N.J.), and that the adoptive transfer of spleen cells from *T.brucei*-infected mice to normal recipients results in infections which are enhanced compared with infection in controls receiving normal spleen cells and the same number of parasites.

Although these experiments suggest that thymus-dependent suppressor cells are involved in the nonspecific suppression of immunity, it is possible that specific suppressor cells are also generated in these infections. We are attempting to analyse in greater detail the mechanism by which the nonspecific suppressor cells act and their role in the pathogenesis of trypanosomiasis.

We thank Peter Simek, Stephan Yuan, Monika Berney and Amy Jones for assistance. This work was supported by grants from the USPHS. A.N.J. is the recipient of a James Hudson Brown Memorial Fellowship.

Immunologic studies in contacts of osteosarcoma in humans and animals

AGENT(S) which could cause unrecognised or subclinical infections in otherwise healthy human household contacts of cancer patients may be detected by epidemiologic studies. Support for this hypothesis is provided by the reports of an increase in tumour specific humoral antibodies, as well as tumour specific cell mediated immunity[1–4] in the household contacts of patients with osteosarcoma, adenocarcinoma of the breast and other malignancies. Clear evidence for the validity of this conclusion has not been obtained. To test this hypothesis, we studied antibodies (both humoral and cellular) in the household contacts of a patient with osteosarcoma. In addition, in an animal model for human osteosarcoma, we characterised the sera and lymphocytes of hamster mothers (in close contact with their offspring) before and after induction of the tumour in their immunosuppressed offspring.

The humoral antibodies were tested by the indirect immunofluorescence test against tumour tissue imprints obtained from a patient (M.Mc.) with osteosarcoma of the femur. The membrane immunofluorescence test was performed with TE-85 cells (from an unrelated patient with osteosarcoma) maintained in tissue culture. Sera from five of the six household contacts of the patient (M.Mc.) showed positive reactions for humoral antibodies against both osteosarcoma imprints and TE-85 cells. Similar positive reactions were observed with the sera from four other (unrelated) patients with osteosarcoma and the patient's (M.Mc.) own serum for the presence of humoral antibodies. Only the serum of one of nine normal individuals showed positive immunofluorescence against both the tumour imprints and cells.

In the animal experiments, sea from mothers of tumour-bearing hamsters were subjected to the immunofluorescence test before the injection of TE-85-M-MSV cells into anti-lymphocyte serum (ALS) treated newborn hamsters. The sera from the hamster mothers were again tested on 5 and 20 d after inoculation of TE-85-M-MSV cells into the offspring (the tumours developed in the offspring 10–14 d after inoculation). Sera from eight of the 10 hamster mothers were positive for antibodies (against tumour imprints and TE-85 cells) on d 20 after the inoculation of the cells into the newborn hamsters. The sera from the same hamster mothers showed a negative reaction for antibodies on the day of the injection of cells and on d 5 after injection. None of the sera from the hamster mothers in the control group showed positive immunofluorescence.

Tumour specific antibodies were demonstrable against osteosarcoma imprints (by immunofluorescence) in the sera of 83% of the tumour-bearing newborn hamsters. 87% of the sera from these animals reacted positively against TE-85 cells. In the control group of newborn hamsters, only 4% of the animals had sera which reacted positively against osteosarcoma imprints and TE-85 cells (Table 1).

For the cell mediated immunity, the lymphocyte microcytotoxicity test was performed as described by Singh *et al.*[5]. The TE-85 cells maintained in tissue culture were used as target cells. Table 2 shows the percentage of inhibition of the target cells by the lymphocytes from the household contacts of the patient (M.Mc.), the patients with osteosarcoma and normal individuals. Significant inhibition by the lymphocytes was observed in five of the six same household contacts, all of the patients with osteosarcoma and one of the nine normal individuals.

In the animal model, the same eight hamster mothers had lymphocytes that exhibited significant cytotoxicity against TE-85 cells at d 20. The lymphocytes from the same mothers exhibited minimal cytotoxicity before the inoculation of cells into newborn hamsters and on d 5 after the cell

Table 1 Tumour-specific antibodies in tumour-bearing newborn hamsters

		Osteosarcoma imprints		TE-85 cells	
	No. of hamsters	Positive sera* per hamster test	%	Positive sera* per hamster test	%
Experimental group	72	60/72	83	63/72	87
Control group	23	1/23	4	1/23	4

For osteosarcoma imprints a standard indirect immunofluorescence test was performed against fixed sections. For membrane immunofluorescent 3 × 10^5 cells ml^{-1} were suspended in the test serum 1:10 dilution and incubated at 4 °C for 30 min. Fluorescent conjugated goat anti-hamster γ-globulin 1:10 dilution were used.

*Sera were drawn on d 20 after the injection of TE-85-M-MSV cells. Controls were normal newborn hamsters (no exposure to TE-85-M-MSV cells).

Table 2 Cytotoxicity of lymphocytes from osteosarcoma patients and their contacts

Experiment no.	Source of lymphocytes		No. of target cells per well 48 h after exposure to: Medium only	Medium plus lymphocytes	% Inhibition of target cells

15	AB	(N)	451.1 ± 21.8	462.0 ± 21.1	7.6 ± 0.34

Subjects were household contacts of patient MMC (HHC), normal individuals unrelated to patient MMC (N), and a normal control who had worked with osteosarcoma cells in the laboratory (NK). Lymphocytes from patients and normal controls were used as effector cells and TE-85 cells were the target cells for the microcytotoxicity test.

*Statistically significant, $P < 0.05$.

†Mean ± s.e.m.

injection. The lymphocytes from control animals showed no significant cytotoxic effect against TE-85 cells.

The results of the lymphocyte microcytotoxicity test, on tumour-bearing hamsters on d 20 (Table 3), showed that 75% of the animals showed significant cytotoxic effect against the target cells. In the control group, only 4% of the animals showed a significant reaction.

Hellström and Hellström[3] reported cellular immunity directed against neuroblastoma in the mothers of children with that tumour. Byers *et al.*[4] demonstrated that household contacts of osteosarcoma patients and patients with adenocarcinoma of the breast had specific immunity against the tumour type with which there had been contact. Furthermore, the range of cytotoxicity values produced by lymphocytes from the household contacts was significantly higher than that of the normal population. In the present investigation, all the osteosarcoma patients undergoing the lymphocyte microcytotoxicity test had higher cell mediated immunity against TE-85 cells than normal individuals. In the animal study, 80% of mothers of the tumour-bearing hamsters developed higher cell mediated immunity than the mothers in the control groups.

Morton and Malgren[6] interpreted the transformation of embryo fibroblasts (in tissue culture) as evidence for a transmissible agent (either horizontal or vertical) in patients with the tumours. An electron microscopic finding of occasional particles resembling murine leukaemia virus (in some biopsy specimens and cells of tissue cultures derived from osteosarcoma) were considered to indicate the presence of a viral antigen or virus-induced tumour antigen in the tested tumour.

In our animal model there was an 80% incidence of humoral antibodies against osteosarcoma imprints and the TE-85 cells in the sera of mothers of tumour-bearing newborn hamsters. This was demonstrated only after the tumours developed and not before tumour development or during tumour formation. The same was true of the cell mediated immunity. The production of antibodies against osteosarcoma in the animal model suggests a change in the immune mechanisms of the hamster mothers in close contact with tumour-bearing animals, and indicates that such a change was related to the development of osteosarcoma in the animal. Our results support the hypothesis that an agent is responsible for transmission of horizontal immunity to close contacts of patients with spontaneously arising osteosarcoma, and suggest that an infectious agent may be an aetiologic factor in human osteosarcoma.

We thank the American Cancer Society for a grant.

Table 3 Lymphocyte cytotoxicity in mothers of newborn hamsters 20 d after injection of TE-85-M-MSV cells in newborns

Source of lymphocytes, cage no.	% Target cell inhibition
34	29.09 ± 4.24
16	63.73 ± 11.52
33	23.00 ± 9.86
29	34.03 ± 8.44
1	33.31 ± 9.67
2	46.41 ± 7.71
4	30.69 ± 8.83
6	60.16 ± 12.62

Lymphocytes from hamster mothers at d 20 were used as effector cells against target cells (TE-85) in a ratio of 1:25 for the microcytotoxicity test. Samples for controls were taken from mothers of newborn hamsters which had been injected with saline instead of TE-85-M-MSV cells and showed no significant inhibition.

$P < 0.05$, statistically significant.

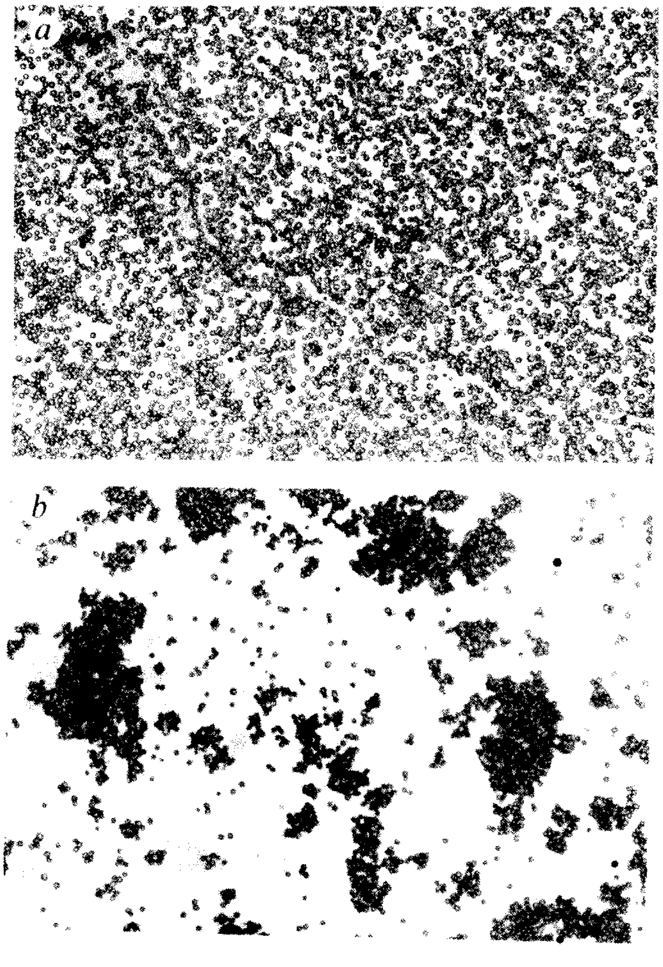
Requirement for magnesium influx in activation of alveolar macrophages mediated by ionophore A23187

NORMAL antibacterial activity in the lung is largely dependent on alveolar macrophage function[1]. Products of antigen-stimulated, sensitised lymphocytes can activate alveolar macrophages, which then exhibit greater adherence, phagocytosis and nonspecific bactericidal capacity than normal[2]. Although the molecular basis of this activation is unknown, influx or intracellular redistribution of divalent cations (Ca^{2+} and Mg^{2+}) has been implicated in other cell types[3-10]. We have therefore examined the effect on alveolar macrophage function of exposure to the ionophore A23187, which selectively binds divalent cations at neutral *p*H and passively transfers them across biological membranes[11,12].

Monolayers of normal rabbit alveolar macrophages were exposed for 1 h to tissue culture medium containing 5 μM A23187 or to normal medium alone. Cells were then washed and reincubated in fresh medium without ionophore for a further 18–72 h. Macrophage function (adherence to culture dishes, bactericidal activity and acid phosphatase content) was then assayed[2,14].

Macrophages studied 18–24 h after exposure to ionophore were similar in their properties to control macrophages, but cells left in normal medium for 40–72 h after 1 h of contact with ionophore, showed evidence of activation (Table 1). They increased in cell agglutinability or clumping (Fig. 1), adherence to tissue culture dishes and bactericidal activity against *Listeria monocytogenes* compared with normal cells (Table 1). The lysosomal hydrolytic enzyme, acid phosphatase, was also increased in the cells stimulated by ionophore.

Fig. 1 Cellular aggregation or agglutinability was perhaps the most striking manifestation of ionophore exposure. It is illustrated by photomicrographs of macrophage monolayers exposed for 1 h to A23187-containing or control media, followed by washing and reincubation in fresh medium without ionophore for 48 h. *a*, The control is characterised by a uniform layer of macrophages; *b*, marked cellular agglutination and clumping is seen after exposure to A23187 (×23.5).



We considered the possibility that A23187, a *Streptomyces* antibiotic[11], contributes to the intracellular killing of ingested *L. monocytogenes*. This was thought unlikely because macrophage bactericidal activity was normal at 18–24 h but had increased at 40–72 h after exposure to ionophore. Direct testing revealed that A23187 at concentrations up to 5 μM (2.6 μg ml^{-1}) in medium TC 199 with normal rabbit serum (NRS) failed to kill *L. monocytogenes* during a 2-h incubation (the time used in macrophage bactericidal assays).

Cells collected by lavage from the lower respiratory tract of male New Zealand rabbits were washed and then diluted in tissue culture medium 199 containing 15% normal heat-inactivated rabbit serum (TC 199-NRS), placed in tissue culture dishes and incubated for 4 h at 37 °C in 95% air–5% CO_2 (refs 2, 13). Nonadherent cells were then removed, and the macrophages were exposed to 5 μM A23187 in TC 199-NRS or to normal medium alone for 1 h. Monolayers were washed and reincubated in fresh TC 199-NRS without ionophore for 40-72 h before studies of macrophage function. At the conclusion of this incubation, determinations of adherence to tissue culture dishes and bactericidal activity against *Listeria monocytogenes* were performed as previously described[2]. For the acid phosphatase assay, macrophages were lysed in 0.1% Triton X-100 (ref. 14). *p*-Nitrophenyl phosphate sodium served as the substrate.

To investigate the need for specific divalent cations in ionophore-mediated activation macrophages were exposed to A23187 in TC 199–NRS or in salt solutions with various concentrations of Ca^{2+} and Mg^{2+} (Table 2). Ionophore in the presence of physiological concentrations of Ca^{2+} and Mg^{2+} (tissue culture medium and balanced salt solution), or physiological Mg^{2+} with markedly decreased Ca^{2+} (10^{-5} M), stimulated acid phosphatase activity. In contrast, exposure of cells to A23187 in a salt solution containing physiological Ca^{2+} and decreased Mg^{2+} (10^{-5} M) produced no increase in enzyme activity. The addition of 10 mM MgEGTA to A23187-containing TC 199–NRS, providing a physiological concentration of Mg^{2+} (3×10^{-3} M) and a marked reduction in Ca^{2+} content (10^{-10} M)[15], abolished the activating effect of the ionophore.

The cell-mediated immune response produces marked changes (activation) in systemic macrophages. Compared with normal macrophages, activated cells are larger, morphologically more complex, and show greater adherence, ingestion, nonspecific bactericidal activity, oxygen uptake,

Table 2 Acid phosphatase content of alveolar macrophages after exposure to A23187-containing solutions

Experimental group	Divalent cations (molar concentration) Mg^{2+}	Ca^{2+}	% Acid phosphatase content*

Control			100
A23187			114.5 ± 6.9¶ (22)
Low Mg^{2+} salt solution	1×10^{-5}	1.8×10^{-3}	
Control			100
A23187			95.2 ± 2.7 (12)

The experimental procedure was as described in Table 1, except that in the experiments indicated the exposure of macrophages to ionophore took place in specified salt solutions rather than in TC 199-NRS. These salt solutions were Earle's or Hanks' balanced salt solution (BSS) or 'calcium-and magnesium-free' BSS, to which Ca^{2+} or Mg^{2+} was added in the indicated concentration. After brief exposure to A23187-containing or control medium, cells were washed and reincubated in fresh culture medium (with normal Ca^{2+} and Mg^{2+} and without ionophore) for 48–72 h before assay.

glucose oxidation and content of hydrolytic enzyme[16]. Acquired resistance to systemic infection with many intracellular organisms depends on these changes. Our demonstration that lymphokines activate alveolar macrophages has implied that this protective mechanism is also intact in the lung[2]. Certain common features of activation in other cell types suggest a potential mechanism for the lymphokine-mediated process in macrophages. Influx or intracellular redistribution of divalent cations has been implicated as the initiating event in activation of various cells, including lymphocytes, fibroblasts and sea urchin eggs[3–10]. Much of the evidence for the importance of divalent cations (especially that ascribed to Ca^{2+}) in cellular activation was obtained using A2318 (refs 3, 5–7).

There are at least three possible mechanisms by which A23187 and divalent cations might initiate cell activation. First, a requirement for Ca^{2+} may be related to induced increases in intracellular cyclic GMP (refs 10, 17, 18). Increases in cyclic GMP concentration (and/or decreases in the ratio of cyclic AMP : cyclic GMP) are associated with proliferation or activation in lymphocytes and fibroblasts[19–23]. Second, the postulated importance of Mg^{2+} in the stimulation of cell proliferation (chick embryo fibroblasts) could be related to the requirement of this cation for transphosphorylation reactions. Thus increasing the concentration of intracellular free Mg^{2+} may activate cellular metabolism and growth[9,24]. Third, A23187 may initiate activation by producing a charge-neutral exchange of $2\,H^+$ for each divalent cation transported across the plasma cell membrane[11,12,25]. This H^+ efflux (exchange of $2\,H^+$ for each Ca^{2+} or Mg^{2+}) may lead to an increase in intracellular cytoplasmic pH; such a change in intracellular pH has been reported to initiate activation of sea urchin eggs[26].

In view of these possibilities we examined the requirements for initiation of alveolar macrophage activation. We found that to activate normal alveolar macrophages A23187 needs both near-physiological concentrations of extracellular Mg^{2+} and very low concentrations (between 10^{-5} and 10^{-10} M) of Ca^{2+}. Thus Ca^{2+} influx alone is not the initiating event for A23187-induced macrophage activation Our results indicate that Mg^{2+} is the major extracellular divalent cation required at the onset of activation. These results apparently contrast with reports that Ca^{2+} influx is the initial event in ionophore-mediated activation of other cells[3,5–7]. It is also true, however, that in some of these studies Ca^{2+} influx was merely assumed to be the basis of the A23187 effect, and other possibilities were not excluded (such as a role for Mg^{2+}). In any case the need for Mg^{2+} in the activation of alveolar macrophages is clear, although the mechanism involved is not.

We thank Carl G. Hughes for technical aid and Jane W. Williams for secretarial assistance. This work was supported by the Medical Research Service of the Veterans Administration. A23187 was supplied by Dr R. L. Hamill of Eli Lilly Co.

Interrelationship of cyclic nucleotides and anaphylactic reactions

THE mode of action of several anti-allergic drugs, which are structurally diverse, has been studied by comparing their inhibition of cyclic nucleotide phosphodiesterase with inhibition of anaphylaxis. The cyclic nucleotide phosphodiesterase activities were measured in microsomal preparations of both human and sheep lung, and the anaphylaxis was observed *in vitro* in passively sensitised human lung and in rats *in vivo* (passive cutaneous anaphylaxis (PCA)). A significant correlation has been found between the inhibition of anaphylaxis and the ratio of the inhibition of hydrolysis of cyclic AMP to the inhibition of hydrolysis of cyclic GMP. A less significant correlation was also found between inhibition of rat PCA and inhibition of hydrolysis of cyclic GMP.

The studies of Austen *et al.*[1-3] have shown that inhibition of anaphylactic release of histamine from human lung tissue can be associated with raised tissue levels of cyclic AMP. Lichtenstein and Margolis[4] have shown that methylxanthines inhibit the antigen-induced release of histamine from human leukocytes and it has been assumed that this is due to their ability to inhibit cyclic AMP hydrolysis[5]. A relationship has been suggested[6-8] between the activity of anti-allergic compounds and their ability to inhibit cyclic 3′,5′-nucleotide phosphodiesterases. Austen *et al.*[2] have also suggested that, in contrast to the effects of cyclic AMP, raised levels of cyclic GMP can potentiate the antigen-induced release of histamine from human lung tissue. If, as is believed, the effect of increasing cyclic AMP levels is to inhibit the release of histamine and of raising cyclic GMP levels is to potentiate histamine release[1-3], the observed pharmacological effect of any agent inhibiting the hydrolysis of both nucleotides is likely to be related to the resultant change in the balance of the two nucleotide levels.

We have therefore investigated the ability of known and novel anti-allergic compounds to inhibit cyclic AMP and cyclic GMP hydrolysis and to inhibit anaphylaxis. Table 1 shows the pharmacological potency of twenty-five compounds in inhibiting anaphylaxis in passively sensitised human lung tissue and/or rat skin. Table 1 also shows the concentrations of the various compounds required to inhibit the hydrolysis of both cyclic nucleotides by 50% (I_{50}) using a microsomal preparation from human lung, and the inhibition constants (K_{I}) using a microsomal preparation from sheep lung. Also shown are the ratios of I_{50} (human lung) and K_{I} (sheep lung) for the hydrolysis of cyclic AMP to that of cyclic GMP. Table 2 shows the regression analyses of the relevant terms. A very significant correlation exists between the ability to inhibit anaphylactic reactions and the ratio of I_{50} cyclic AMP to I_{50} cyclic GMP or K_{I} cyclic AMP to K_{I} cyclic GMP. Figure 1 illustrates one of these relationships, that is that between potency of compounds in the human lung and the I_{50} ratio determined in human lung microsomes. This result indicates that com-

Inhibition of anaphylaxis in the human lung was measured using macroscopically normal tissue specimens obtained at lobectomy. Lung parenchyma was prepared and sensitised as described before[9]. The effects of drugs on the release of histamine were determined by an incubation method[10], using an extract of *D. farinae* as antigen. The drugs were added immediately before challenge. Histamine was assayed fluorimetrically[11]. Potency of drugs relative to disodium cromoglycate was calculated by comparing the molar concentrations required to produce equivalent inhibition of histamine release (30–40%). In the rat, passive sensitisation of skin areas was produced by intradermal injection of *Nippostrongylus brasiliensis* antiserum. After 48 h rats were challenged intravenously with *N. brasiliensis* extract. The compounds were administered intravenously immediately before challenge. The effective dose of each compound was measured as the minimal concentration to give 100% inhibition of the cutaneous reaction (ID_{100}) in two rats. Potency of drugs relative to disodium cromoglycate was calculated as the ratio of ID_{100} disodium cromoglycate (M) to ID_{100} test drug (M). In preparation for phosphodiesterase assay human lung was chopped with a McIlwain chopper and then ground with sand. The resulting homogenate was centrifuged to obtain the 100,000*g* pellet which was resuspended in 0.1 M Tris buffer, *p*H 7.4. The assay system (0.2 ml) contained 0.16 μM ^{3}H-cyclic nucleotide, 4.5 mM $MgSO_4$ and microsomes (0.5–1.0 μg per ml protein) in Tris buffer 0.1 M, *p*H 7.4. Addition of 5′-nucleotidase was found to be unnecessary. Enzyme activity was measured after 20 min at 37 °C as the rate of formation of tritiated products[12]. Each compound was tested twice using five concentrations in duplicate. The I_{50}s were obtained graphically and averaged. Sheep lung microsomal fraction was prepared as for human lung and the inhibition of phosphodiesterase activity was measured as above, but using the modification described by Boudreau and Drummond[13]. This allows for the quantitative recovery of adenosine, guanosine and their metabolites, which are produced when assaying crude enzyme preparations or tissue homogenates. After the discovery of a calcium-dependent protein activator for bovine brain phosphodiesterase[14], 0.5 mM calcium chloride was added to the assay medium to maximise phosphodiesterase activation. Substrate concentration was varied from 3.33 to 20 μM. Values of K_{I} were calculated by double reciprocal plot, using not less than four independent determinations.

*Suffixes refer to the publication in which the compounds are described.

†A compound with a number in parentheses is exemplified by that number in patent claim or paper.

The data in Table 1 were submitted to multiple regression analysis using a DEC System PDP—10 computer. NS, not significant at the 0.1 level.

*$R(I_{50}) = I_{50}$ cyclic AMP/I_{50} cyclic GMP human lung; $R(K_1) = K_1$ cyclic AMP/K_1 cyclic GMP sheep lung.

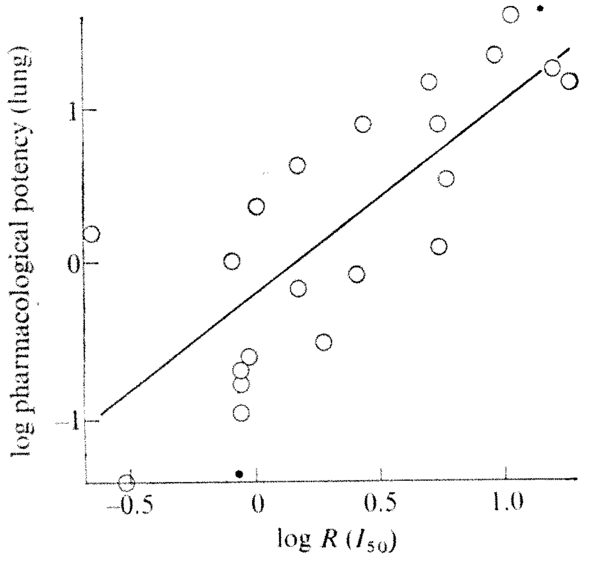
pounds which are more potent inhibitors of the anaphylactic reaction inhibit the hydrolysis of cyclic GMP more effectively than that of cyclic AMP. We find that the correlation does not hold for the supernatant enzyme activity from human lung (unpublished work of C.J.C.). This suggests that the effect of the cyclic nucleotides takes place in a membrane environment.

Relationships of lesser significance are obtained between inhibition of cyclic GMP hydrolysis and pharmacological potency in the rat. These results indicate that although the balance between the two cyclic nucleotides seems to be critical in determining the anti-allergic activity of a compound, cyclic GMP seems to be the more important factor in the rat PCA test.

In some cases it seems to be difficult to reconcile the drug concentrations effective in inhibiting histamine release from human lung fragments with those which inhibit human lung microsomal phosphodiesterase. The apparent discrepancy could possibly be related to the lipophilic properties of the drugs concerned and the sites of the enzymes involved. Direct measurement of drug-induced changes in cyclic nucleotide levels within the membranes of target cells would provide a better understanding of their interrelationship. Further work is planned in an attempt to elucidate these points.

Cyclic AMP and cyclic GMP have been suggested to have antagonistic actions as intracellular messengers and regulators in certain biological systems[30]. There have been several reports of control systems of this type[31–33]. It seems likely that such a mechanism is operating here and that the selectivity of the inhibitor between the two cyclic nucleotide phosphodiesterases governs the biological activity. The implication of our results is that histamine release is reduced more effectively when cyclic GMP levels are increased with respect to cyclic AMP levels. This result is in opposition to the concept discussed by Austen *et al.*[1–3], but they present only circumstantial evidence, linking increased cyclic GMP levels with increased histamine release. No workers, as far as we know, have measured the levels of both nucleotides in human lung simultaneously. It is interesting that McElroy and Philip[34] also find that the ratio of K_1s but not the individual K_1 for each cyclic nucleotide correlates with inhibition of ADP-induced aggregation in platelets.

Fig. 1 The logarithm of the pharmacological potency plotted against the logarithm of the I_{50} ratio. The straight line was obtained by regression analysis. Data are from human lung.



The fact that highly significant correlations were obtained between selective inhibition of phosphodiesterase activity and pharmacological potency in *in vitro* and *in vivo* tests, involving different species and different tissues, may reflect a basic common mechanism of fundamental importance in allergic reactions.

We thank Ms M. Ford, P. Hughes and S. Clements and Mr V. J. Smith for technical assistance. We also thank Dr K. Crowshaw for helpful criticism, Mr G. Flavell for specimens of human lung, Professor J. Pepys for human serum and *D.farinae* extracts and the pharmaceutical firms who donated samples.

Sperm-associated sialyltransferase activity

FERTILISATION begins with a specific adhesion between sperm and egg and culminates with the fusion of the male and female pronuclei. In mammals, sperm seem to recognise the zona pellucida surrounding the egg[1]. This adhesive interaction is the first of many that will take place during subsequent embryogenesis. In molecular terms, these later cell–cell interactions are not generally understood, and the mechanism of sperm–egg recognition is unknown. Conceptually, advances in this area have been rare since Lillie presented the fertilisin hypothesis, and even this has been questioned[2]. There is evidence to support a model for intercellular recognition that utilises the molecular complementarity inherent in cell surface glycosyltransferases and their respective acceptor molecules[3,4]. The transferases catalyse the addition of sugars, from sugar nucleotides, to the non-reducing termini of saccharide acceptors. The enzymes are highly specific for both the donor sugar nucleotide and the acceptor, usually an oligosaccharide. For example, sialyltransferases are the class of glycosyltransferases that transfer sialic acid (*N*-acetylneuraminic acid) from cytidine monophosphate-*N*-acetylneuraminic acid (CMPNAN) to either glycoprotein, glycolipid, or free oligosaccharide acceptors[4]. Glycosyltransferases have been reported on the external surfaces of many different cell types and, in some cases, enzyme–substrate complexes between the transferases and their acceptors may be instrumental in the cellular recognition that occurs (reviewed in ref. 5). We report here a study of mouse sperm–egg interactions in terms of the transferase–acceptor hypothesis.

CMPNAN : asialofetuin sialyltransferase activity was associated with intact sperm, although no endogenous acceptors for the enzyme were detected. Autoradiographic assays supported the absence of endogenous surface sialyltransferase activity on intact sperm, but showed moderate activity on mouse ova from C57Bl females superovulated by injection of 10 U of gonadotropin from pregnant mare serum (Sigma) and, after 48 h, by injection of 10 U of human chorionic gonadotropin (Sigma). Ova were collected from the dissected uterine ampullae 16 h after injection of the human chorionic gonadotropin. When sperm and ova were incubated together with the sialic acid donor, additional dense grain patches were found on the ova surfaces. These accumulations were often associated with penetrated sperm (Fig. 3). Ova incubated identically, but without sperm, did not show these patches (Fig. 2).

Sperm were obtained from the cauda epididymis and vas deferens of mature male C57Bl mice by dissection and collection in a saline solution, *p*H 7.3, containing (in g $^{-1}$): NaCl, 7.13; glucose, 1.0; KCl, 0.4; phenol red, 0.004, and HEPES, 2.35. This sperm suspension was centrifuged once at 10*g* for 4 min to sediment tissue debris. The supernatant sperm suspension was then washed three times by centrifugation (500*g*, 6 min) and resuspended in the saline solution described above.

The first, 500*g* supernatant from the sperm preparation and the corresponding sperm pellet contained approximately equivalent levels of sialyltransferase activity toward the exogenous acceptor asialofetuin. This supernatant enzyme was probably derived from seminal fluid, because levels of activity decreased in the next two supernatants while the activity of the sperm pellet remained constant. The activity observed with intact sperm may result from a sialyltransferase that is initially in seminal fluid and, secondarily, adsorbed on to sperm rather than being an intrinsic part of the sperm plasma or acrosomal membrane. In the conditions described in the legend to Fig. 1, and with 10^6 sperm as the

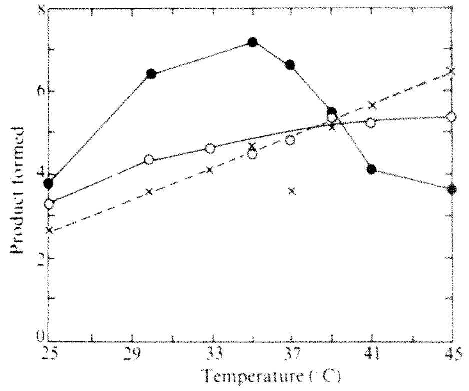

Fig. 1 Reaction rates of murine sperm enzymes as a function of temperature. Sialyltransferase activity toward asialofetuin, in pmol ^{3}H-sialic acid transferred per h per 10^6 sperm (●), acid phosphatase activity, in μmol *p*-nitrophenol formed per h per 10^6 sperm (○) and β-galactosidase activity, in μmol *p*-nitrophenol formed per h per 10^6 sperm (×). Asialofetuin was prepared from fetuin (Sigma) by mild acid hydrolysis in 0.1 N H_2SO_4 for 75 min at 80 °C. The hydrolysate was adjusted to *p*H 7.3 with 0.25 N NaOH and dialysed exhaustively in 0.01 M HEPES, *p*H 7.3, at 20 °C (5 ml hydrolysate against 3 × 700 ml dialysate over at least 24 h). Similarly, ^{3}H-NAN was obtained from CMP-^{3}H-NAN (New England Nuclear) by mild acid hydrolysis in 0.3 N HCl for 15 min at room temperature. The hydrolysate was neutralised with 0.3 N NaOH and assayed by descending paper chromatography on Whatman No. 1 paper with 95% ethanol and 1 M ammonium acetate (5:2) as a solvent. Quantitative cleavage of the CMP-^{3}H-NAN occurred in a concentrated solution (55 μl CMP-^{3}H-NAN at 2.33 Ci mmol^{-1} was desiccated and hydrolysed in 25 μl of HCl). For sialyltransferase assays 0.125 nmol of CMP-^{3}H-NAN, 1.25 mg asialofetuin and 25 μl of 10 mM $MgCl_2$ were desiccated in a small test tube (neither $MgCl_2$ nor $MnCl_2$ had any significant inhibitory or stimulatory affects). Reactions were initiated by adding 25 μl of the washed, intact sperm suspension to each tube before incubation at 35 °C. The reactions were stopped by the addition of 10 μl of ice-cold 0.25 M EDTA and by immediate chilling to 0 °C. Although cations were not required for the sialyltransferase reaction, the addition of EDTA consistently lowered electrophoretic background activities. The amount of ^{3}H-sialic acid transfer was determined by high voltage electrophoresis of 20 μl of the reaction mixture using methods described before[7]. Transfer to endogenous acceptors was determined by omitting asialofetuin from the reaction tubes. For acid phosphatase and β-galactosidase assays, 25 μl of the washed sperm suspension was added to 200 μl of a 50 mM citrate buffer, *p*H 5.1, containing either *p*-nitrophenyl phosphate or *p*-nitrophenyl β-D-galactopyranoside (both at 1 mg ml^{-1}, Sigma). After 1 h, the reactions were terminated by the addition of 1.5 ml ice-cold 0.02 M NaOH and the values of A_{400} were recorded and converted to μmol of product formed using a conversion factor of 0.245 Δ units per μmol free *p*-nitrophenol.

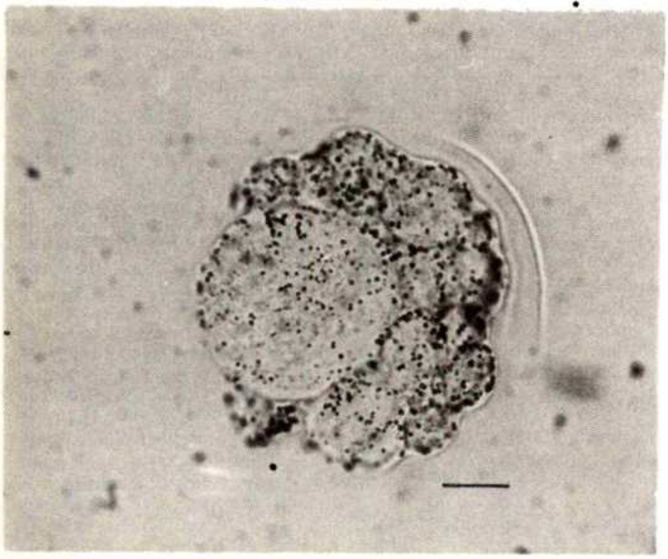
enzyme source, the rate of transfer was 4.5 pmol of sialic acid transferred per h at 35 °C. This rate was linear with time for at least 150 min. If asialofetuin was omitted from the reaction mixtures there was no detectable endogenous activity with washed sperm.

Figure 1 shows that the sialyltransferase activity on intact sperm was highest at 35 °C, the approximate temperature of the mouse testis[6], and that it decreased at higher or lower temperatures. This contrasts with sperm acid phosphatase and β-galactosidase, for which activity increases with temperature up to at least 45 °C.

When ova alone were incubated with CMP-^{3}H-NAN for 1 h and examined autoradiographically, they showed a definite endogenous incorporation that was significantly above background but diffusely distributed on the ova and surrounding cumulus cells (Fig. 2). Ten ova were assayed in this fashion in three separate experiments, and all showed the same pattern. By contrast, when 12 ova, in three experiments, were incubated with sperm for 1 h, all the eggs contained at least one very dense patch of silver grains in addition to the diffuse pattern seen on all eggs. Figure 3*a* shows a brightfield micrograph of an egg incubated with sperm and processed autoradiographically. This egg has three, clear deposits of silver grains in which the density of the grains is much greater than that of the surrounding area. The same egg is shown under phase contrast in Fig. 3*b*. Two of the dense grain deposits (arrows) in Fig. 3*a* are clearly associated with sperm that have penetrated the egg and whose tails are visible in phase contrast in Fig. 3*b* (arrows). The third patch of silver grains on the egg (leftmost edge of the egg in Fig. 3*a*) cannot be linked unambiguously to a single sperm although there are several possible candidates visible when the actual specimen is viewed at a number of focal planes in phase contrast. Grain accumulations are also seen on cumulus cells of eggs incubated with sperm (Fig. 3*a*) but not on cumulus cells of eggs incubated without sperm (Fig. 2). The localised, spatial correlation between grain patches and sperm indicate that the transfer is mediated by sperm-associated and not soluble enzyme activities.

In these incubations, hydrolysis of CMP-^{3}H-NAN did occur but the extent of hydrolysis did not exceed 17% of the input sugar nucleotide. Further, this level of free ^{3}H-NAN cannot account for any of the activities reported here because, when ^{3}H-NAN was substituted for CMP-^{3}H-NAN at identical concentrations (0.125 nmol per 25 μl) and specific activities (prepared as described in the legend to Fig. 1), there was no sialic acid transfer to asialofetuin by sperm.

Fig. 2 Brightfield micrograph of a mouse egg incubated in CMP-^{3}H-NAN and developed autoradiographically. There is a definite incorporation of radioactivity above background levels on the egg as well as on cumulus cells partially surrounding the egg, and this incorporation is distributed randomly. The bar represents 25 μm.



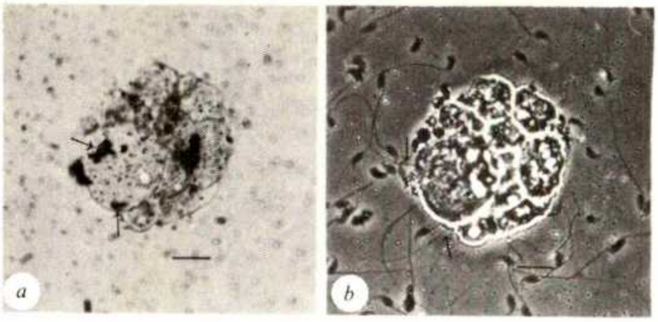


Fig. 3 Mouse egg incubated as in Fig. 2 but in the presence of washed sperm. *a*, Brightfield micrograph showing three dense accumulations of grains over the egg and several accumulations over the cumulus cells. These patches of grains are in addition to the general, evenly distributed incorporation seen in eggs incubated without sperm. Arrows indicate two grain patches on the egg. *b*, Phase contrast micrograph of the identical field shown in *a*. Here the sperm are easily seen. Arrows show the tails of sperm that have penetrated the egg in precisely those areas where two of the grain accumulations can be seen (arrows) in *a*. The bar represents 35 μm. Autoradiographic assays were performed using concentrations of CMP-^{3}H-NAN identical to those described in the legend to Fig. 1, except that the contents of the incubation tubes containing either ova alone or ova with washed sperm were first placed on a slide kept on a humidified chamber for the duration to the incubation. The reactions were stopped by gentle rinsing of the ova, or ova with sperm, with saline followed by fixation in 10% formalin. The slides were then stained lightly with haematoxylin and processed by standard autoradiographic techniques.

These data show that a CMPNAN : asialofetuin sialyltransferase is associated with mouse sperm and suggest that intact sperm can transfer sialic acid to acceptors on egg membranes. In the absence of added CMPNAN, it is possible that an enzyme–substrate complex would be more stable and could be one of the mechanisms whereby a sperm recognises and adheres to an egg. Although we have no data to suggest that the enzyme activity expressed by intact sperm results from intrinsic, as opposed to adsorbed, transferases, even an adsorbed enzyme could function in the suggested manner.

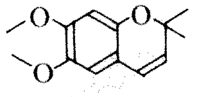
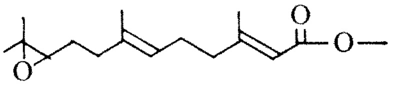
Precocene II inhibits juvenile hormone biosynthesis by cockroach corpora allata *in vitro*

BOWERS *et al.*[1] reported that a chromene derivative isolated from plants of the genus *Ageratum* interferes with the development of insects from several orders. They named the most active component of the plant extract precocene II (I), because exposure of young larval stages of test insects to the compound leads to precocious metamorphosis into unviable or moribund miniature adults. Also, exposure of adult females of several insect species causes sterility by preventing normal vitellogenic development of the oocytes, and in at least one case[1] this effect can be overcome by hormone replacement therapy with C_{16} juvenile hormone (C_{16}JH: (II)). These effects suggest that precocene II acts



I



II

antagonistically to the natural JHs which are responsible for the proper suppression of metamorphosis in larval insects[2], and for the activation of ovarian growth and other reproductive phenomena in adult females of most insects[3]. Precocenes constitute a new type of insect growth regulator, and have been referred to as 'fourth generation insecticides'[1]. We envisaged two ways *a priori*, in which precocene might act in the whole animal: either by blocking the biosynthesis of JHs, or by blocking the action of natural JHs, that is, their safe transport through the haemolymph followed by effective action at the various target sites. We have concentrated on one aspect of the former possibility, and have investigated whether or not active corpora allata from adult females of the cockroach *Periplaneta americana* are directly inhibited by exposure to precocene II *in vitro*.

We used minor modifications of the quantitative assay for inhibitors of JH biosynthesis developed by Pratt and Finney[4], which is based on (1) the predictability of synthetic activity in corpora allata taken from adult mated females at specified times during the gonotrophic cycle, (2) the incorporation of label from methyl-^{14}C-methionine into C_{16}JH, and (3) the linearity of this incorporation for at least 5 h *in vitro*[6,7]. Because of natural increases in the reproduc- *in vitro* to concentrations of precocene II of 10^{-4} M and corpora allata are now maximally active 0.75 d after the mid-brown stage of ootheca formation[5], affording rates of C_{16}JH biosynthesis which range from 28 to 45 pmol per pair of glands per h. Figure 1 shows that spontaneously active corpora allata can be inhibited rapidly by exposure *in vitro* to concentrations of prococene II of 10^{-4} M and higher; moreover, the inhibition of C_{16}JH biosynthesis measured in these standard conditions is essentially complete at concentrations in excess of 10^{-3} M. The influence of precocene II on C_{16}JH biosynthesis was quantitatively indistinguishable from its effect on total ester production (methyl farnesoate + C_{16}JH). This level of inhibitory activity is approximately commensurate with that of some propynyl and methylenedioxyphenyl ethers previously examined but much lower than that of those methylenedioxyphenyl ethers which bear a strong structural resemblance to natural JHs and have intrinsic JH-mimicking activity[4]. There is no doubt that precocene II can act as a powerful direct inhibitor of the corpus allatum which suggests that analogous structures may have this activity at much lower concentrations, as is the case with methylenedioxyphenyl series.

That the observed level of methyl farnesoate in the glands treated with precocene II was reduced in proportion to the reduction in the rate of C_{16}JH biosynthesis might suggest that the site of action is earlier than the final epoxidative step in the biosynthetic pathway. Failure to accumulate methyl farnesoate in the presence of monooxygenase inhibitor, however, might also occur if internal feedback mechanisms prevented the overproduction of farnesenic acid and hence methyl farnesoate[4].

To investigate this possibility, we have made use of the fact that addition to the culture medium of the presumed precursor farnesenic acid results in a significant stimulation of the rate of C_{16}JH biosynthesis, regardless of the spontaneous level of activity of the glands. The exogenous ^{3}H-farnesenic acid is incorporated efficiently into the newly synthesised C_{16}JH (refs 8 and 9). Moreover, large quantities of methyl farnesoate accumulate within the glands in these conditions because of a limited epoxidative capacity. Apparently there is no rapid end-product inhibition of the *O*-methyl transferase. Thus by carrying out trials with precocene II in the presence and absence of exogenous farnesenic acid we were able to determine whether the inhibitor has an effect on JH biosynthesis subsequent to the point of entry of farnesenic acid into the biosynthetic pathway. The optimum concentration of farnesenic acid for stimulation of C_{16}JH biosynthesis by corprora allata from the locust *Schistocerca gregaria* is known to be 2–2.5 × 10^{5} M (ref. 10). Glands from *Periplaneta americana* respond optimally to slightly higher concentrations (unpublished results of G.E.P.) and so a concentration of 4–4.5 × 10^{-5} M was used. By killing animals between ovulation and ootheca formation (2.75 d after the mid-brown stage of the previous ootheca) we obtained corpora allata exhibiting low spontaneous rates of C_{16}JH biosynthesis (2–5 pmol per pair of glands per h)[5]; in the presence of optimal concentrations of farnesenic acid, these glands afforded rates of C_{16}JH biosynthesis of 40–55 pmol per pair of glands per h, and total esterification rates of 60–95 pmol per pair of glands per h.

Analysis of the isotope incorporation ratio in the C_{16}JH indicated that in these 'stimulated' conditions, 91–98% of

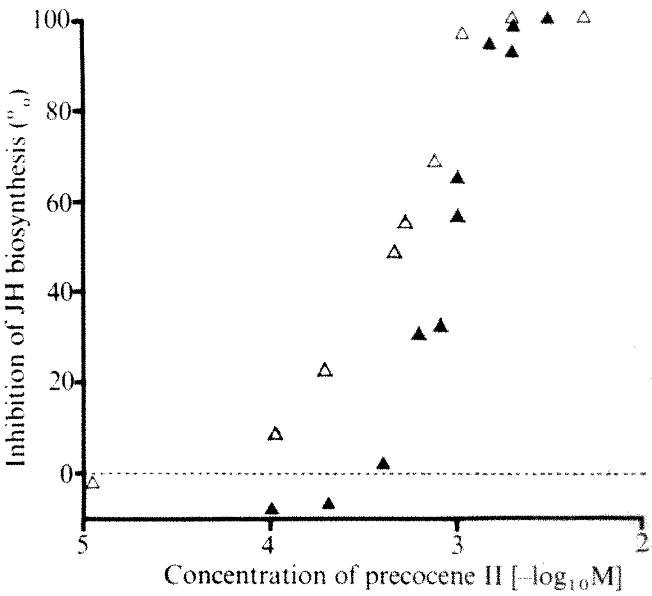


Fig. 1 Effect of precocene II concentration on its ability to inhibit biosynthesis of C_{16} JH *in vitro* during a 3-h incubation with label after a 30-min preincubation. △, Response of corpora allata synthesising spontaneously at their maximum physiological rate; ▲, response of glands taken at a time of minimum spontaneous activity but stimulated with optimum concentration of exogenous farnesenic acid. Each point represents the performance of four, six or eight pairs of glands. The two glands from each member of the group were bilaterally randomised between control and experimental tubes, and preincubated in 0.1 ml of sterile augmented medium TC-199 for 30 min with or without precocene II, at 30 °C; the medium was removed and replaced with the same medium fortified with methyl-^{14}C-methionine to final specific radioactivities of 21–23 mCi mmol^{-1} in different experiments. After 3 h incubation with labelled methionine the entire contents of the tubes were brought to *p*H 4.5 with an equal volume of 1% disodium ethylene-diamine-tetracetate, and analysed for the methyl farnesoate and C_{16}JH that had been biosynthesised[6,9]. Appropriate sections of the chromatograms were counted in 11 ml of 7.3% naphthalene, 0.7% butyl-PBD, 0.04% glacial acetic acid, 11% water, in 1:4 dioxan, after vigorous shaking for 1 h and being left overnight in the dark in a Wallac 8100 LSC set for double-label ^{3}H,^{14}C counting.

the hormone is made from exogenous acid, so that the assay approximates closely a test for the ability of precocene II to inhibit esterification and epoxidation reactions at the end of the biosynthetic pathway. Figure 1 shows that we obtained a very similar result for the inhibition of both spontaneous and farnesenic-acid-dependent synthesis; moreover, the rate of esterification of the ^{3}H-farnesenic acid (that is the rate of formation of both methyl farnesoate and C_{16}JH) showed the same sensitivity to precocene II inhibition as did the terminal epoxidation to the hormone. One interpretation of these results is that the effect of precocene II is manifested most importantly at the penultimate esterification stage in the biosynthetic pathway. The results shown in Fig. 1 also imply that the glands are slightly less sensitive to precocene II when assayed in the presence of optimum farnesenic acid concentrations, than when assayed at the lower rates of flux through the last two stages which obtain in conditions of maximum spontaneous activity in the absence of added precursor acid. A better understanding of this apparent protecting effect of exogenous farnesenic acid might afford a clue to the molecular mode of action of precocene II.

To see whether precocene II has a progressive effect on JH biosynthesis, we examined the effect of varying the duration of the non-radioactive preincubation on the ability of critical concentrations of precocene II to inhibit hormone radiobiosynthesis. We maintained sterile procedures throughout the experiment, and reduced the duration of the labelled incubation to 2 h. Such a reduction in labelling time results in an underestimation of the actual rates of biosynthesis, because of the time-lag in the attainment of full isotopic equilibrium in the newly synthesised hormone from methyl-^{14}C-methionine[6]. The results presented in Table 1 suggest that there is an approximate doubling in the effectiveness of precocene II over the 6 h of our study. This simple interpretation however, assumes that precocene II has no effect on the radiochemical lag period. If precocene progressively inhibits either the uptake or metabolism of methionine so as to increase the time taken for the methyl-donor substrate pool serving the *O*-methyl transferase to reach isotopic equilibrium, this would manifest itself as an apparent enhancement of the inhibition of C_{16}JH biosynthesis. Direct measurements have not been reported of intracellular pools of methionine or *S*-adenosyl methionine[11] in the corpora allata of any species. On the other hand, our results make it unlikely that the glands rapidly inactivate or adapt to the inhibitor.

Although precocene II inhibits C_{16}JH biosynthesis in the corpora allata of adult female *P. americana* only at relatively high concentrations compared with some other compounds tested[4], its action on the corpus allatum is interesting for two reasons. First, it is a natural product, and second it has dramatic 'anti-juvenile hormone' effects in several insects, notably hemipterans[1]. Unfortunately, the chemical identity of the natural juvenile hormone of sensitive hemipterans has not yet been established. Precocene II has only weak activity in adult female *P. americana* as an 'anti-juvenile hormone', which is in accord with the high ID$_{50}$ *in vitro* reported here, and could also be a result of high rates of metabolism in this species. Although we have found that precocene II is an effective inhibitor of C_{16}JH biosynthesis in isolated corpora allata, this does not preclude the possibility that it also interferes with other parts of the juvenile hormone control pathway, such as haemolymph transport and target site recognition, which have yet to be directly investigated. It also remains to be discovered whether precocenes are specific inhibitors of the penultimate step in JH biosynthesis, or alternatively inhibit biosynthesis through nonspecific or indirect actions on cellular metabolism. We do not exclude the possibility that precocenes are general metabolic depressants, or inhibit the synthesis of enzymes in the JH biosynthetic pathway which have a rapid turnover.

Table 1 Influence of preincubation time on percentage inhibition of JH biosynthesis by precocene II *in vitro*

Preincubation time (h)	Precocene II 0.25 mM (%)	concentration 0.5 mM (%)
0	20*	20
0.5	20	52
2	20	60
4	71	91
6	64	98

Groups of spontaneously active corpora allata, bilaterally randomised into control and experimental sets, were preincubated in standard culture medium with or without precocene II for up to 6 h. Incubation medium was aspirated off and replaced with the same medium plus labelled methionine. After 2 h further incubation, the rates of production of C_{16}JH were determined by addition of nonradioactive carrier, extraction, thin-layer chromatography and liquid scintillation counting. The percentage inhibitions shown reflect the performance of not less than six pairs of corpora allata in each case.

*Observed inhibitions of less than 20% are not significantly different from zero.

We are grateful to the late Dr A. F. White for ^{3}H-E,E-farnesenic acid and nonradioactive carrier compounds, and to Mrs K. M. Stott for technical assistance.

Facultative blood–brain barrier and neuronal adaptation to osmotic stress in a marine osmoconformer

In most vertebrate and higher invertebrate animals cellular functions are critically dependent on the relative stability of the chemical composition of the body fluids, a requirement epitomised by Claude Bernard's dictum: "la fixité du milieu intérieur c'est la condition de la vie libre"[1]. In higher vertebrates[2,3], and in insects[4], but not apparently other invertebrates[5,6], the ionic homeostasis of the neuronal environment is augmented by extremely effective blood–brain barrier systems. The nerve cells of euryhaline osmoconformers, however, are exposed to considerable fluctuation in the osmotic and ionic concentrations of the body fluids[7]. As an example we studied the serpulid worm, *Mercierella enigmatica* (Fauvel), which occurs in waters in which the salinities vary from 1 to 55‰ (refs 8–10) and which can withstand relatively rapid variations in the osmotic concentration of the blood of between 43 and 1,620 mOsm (ref. 11). We report here that in spite of such extreme variations

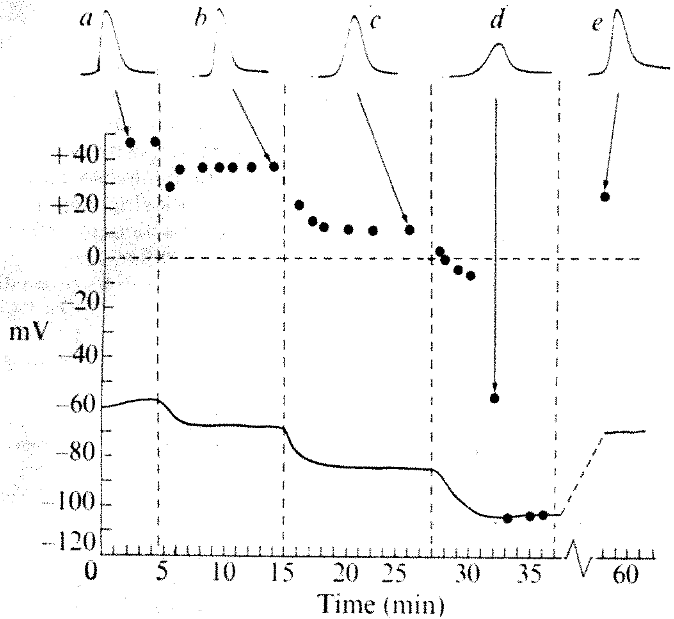

Fig. 1 Effects of isosmotic dilution on action and resting potentials. Isosmicity (1,024 mOsm) was maintained by addition of sucrose to the physiological saline. The intracellular recordings were made with conventional glass microelectrodes (10–20 MΩ tip resistance) from the paired giant axons (30 µm in diameter) in pinned, dissected worms. The axons were stimulated with insulated silver wire electrodes. The standard saline used was based on the ionic and osmotic concentration of the blood of seawater-adapted animals[14] and had the following composition, in mM: Na^+, 482.3; K^+, 30; Mg^{2+}, 77; Ca^{2+}, 31; SO^{2-}_4, 26; Cl^-, 663.8; OH^-, 12.5 and PIPES, 7.5 (*p*H 6.9). *a*, St saline only; *b*, 50% saline in sucrose; *c*, 25% saline in sucrose; *d*, 10% saline in sucrose; *e*, Std saline.

in osmotic and ionic concentration, the axons of *Mercierella* function using ionic mechanisms which seem essentially similar to those of other marine invertebrates, such as the giant axons of the squid[12] or the polychaete, *Myxicola infundibulum*[13]. The resting potential approximates to an ideal potassium electrode (with 58.8 mV alteration for decade change in $[K^+]_o$), the action potentials are sodium-mediated (exhibiting a 55.8 mV alteration for decade change in $[Na^+]_o$) and are blocked by externally applied tetrodotoxin at about 10^{-7} M.

The axonal responses to saline diluted with isosmotic sucrose differed markedly from those observed during exposure to hyposmotic (distilled water-diluted) saline. Isosmotic dilution caused a significant hyperpolarisation, rapid decline in the overshoot of the action potential and eventual conduction block (Fig. 1). The hyperpolarisation probably results from dilution of the external potassium which, at 30 mM, is in a sensitive part of the Nernst slope. The decline in overshoot results from the reduced concentration of sodium ions at the axon surfaces. These responses differ from those observed during hyposmotic dilutions, when axonal function persisted in preparations exposed to dilutions down to 1.0% (Fig. 2) or, in other experiments, to 0.5%. Action potentials also continued in diluted, sodium-free saline (Fig. 2). In contrast, exposure to diluted sodium-free saline caused a rapid decline in overshoot in isosomotic conditions.

Potassium depolarisation of the axon membrane was critically dependent on the osmotic concentration of the bathing medium. Rapid axonal depolarisation occurred in isosmotic saline (Fig. 3). The kinetics of this potassium depolarisation indicate that the inward and outward movements of this cation, between the axon surface and the bathing medium, occurred with half times of 31.0±3.1 and 32.2±3.1 s ($n = 6$), respectively. In hyposmotic saline, however, no appreciable

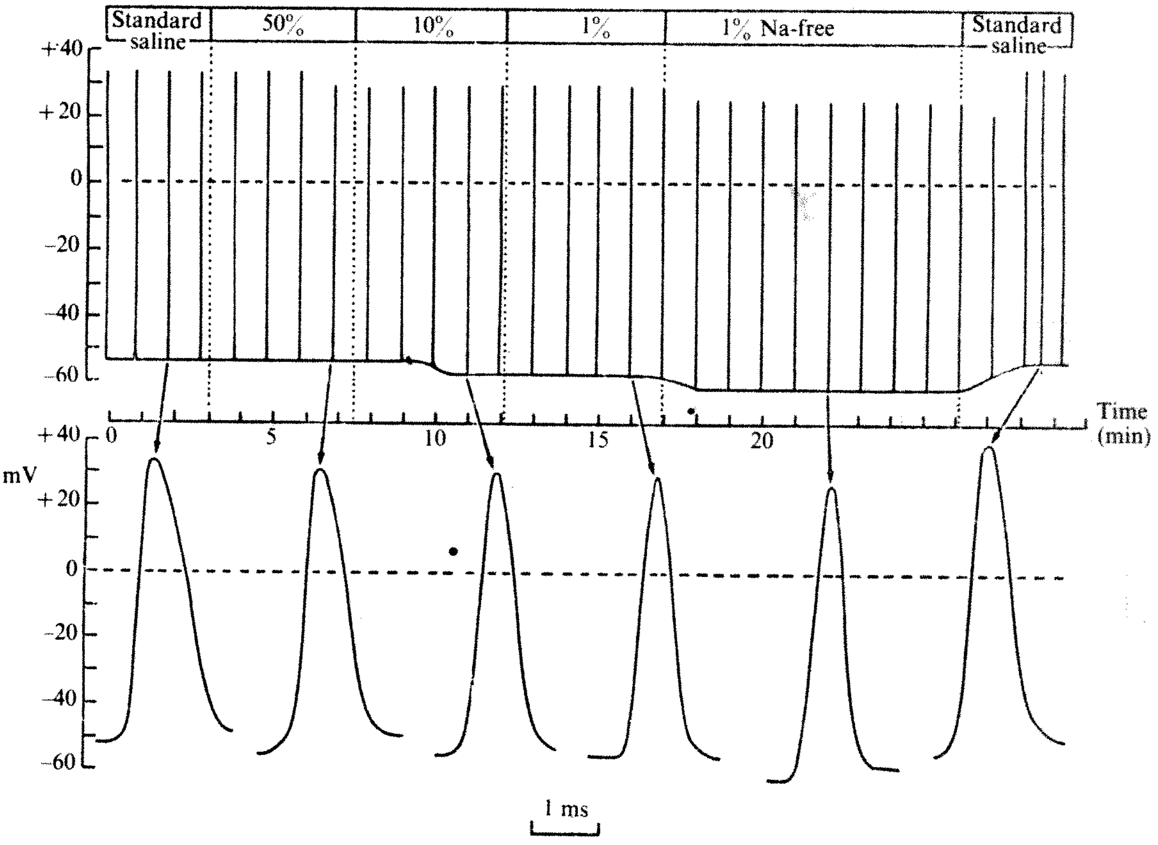

Fig. 2 Effects of hyposmotic dilution on axonal action and resting potentials. Normal physiological saline (1.024 mOsm) was diluted with distilled water down to 1% strength. Sodium-free saline was prepared by substituting Tris ions for Na^+. The potentials were recorded by a transient signal processer and displayed on a chart recorder.

axonal depolarisation was seen after an increase in the external potassium concentration (Fig. 3).

The absence of potassium depolarisation and the lack of effect of sodium-free saline in hyposmotic conditions suggest that a drastic change in accessibility of the axon surfaces occurs during dilution of the bathing medium. This isolation of the immediate fluid environment of the axons was readily reversible, and was abolished when sucrose was added to the bathing medium to restore isosmotic conditions.

Mercierella can survive in distilled water. Axons from individuals adapted to such conditions were able to function in standard saline diluted to 10% strength (Fig. 4*a*). Exposure to sodium-free 10% strength saline caused a rapid loss of axonal function, which indicates that the axon surfaces are accessible in hyposmotically adapted animals. In these conditions further dilution of the bathing medium did not reduce access to the axon surfaces, as exposure to 1% standard strength saline resulted in a rapid decline in the overshoot and irreversible conduction block.

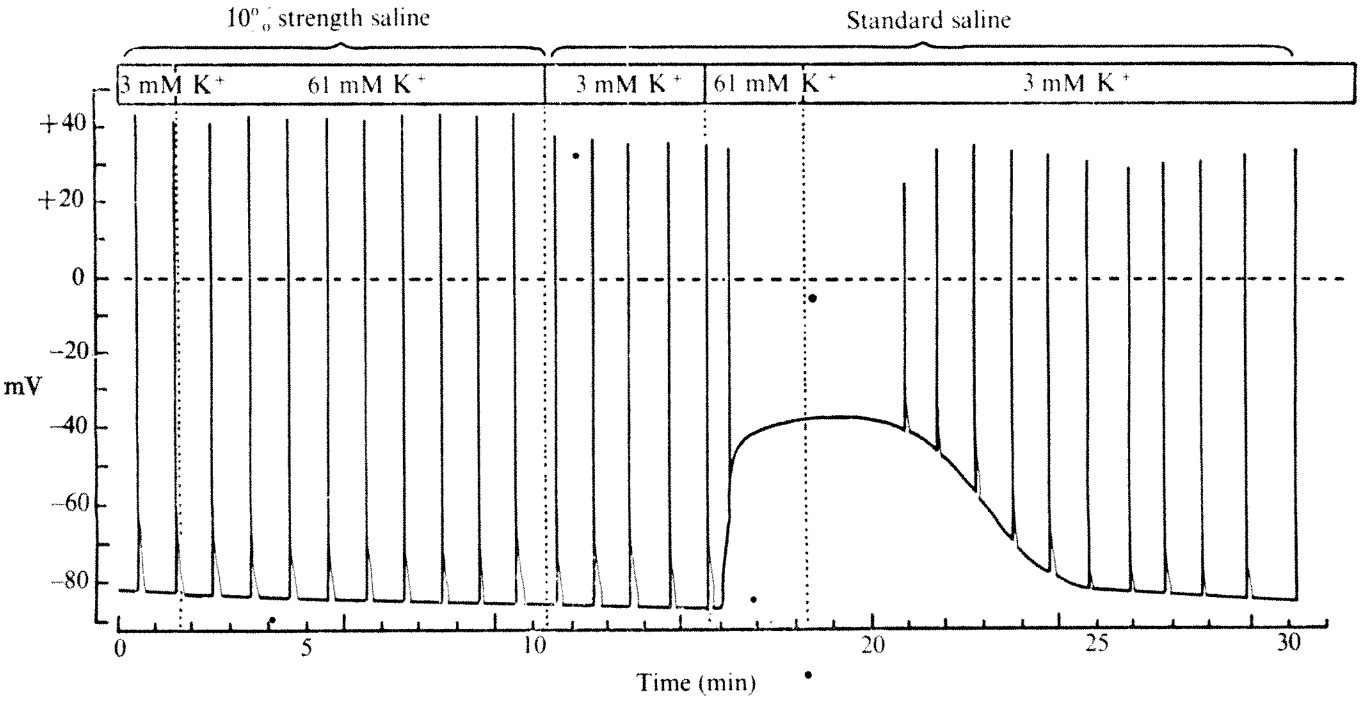
The structural basis of the osmotically-induced diffusion barrier is uncertain. Electron micrographs show that the giant axon is wrapped by narrow glial processes, which are associated with one another by occasional gap junctions, and that this glial–axonal complex is surrounded by extracellular material containing collagen-like fibres. The glial coverage of the axon seems to be incomplete, even in hyposmotic media, so that in these glial-depleted areas the axon abuts directly on to the extracellular material. This organisation is difficult to reconcile with a glial diffusion barrier. Furthermore, the absence of appreciable potassium depolarisation in hyposmotic conditions (Fig. 3) might argue against a cellular barrier, as restricted intercellular access through a peripheral glial layer would be expected to produce relatively large extraneuronal potential changes resulting from depolarisation of the outwardly-directed cell membranes as is the case in insect[15] and crustacean[16] perineuria. Alternatively the osmotically-induced restriction to the access of water-soluble cations might result from changes in the permeability properties of the extracellular matrix which surrounds the axon surfaces.

The accessibility and ability of the axons of hyposmotically-adapted individuals to function at reduced $[Na^+]_o$ (48.2 mM) contrasts with the situation in the axons of seawater-adapted animals. In the latter the axons are protected during hyposmotic stress, and exposure to 10% standard strength sodium (48.2 mM) in isosmotic conditions causes conduction block (Fig. 4*b*). This indicates that the axons can adapt to conduct action potentials at drastically reduced external sodium concentrations.

Adapted axons bathed with 10% strength saline showed smaller overshoots (20.8 ± 1.8 mV, $n = 5$, compared with 38.1 ± 1.1 mV, $n = 20$) and larger resting potentials (69.8 ± 1.5 mV, $n = 5$, compared with 53.6 ± 1.4 mV, $n = 20$) than unadapted axons in normal saline. The total amplitude of the action potential was thus virtually unchanged (Fig. 4*b*). The resting potentials of adapted axons in 10% saline (3.0 mM K^+) were significantly smaller than those of unadapted axons in normal saline containing 3.0 mM K^+ (96.8 ± 2.2 mV, $n = 5$). This suggests that hyposmotic adaptation involves a reduction in $[K^+]_i$ and/or a decrease in potassium permeability of the axon membrane. Similarly, the ability of adapted axons to produce overshooting action potentials at a tenth of the standard sodium concentration (48.2 mM) implies that adaptation involves an appreciable reduction in $[Na^+]_i$. For example, if the sodium selectivity of the active membrane was similar to that of unadapted axons (55.8 mV for decade change in $[Na^+]_o$, then with $[Na^+]_o = 48.2$ mM and an overshoot of 20.8 mV it can be calculated that $[Na^+]_i$ would be approximately 21 mM, compared with 90 mM in unadapted axons bathed in normal saline.

Our observations indicate that two physiological mechanisms are involved in hyposmotic adaptation of this axon. Immediate protection from hyposmotic stress is achieved by a facultative blood–brain barrier which effectively isolates the axon from the diluted body fluids. This isolation enables the axons to adjust more slowly and, eventually, to function when bathed directly

Fig. 3 Effects of increased potassium (61 mM) in hyposmotic (10%) and normal saline. The potassium concentration of normal saline (30mM) was reduced to 3 mM to maintain similar concentrations to that in 10% standard strength saline.



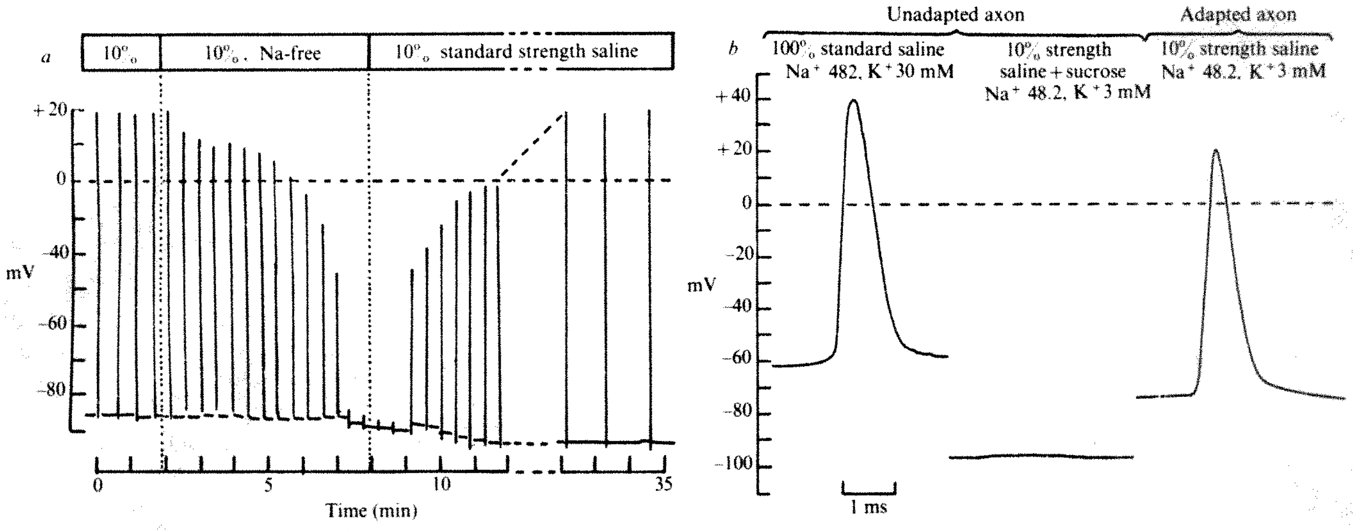


Fig. 4 Axonal action potentials recorded from individuals reared for 10 weeks in flowing distilled water. *a*, The effects of sodium deficiency during exposure to 10% standard strength, hyposmotic, saline. *b*, Action potentials recorded from an unadapted axon, in normal saline, and from a hyposmotically adapted one in 10%, hyposmotic saline. Exposure of the unadapted axon to isosmotic (sucrose-substituted) 10% strength saline caused conduction block and hyperpolarisation of the axon membrane.

by dilute media which would be insufficient to maintain excitability in unadapted nerve cells.

Isometric contractile properties of single isolated smooth muscle cells

THE use of multicellular strips to study contractile properties of smooth muscle cells rests on the assumption that properties of individual cells are directly reflected in the behaviour of whole tissues. Both the heterogeneity of the contractile state of the cell population in the intact strip, and the complex interconnections between cells and extracellular fibrous elements, however, must influence measured mechanical properties. Methods for isolating viable single smooth muscle fibres from the stomach of the toad, *Bufo marinus*[1,2] now make it possible to make direct measurements of force generation in single cells. I report here a technique for isometrically measuring the force of contraction of a single isolated smooth muscle cell. The method was used to investigate the kinetics and magnitude of force development in a single smooth muscle cell. The results reveal that the maximum force per cm^2 of a single cell is comparable with that of whole tissue. The onset of active force development after stimulation is exceptionally slow. Analysis of this delay suggests that it resides in step(s), perhaps unique to smooth muscle, whereby Ca^{2+} activates the contractile machinery.

Suspensions of isolated single smooth muscle cells were prepared by enzymatic digestion of the stomach muscularis from *Bufo marinus* by a modification[2,3] of the procedure of Bagby *et al.*[1]. Individual cells were tied in a knot at each end around a probe as shown in Fig. 1*a*. One probe was attached to an ultrasensitive force transducer[4] able to measure forces as small as a few μg while the other probe was attached to a micromanipulator. Attachment of a cell to the probes was facilitated by the anionic exchange resin particle at the end of each probe. An electrostatic attraction between the resin particle and the cell facilitates a weak attachment of a probe at each end of the cell. This attachment is strengthened by tying the cell in a knot around each probe using a micromanipulator. The resulting attachment is sufficiently strong to withstand the force of contraction of the cell. When experiments failed they did so quite often because the cell ripped itself in half, rather than pulling free at its attachment. Activation was accomplished by passage of a brief electric current between two Ag–AgCl 'paddles' (350 μm diameter) placed on either side of the cell.

A typical contractile response to a single submaximal shock is shown in Fig. 1*b*. In this cell a peak contractile force of 179 μg was achieved in 11.5 s. In 20 cells stimulated in a similar manner the average time to peak force was 11.0+1.0 (s.e.) s. The mean half-time for relaxation in these cells was 7.7±0.9 (s.e.) s. Peak contractile force depended on stimulus intensity, as shown in Fig. 1*c*. In isotonic studies of similar isolated cells the extent of shortening also varied as a function of stimulus magnitude[2,5]. The maximum contractile force recorded from more than 80 single smooth muscle cells was 2.6 kg cm^{-2}, which is similar to the maximum force measured in intact smooth muscle strips[6,7]. The maximum force per cm^2 produced by a single smooth muscle cell is also comparable with the maximum force produced by a single frog skeletal muscle fibre[8].

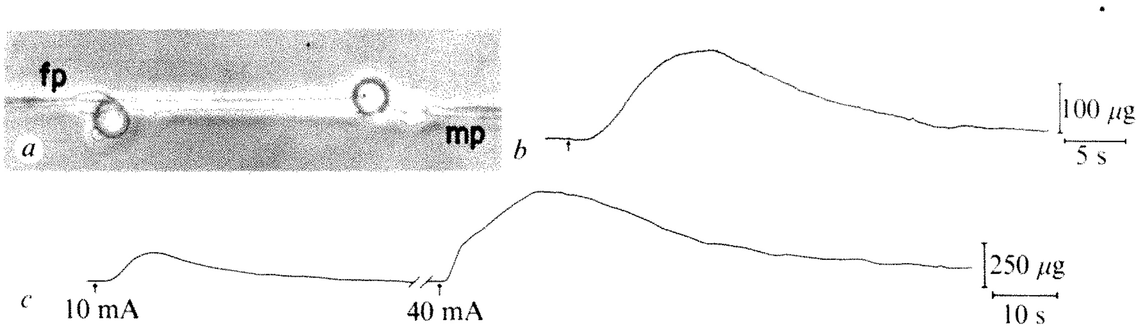

Fig. 1 *a*, Photomicrograph (phase contrast, × 390) of a single smooth muscle cell knotted at each end around a probe to facilitate isometric measurements of force. One probe (fp) was attached to a force transducer whereas the other probe (mp) was attached to a Kopf Hydraulic Microdrive (Model 1207S) or a Burleigh Piezoelectric Translator (Model PZ-30). When using the piezoelectric translator an eddy current sensor (Kaman Sciences, Model KD-2000-.5SU) was used to measure displacement amplitudes and timecourse. The microdrive was used for large amplitude stretches, and the piezoelectric device for small sinusoidal oscillations. Cell length was adjusted so that resting force was between 5 and 12 μg. Experiments were performed at room temperature (19–22 °C). Most cells used were exposed to 10 μM isoproterenol to ensure that they remained relaxed during the knotting procedure. At this concentration isoproterenol has a potent relaxing effect on the isolated cells which can be overcome by electrical or other stimulation[3,6]. *b*, Isometric recording of contractile response of a single smooth muscle cell to a submaximal electrical stimulation. Stimulus was a 1-ms square wave of 14-mA amplitude and occurred at the arrow. Maximum force achieved was 179 μg, or 0.41 kg cm^{-2}. Cross-sectional area of individual fibres on which force measurements were made was calculated assuming the cells to have a circular profile. Cell diameter was measured midway along the length of the cell from video recordings through a microscope; the video image gave a × 500 magnification of the cell. Cross sections of fixed single smooth muscle cells revealed a basically circular profile. *c*, Isometric recordings of contractile response of a single smooth muscle cell to two levels of electrical stimulation. The stimulus, a 1-ms square wave whose amplitude is indicated below the records, was initiated at arrow. Maximum forces achieved were 155 μg (0.55 kg cm^{-2}) and 512 μg (1.81 kg cm^{-2}) in response to 10- and 40-mA pulses, respectively.

Considering the much lower myosin content in smooth muscle (20% of that in skeletal muscle[9]) it is remarkable that similar forces can be generated. Although myosin in smooth muscle seems to be organised into slightly longer filaments (2.2 μm) than in striated muscle (1.5–1.6 μm)[10], the increased filament length *per se* can account only to a small extent (27%) for the apparent increase in force per cm^2 per g myosin. An additional explanation may derive from studies of changes in the ultrastructure[2,11] birefringence[12], and orientation of birefringent 'fibrils' in isolated smooth muscle cells[13] during isotonic contraction, which suggest that contractile elements are oriented obliquely to the cells' long axis. As Rosenblueth pointed out[14], with this arrangement there are more force-generating elements effectively in parallel within the cell than if the same elements ran end-to-end in series, as in skeletal muscle.

There is a considerable delay between electrical activation of a smooth muscle cell and the onset of active force development. The mean latency between a single 1-ms shock of supramaximal intensity and the development of force was 214 ± 13 ms (mean ± s.e.; 60 cells). The time course of the onset of force development in a single cell is shown in Fig. 2*a*, where there is a delay of 170 ms between stimulation and an increase in force. Values for the latency in the 60 cells studied varied from 50 to 500 ms, so that Fig. 2*a* represents one of the shorter latencies. Previously, when preliminary results were presented, even longer latencies were noted, but re-examination of the force recordings containing these very long latencies (>2,000 ms) revealed that the cells were not maximally activated, as judged by the very low values for peak d*P*/d*t*. The latency in the smooth muscle cells reported here is very much longer than that in skeletal muscle in similar conditions (2 ms in frog skeletal muscle at 20 °C (ref. 16)); it is also longer than the minimum latency observed in amphibian cardiac muscle (15–20 ms in frog ventricle[17]). Long delays for development of active force have also been noted in intact strips of smooth muscle. For example, there is a 80–160-ms interval between an action potential and the onset of contraction (measured indirectly) in uterine strips at 30 °C (ref. 18).

Although the rate-limiting step responsible for the long latencies in the isolated smooth muscle cells has not been identified, several potential causes for the long delay can be eliminated. The long latencies cannot be attributed to an effect of isoproterenol (10 μM), present in most experiments because, in the absence of isoproterenol, similarly

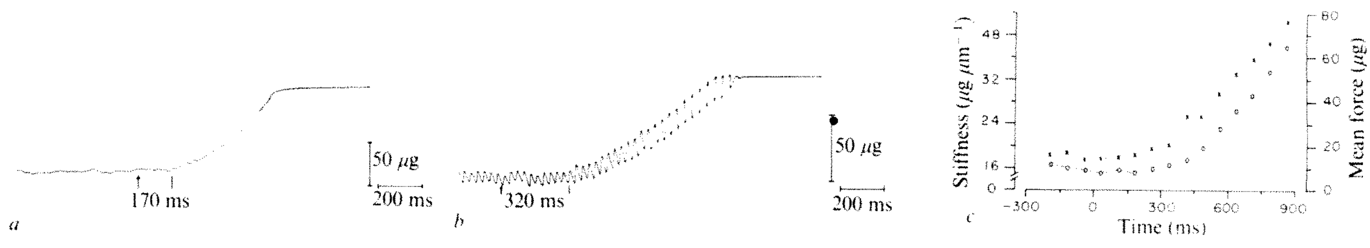

Fig. 2 *a*, Isometric recording of the contractile response of a single smooth muscle cell to supramaximal electrical stimulation. Stimulus (1-ms, 55-mA square wave) was initiated at the arrow on the record. 170 ms elapsed between stimulation and onset of measurable active force. Maximum force developed by this cell was 698 μg (1.1 kg cm^{-2}). Due to the high gain used to facilitate early detection of active force development, amplifier saturates (flat right-hand portion of record) 700 ms after stimulation. *b*, Isometric recording of the contractile response of a single smooth muscle to supramaximal electrical stimulation while undergoing sinusoidal length oscillations. Stimulus (1-ms, 62-mA square wave) was initiated at the arrow. Sinusoidal length oscillations (33 Hz) were 0.5 μm peak to peak. Cell length between knots was 186 μm. Flat portion of the record (right-hand portion of trace) indicates saturation of amplifier at high gain used. Maximum force achieved was 249 μg (0.56 kg cm^{-2}). *c*, Average force (○) and stiffness (×) as a function of time before and after electrical stimulation for the cell in Fig. 2*b*. Stimulation occurred at zero time. Mean force was taken as the midpoint of the force trace in Fig. 2*b*. The plotted values for stiffness represent the mean stiffness during successive 75-ms periods; the latency for the onset of active force development was 320 ms; stiffness did not increase until active force was measurable.

long latencies were noted (254 ± 34 ms; mean ± s.e.; $n=4$). The delay does not seem to be in the ability of the contractile apparatus, once activated, to produce measurable force. If slack within the contractile system, or a delay between attachment of cross-bridges and the initiation of their cycling were responsible for the long latencies, muscle stiffness, which is associated with cross-bridge attachment in striated muscles[19–23], would probably increase before active force development. This is not the case. When muscle stiffness is measured either by applying small sinusoidal length oscillations (10–100 cycles s^{-1}; 0.5–2 μm amplitude) to the muscle or when rapid larger amplitude stretches are performed before and then at various times after stimulation, no increase in stiffness is measured until after active force is produced (Fig. 2*b* and *c*; Table 1). Although it might be argued that stiffness in smooth muscle, unlike that in other muscles, is unrelated to cross-bridge attachment, this is unlikely, because a generally linear relation between stiffness and active force development has been noted in individual fibres (Fig. 2*b* and *c*). A similar relation between stiffness and active force[24] was seen in intact smooth muscle tissues but the unknown contribution of extracellular elastic elements to such measurements makes the interpretation of results on intact tissue uncertain. The possibility that the latency reflects the time required to eliminate slack within the contractile system is further rendered unlikely by the observation that a rapid stretch of 9–11 μm (accomplished as a ramp in 60 ms) given 40 ms after the stimulus did not reduce the mean latency (285 ± 20 ms; $n=7$) below that of a control group (249 + 33 ms; $n=7$). These results indicate that the latency must reside in a step between the stimulus-induced potential change and the attachment of cross-bridges.

Table 1 Relative resistance to quick stretches applied before and after stimulation

Time between onset of stimulus and completion of quick stretch* (ms)	Resistance to stretch† relative to unstimulated cell	Force just before quick stretch‡
50–100	0.96 ± 0.10 (n = 9)	0
100–200	0.94 ± 0.11 (n = 8)	0
1,060	3.21 ± 0.49 (n = 3)	0.12 P_{max}

*Stretches applied as a ramp at 1 μm per 6.2 ms. Stretch amplitude averaged 8 μm; normalised for cell length this corresponds to an average of 5.3% of cell length just before the quick stretch.

†Resistance to stretch was taken as the peak transient increase in force resulting from the sudden length increment. Values are the mean ± s.e. of the ratio of the resistance to identical length increments applied several seconds before and then at the time noted after stimulation. The number of cells is indicated in parentheses.

‡Active force existing in the fibre at the initiation of quick stretch relative to the maximum measured force. Value is the mean for the number of the number of cells used in resistance determination.

Table 2 Effect of a preceding submaximal activation on the latency between supramaximal electrical stimulation and the onset of active force

Conditions	Latency (ms ± s.e.)
Supramaximal stimulus	201 ± 42 (n = 11)
Supramaximal stimulus, applied during submaximal contraction*	166 ± 26 (n = 8)

Latencies were determined after a supramaximal stimulus (1-ms, 50–60-mA square wave) for the number of cells in parentheses. Only latency data from those suspensions where the effect of a supramaximal stimulus alone and the effect of a supramaximal stimulus applied after a submaximal stimulus was tested have been included in the mean latencies.

*Submaximal contraction was initiated by a 10–15-mA stimulus, 1-ms square wave; supramaximal stimulus was applied during the plateau of the submaximal contraction.

On theoretical grounds it is unlikely that the long delay reflects the time required for diffusion of Ca^{2+} from its site of release to the myofibrils. Even if Ca^{2+} had to diffuse from the surface membrane to a myofibril at the central axis of the cell (a 'worst case') diffusional equilibration would be 90% complete within 10 ms (ref. 25). As indicated above, typical latencies are much longer than this. Unlike cardiac muscle[17,26], the latency for force development in smooth muscle does not seem to reflect the time required for a slow but continuous release of Ca^{2+} to achieve a threshold required for observable tension development. Such a release mechanism might be slow in an absolute sense or might be effectively slow due to close matching of rates for Ca^{2+} release and re-uptake. If the latency reflected the time for a slow release of Ca^{2+} to achieve a threshold level, then the latency to a suprathreshold stimulus ought to be greatly reduced in a cell already producing some active force, due levels would presumably be above the hypothetical thresh- to a preceding submaximal activation. In such cells Ca^{2+} hold when the supramaximal stimulus is applied. As Table 2 shows, there is no significant reduction in the latency to a supramaximal stimulus in cells already producing active force due to a shortly preceding submaximal stimulus. A further argument against the long delays reflecting the time required to achieve a threshold level of Ca^{2+} rests on the finding that the latency was not affected either by raising Ca^{2+} in the medium from 1.8 to 20 mM or by eliminating Ca^{2+} from the medium.

These observations on the latency of force generation suggest either that the long delay resides in the coupling of transmembrane potential changes to the opening of a Ca^{2+} gate or that there is a considerable delay between the arrival of Ca^{2+} at the contractile proteins and the formation of cross-bridges between myosin and actin. A possible explanation for the long delays is suggested by a recently reported[27,28] difference in the mode of activation of vertebrate smooth and striated muscle. In smooth muscle it has been proposed[29,30] that Ca^{2+} activation is accomplished by phosphorylation of a myosin light chain, and the delays could be imposed by the phosphorylation. In striated muscles where the latency is much shorter, activation seems merely to involve Ca^{2+} binding to troponin followed by a slight rotation of the troponin–tropomyosin complex[31–35]. Continued studies of the mechanical properties of isolated single smooth muscle cells may aid in further understanding both the activation process and the mechanism of force generation in smooth muscle.

Increased optical transparency associated with excitation–contraction coupling in voltage-clamped cut skeletal muscle fibres

Contraction of a skeletal muscle fibre is triggered by depolarisation of its transverse (T-) tubules[1], which occurs physiologically with the spread of an action potential into the T-system[2]. The T-tubule depolarisation gives rise to calcium release[3,4] from the adjacent but separate[5,6] sarcoplasmic reticulum (SR). The released calcium binds to troponin, removing the inhibition of actin–myosin interaction and enabling contractile activity[7]. Little is known about the nature of the T-tubule–SR interaction. It has been suggested that movement of charged molecules or dipoles in the T-tubule membrane is the initial voltage-sensitive step in the chain of events leading from T-tubule depolarisation to SR calcium release[8], and membrane charge displacement currents which may reflect such movements have been observed and characterised[8–10]. We report here a study of subsequent changes which may be related to calcium release.

Whole muscles or muscle fibre bundles stimulated to produce propagated action potentials exhibit an increase in optical transparency shortly after the action potential[11,12]. In these conditions the transparency increase follows a time course generally similar to that of latency relaxation[11], the fall in muscle tension which precedes the much larger tension development with contraction[13]. Much of the observed difference in transparency and relaxation time courses may be attributable to distortion of the latter due to asynchronous mechanical activation by a propagated action potential[13]. Latency relaxation has been explained on the basis of a mechanical change in the SR accompanying calcium release[13,14], so the transparency increase may similarly reflect SR changes associated with calcium release. We have investigated the time- and voltage-dependence of the transparency increase using voltage-clamped cut muscle fibre segments prepared so as to retain their contractile ability on electrical depolarisation.

With a high-K, Ca-free relaxing solution (120 mM K glutamate, 2 mM $MgCl_2$, 0.01 mM EGTA, 5 mM Tris-maleate buffer), single semitendinosus or ileofibularis muscle fibres from room temperature-adapted summer frogs (*Rana pipiens*) were cut about 0.5–1 cm from the tendon and mounted in a two pool leucite chamber. A single vaseline gap about 0.5–0.6 mm wide separated the pool containing the closed intact fibre segment from the pool containing the cut end. After mounting the fibre, the pools were changed from relaxing solution to the experimental solutions and experiments run at 3.4–4.6 °C.

Both the voltage difference and total current flowing between the pools were monitored and used with an analogue amplifier compensating circuit to produce a voltage V_m' equal to the fibre membrane potential just beyond the gap in the closed end pool. The compensating circuit corrected for voltage drops along the internal resistance of the length of fibre in the gap in a manner similar to standard 'compensated feedback'[15] and also corrected for leakage current across the gap outside the fibre (our work in preparation). A microelectrode was inserted in the closed fibre segment just beyond the gap in order to set the compensating circuit, but the electrode could be removed after setting the circuit. Thereafter, a voltage clamp circuit was used to maintain V_m' at a holding potential of −100 mV and to produce voltage pulses from the holding potential. Using cut fibres isolated from cold-adapted frogs, strength–duration curves for just detectable movement on depolarisation at 3–4 °C (ref. 16) closely resembled those reported for intact fibres under similar conditions[17]. Cut fibres from room temperature-adapted frogs required larger depolarisations for contraction (our unpublished work).

A reduced size image of a uniformly illuminated slit was focused on the fibre and the slit width adjusted so that the slit image, which was in all cases parallel to the fibre and 170 μm long, occupied the middle third to half of the fibre width. After positioning the fibre and focusing and adjusting the slit under the light microscope, a prism in the microscope was moved out of the light path. This focused the image of fibre and slit on a photodiode used for monitoring the transmitted light intensity. Measured changes ΔI in transmitted light intensity were divided by the light intensity I transmitted by the resting fibre.

In all experiments care was taken to keep the depolarisations of a given duration below the level which produced microscopically visible movement. $\Delta I/I$ records for larger pulses which did produce movement exhibited a second component, a decrease in transparency, which occurred during the falling phase of the transparency increases described below. This component was not characterised.

Figure 1*A* presents $\Delta I/I$ records for pulses of four different durations, with the amplitude of each pulse preselected on the basis of being within a few mV of the threshold for visible movement at that duration. The peak value of $\Delta I/I$ in each case was approximately the same. The $\Delta I/I$ time courses, however, differed considerably. Increasing the size of the depolarisation decreased the ΔI latency and increased the maximum rate of ΔI increase following the latent period. A repeat run using the first pulse (record 1*Ae*) shows that drift in the preparation with time was negligible. The time courses of all records in Fig. 1*A* are too slow for the transparency increase to be originating directly from membrane potential changes across surface[18] or T-tubule[19] membranes. It probably originates from either an SR change accompanying calcium release or from a subsequent contractile filament change preceding mechanical activity. Considering that different amplitude and duration pulses which were all close to threshold for mechanical activity were also all accompanied by about the same peak increase in transparency, the $\Delta I/I$ amplitude seems to be related to either tne amount of calcium released from the SR or to the degree of change in the myofilaments.

Figure 1*B* shows the relationship between V_m' during the pulse and the latency $L_{\Delta I}$ and maximum rate of rise $\mathrm{d}(\Delta I/I)/\mathrm{d}t_{\max}$ of

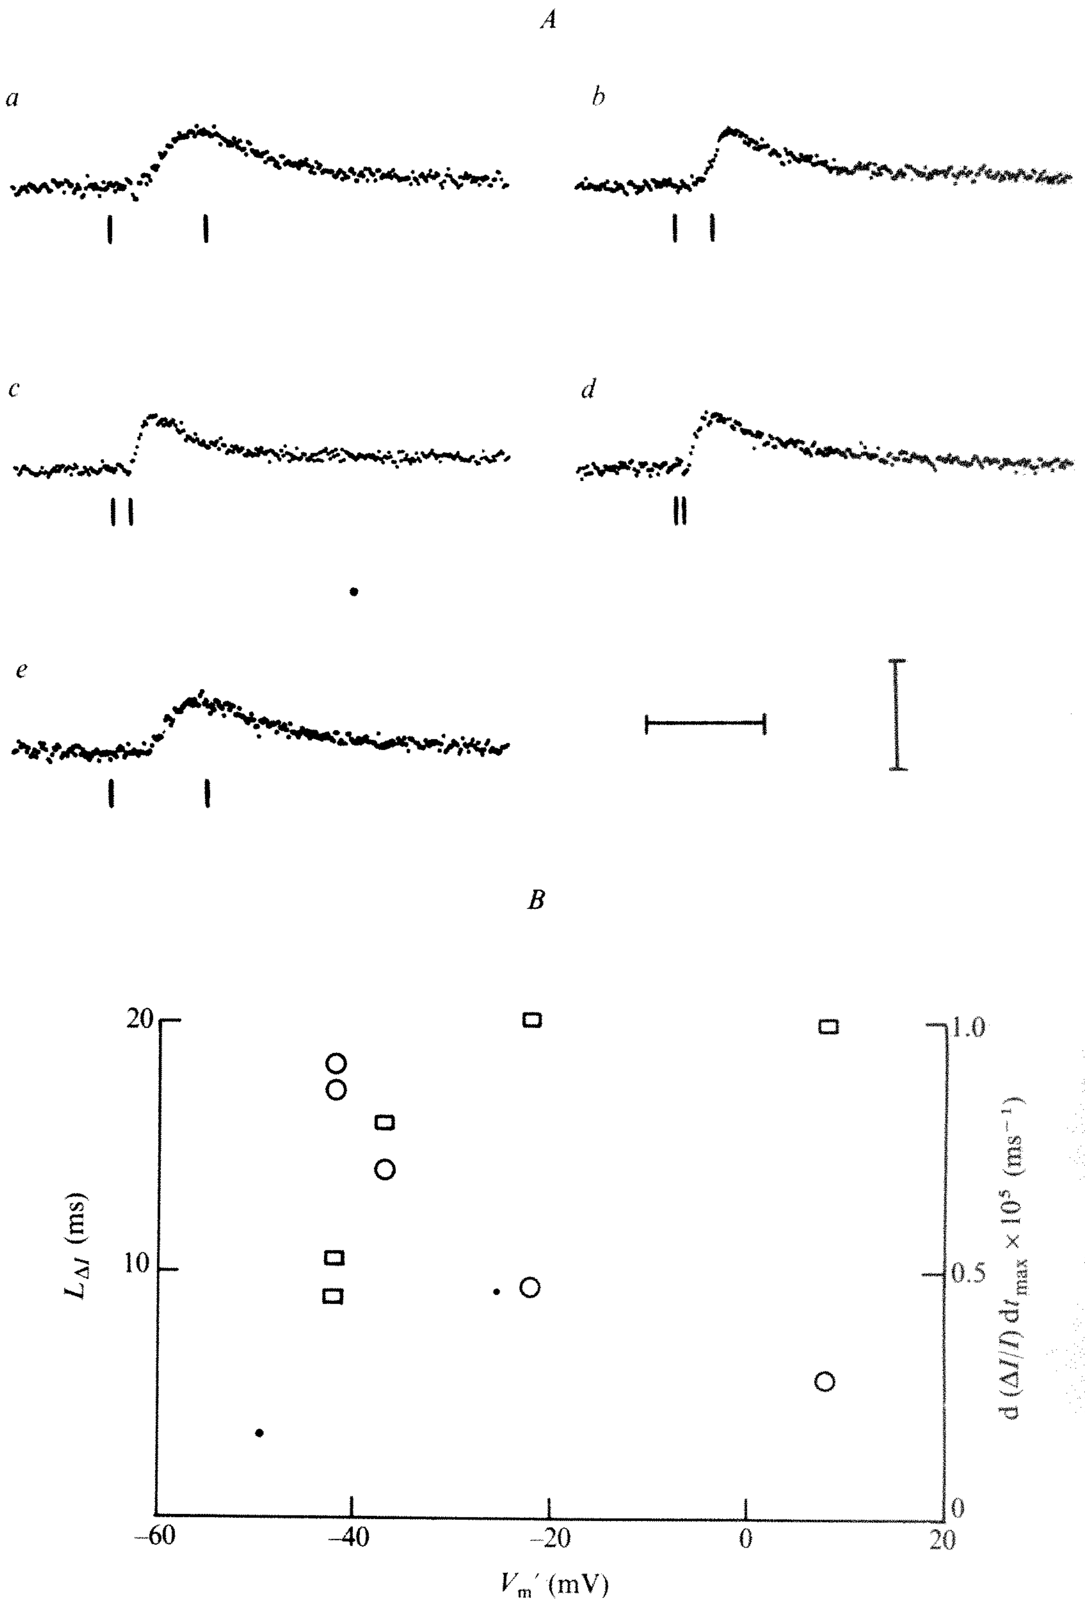

Fig. 1 Transparency changes due to pulses close to threshold for initiating microscopically visible movement. *A*, $\Delta I/I$ records for pulses to the following V_m' values (mV) for the durations (ms) indicated in parentheses. *a*, −42 (50); *b*, −37 (20); *c*, −22 (10); *d*, +8 (5); *e*, −42 (50). Each record gives the average of 10 individual traces. The horizontal calibration bar represents 60 ms, and the vertical 2×10^{-4}. Here and in Figs 2 and 3*A* the vertical lines below each trace mark the first and last interval during the pulse. *B*, Latency ($L_{\Delta I}$) in the onset of the transparency increase (○) and maximum rate of transparency increase $d(\Delta I/I)/dt_{max}$ (□) as a function of membrane potential during the pulse for the traces in part *A*. The parameters were determined from a least squares fit of a straight line through the apparently linearly rising phase of $\Delta I/I$. The closed (tendon) end pool contained 75 mM $(TEA)_2SO_4$, 5 mM Cs_2SO_4, 7.4 mM total $CaSO_4$, 5 mM Tris-maleate buffer, and tetrodotoxin (TTX) at 10^{-7} g ml^{-1}. The open end pool contained 120 mM Cs glutamate, 2 mM $MgCl_2$, 0.5 mM ATP, 1 mM EGTA and 5 mM Tris-maleate buffer (applied 70 min before start of this run). These and all other solutions had *p*H values of 7.0±0.1 at room temperature. Sarcomere length $S = 3.01$ µm, length l_c of intact fibre in the closed end pool = 500 µm, fibre width *d* in the plane perpendicular to the microscope axis = 64 µm. Fibre 68, 3.8 °C. Fibres were illuminated using a battery-powered tungsten-halogen lamp, condensing lenses, a slit of adjustable width, a 525-nm central wave length 25-nm half-peak bandwidth interference filter (Baird Atomic 35-14-7), a microscope objective (10×, 0.25 NA: Nikon 77795) as final condenser, and a glass cover slip as the chamber floor and were observed using a compound microscope with a water immersion objective (40×, 0.75 NA : Zeiss 56 17 02) and 10× wide-field eye pieces (Nikon). A photodiode (Electro-Nuclear PDS-050GB) connected to a current measuring operational amplifier circuit was used to monitor transmitted light intensity *I*. Intensity changes ΔI were monitored by using an a.c. coupled high-gain amplifier (Tektronix 3A9, 1 kHz bandwidth) in series with the photodiode amplifier. A voltage-to-frequency converter (Anadex 1700-5044-00) and digital counters were used to digitise the average output voltage of the 3A9 amplifier for successive 1-ms intervals[9] and a PDP-computer (Digital Equipment Co.) was used to store and signal average the ΔI records. *I* values of resting fibres were monitored by using a d.c. coupled digital voltmeter (Fluke 8000A).

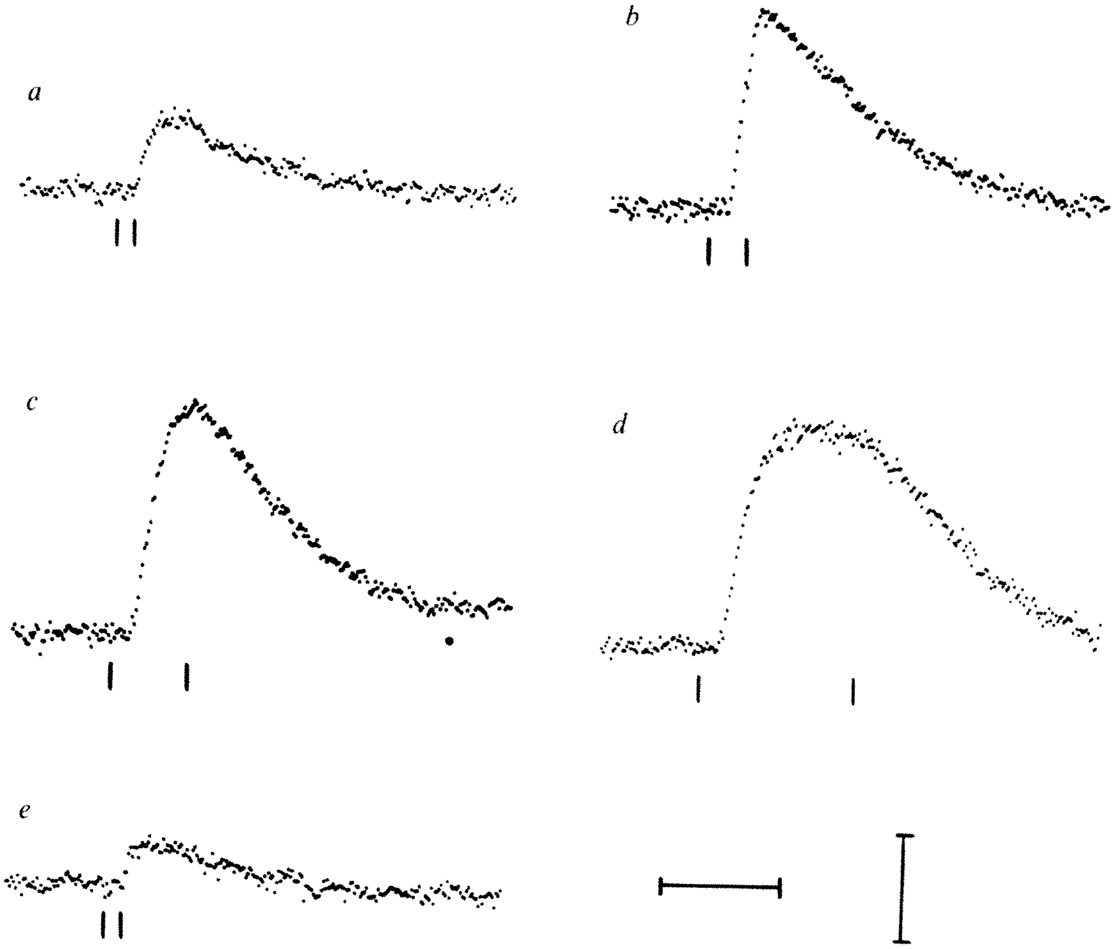

Fig. 2 Effect of pulse duration on the transparency increase. V_m' during all pulses = −14 mV. Pulse durations (ms): *a*, 10; *b*, 20; *c*, 40; *d*, 80; *e*, 10. Each record is an average of five individual traces. Before and after this run, small fibre movements were observed by using the 40- and 80-ms pulses, but not with the 10- and 20-ms pulses. The horizontal calibration bar represents 60 ms, vertical 2×10^{-4}. Solutions used were as in Fig. 1 (applied 200 min before start of this run). S = 2.81 µm. l_c = 510 µm, d = 73 µm, Fibre 69, 4.0 °C.

$\Delta I/I$ for the records in Fig. 1*A*. The minimum latency of 6–10 ms observed in this and other fibres for pulses to V_m' values slightly positive to 0 mV is consistent with the values of 6.5–7.9 ms for the time to onset of latency relaxation in massively stimulated frog sartorius muscles at 0 °C (ref. 20). Latencies such as those in Fig. 1*B* cannot be accounted for on the basis of delays in membrane charge movement[8-10]. If the transparency increase originates from the SR, the latencies suggest that there must be either one or more intermediate steps between charge movement and the SR change or that a number of charges must move before the SR change can occur. If it originates from myofilament changes, the latencies would be made up of both the response time of the SR and the time for released calcium to reach and react with the myofilaments.

In many cases the final decay of $\Delta I/I$ was exponential, with time constants of 33–85 ms in 6 fibres. With other records, a better fit was obtained using an exponential decay to a new baseline level, perhaps indicating the presence of a small amount of another ΔI component in these records.

Figure 2 presents records from another fibre for a run in which pulses of the same amplitude but different durations were used. Increasing the pulse duration from 10 to 20 ms caused a large increase in the maximum $\Delta I/I$ (records *a* and *b*), whereas further lengthening the pulse to 40 ms (*c*) caused only a slight further increase in $\Delta I/I$. Increasing the pulse duration from 40 to 80 ms (*c* and *d*) caused no further increase in amplitude but introduced a plateau phase into the $\Delta I/I$ record.

A third type of experiment involved pulses of constant duration but varying amplitude. Figure 3*A* presents records from this type of experiment carried out using 60-ms pulses with a fibre in Ringer solution which showed no movement for relatively large and long pulses. In this case the signal-to-noise ratio of the $\Delta I/I$ records was sufficiently large that signal averaging was unnecessary and single sweeps could be used. If present, any changes in I for negative pulses to V_m' values of up to −166 mV (record *a*) or for positive pulses to V_m' values down to −44 mV (record *b*) were obscured by baseline noise. Larger depolarisations caused transparency changes which increased with the size of the depolarisation. The variation of peak $\Delta I/I$ with pulse V_m' for the records in Fig. 3*A* is shown in Fig. 3*B*. These peak values represent the maximum $\Delta I/I$ attainable at the given V_m' in this fibre since in each case the pulse ended after the peak in $\Delta I/I$ had been attained. Pulses to voltages slightly positive to 0 mV seemed to have produced a maximal increase in transparency.

The transparency increase which we have studied may originate from either SR or myofilament changes preceding and related to mechanical activity. It does not seem to be a movement artefact, however, because pulses causing no detectable movement can produce transparency increases, and pulses which cause movement also produce a later component of decreased transparency which coincides in time with the movement (our unpublished observation). If the transparency increase is due to myofilament changes, the similarity of its time course to that of latency relaxation would support the hypothesis that latency relaxation also originates in the myofilaments[21] and not in the SR. Independently of the origin of the ΔI signals, the manner in which $d(\Delta I/I)/dt_{max}$ and peak $\Delta I/I$ increase and $L_{\Delta I}$ decreases with increasing depolarisation seems generally consistent with the voltage dependence of membrane charge movement.

The transparency increase time courses reported here resemble the time courses of fluorescence changes seen in intact

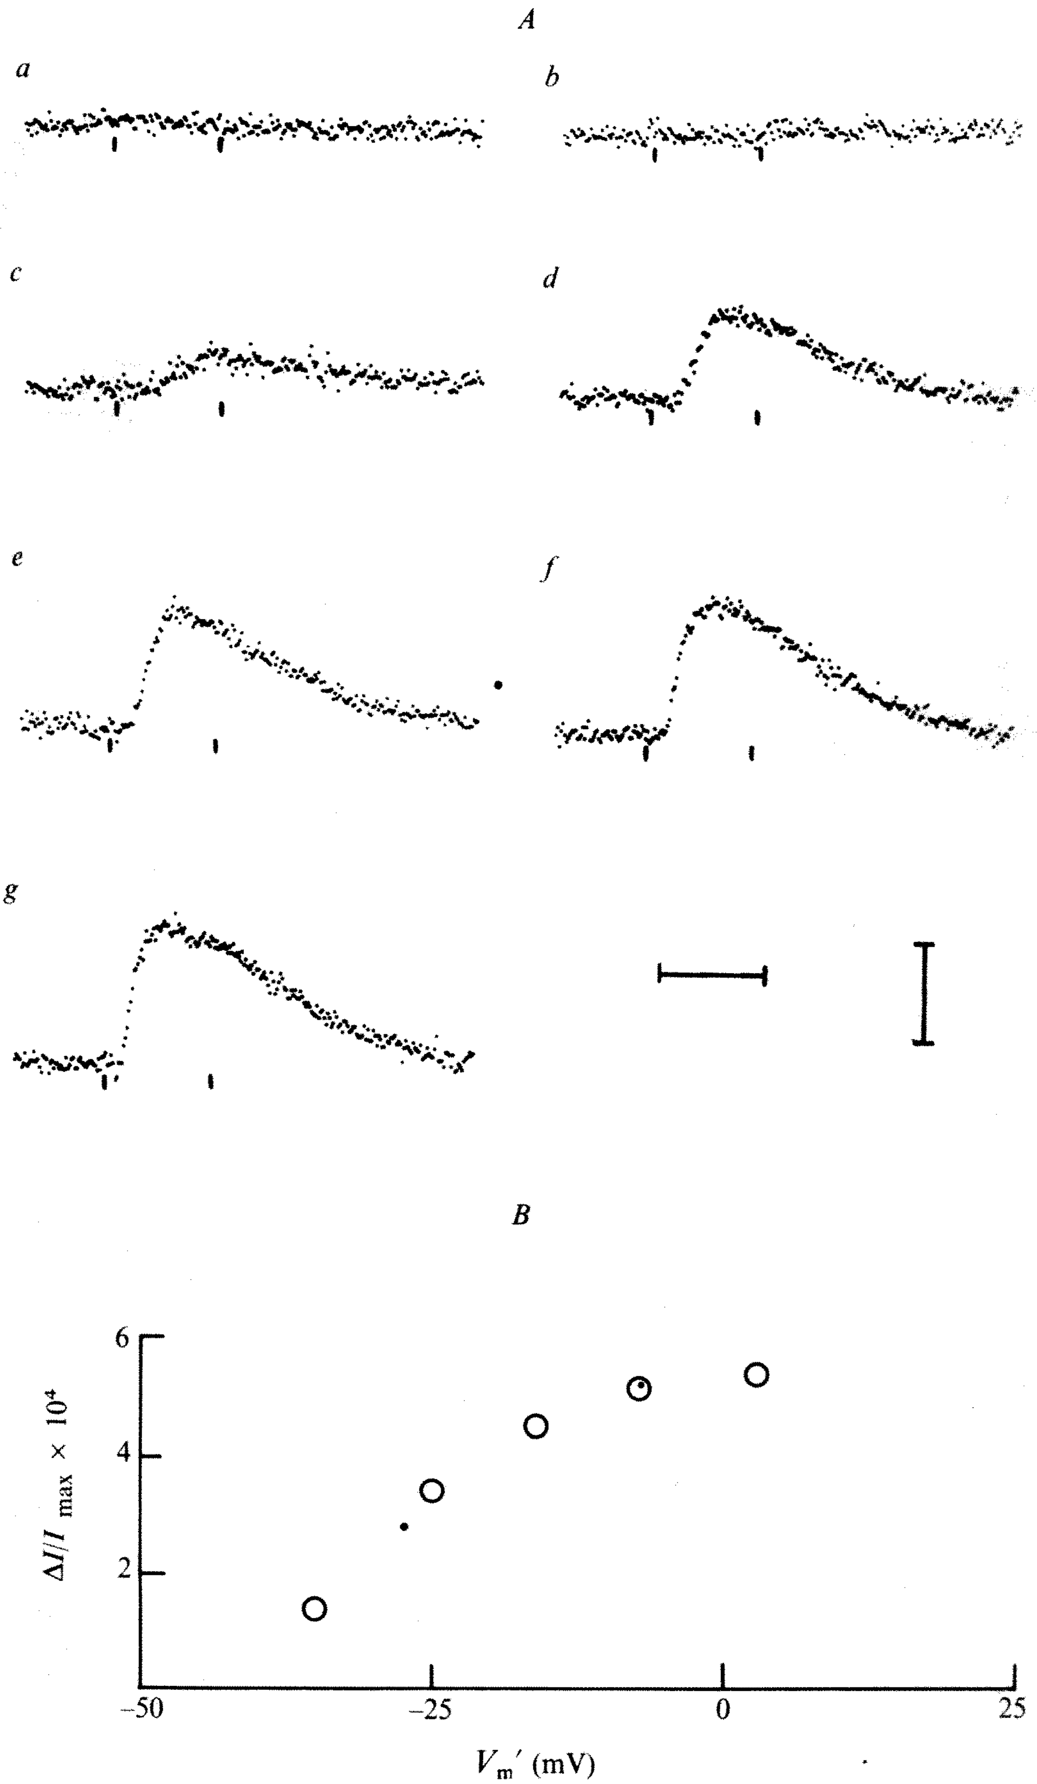

Fig. 3 Effect of pulse amplitude on the transparency increase. *A*, $\Delta I/I$ records for 60-ms pulses to the following V_m' values (mV): *a*, −165; *b*, −44; *c*, −35 *d*, −25; *e*, −16; *f*, −7; *g*, +3. Each record represents a single trace, without signal averaging. The horizontal calibration bar represents 60 ms, vertical 4×10^{-4}. *B*, Maximum $\Delta I/I$ as a function of membrane potential during the pulse for the records in (*A*). The closed end pool contained Ringer's solution (115 mM NaCl, 2.5 mM KCl, 1.8 mM $CaCl_2$, 1 mM Tris-maleate buffer) with TTX at 10^{-7} g ml^{-1}. The open end solution was identical to that in Figs 1 and 2 except that K glutamate (120 mM) was used in place of Cs glutamate (applied 65 min before the start of this run). $S = 2.69$ µm, $l_c = 500$ µm, $d = 84$ µm. Fibre 64, 3.9 °C.

muscles stained with a penetrating membrane potential-sensitive fluorescent dye and depolarised by current steps applied through fluid electrodes[22], although exact comparison is not possible because of differences in experimental conditions. Since intact single muscle fibres exposed to fluorescent dyes exhibit fluorescence and birefringence changes having similar time courses in response to action potentials[23], it seems likely that the fluorescence changes observed using penetrating dyes[22,23], the second component birefringence change[24] and the transparency increase reported here may all monitor the same events.

This work was supported by grants from the Muscular Dystrophy Association and the NIH. LK was a Muscular Dystrophy Association post-doctoral fellow. We thank Dr A. Peres for assistance with optical apparatus, Dr P. W. Davies for suggesting the use of glutamate as internal anion, Dr S. M. Baylor for a computer program, Mr. J. Young for the computer interface, Mr G. Harris for mechanical components and Professors E. Varga and P. Horowicz for cooperation.

Transfer of virulence *in vivo* and *in vitro* in *Agrobacterium*

TRANSFER of virulence from a pathogenic to a non-pathogenic strain of *Agrobacterium* has been reported to occur *in vivo*[1,2] and is due to the transfer of a plasmid which codes for virulence[3,4]. In the experimental conditions described, virulence transfer can be detected only after several weeks. The reason for this delay is not clear. The most likely explanations are (1) that infrequent transfer occurs long before it can be detected, detection being dependent on a subsequent increase in the ratio of converted to unconverted recipients or (2) that conditions suitable for virulence transfer occur only after donor and recipient have been in contact for several weeks. The main difficulty in distinguishing between these two alternatives is technical. When pathogenicity testing is used to detect virulence transfer, low frequency transfer is impossible to detect unless thousands of inoculations are made at each assessment. It is known, however, that the virulence plasmid codes for characters other than virulence[5–7]. One of these is utilisation of octopine and, as Kerr[8] has pointed out, this could be used instead of pathogenicity testing to detect plasmid transfer. This communication describes both *in vivo* and *in vitro* transfer of virulence using octopine utilisation to detect plasmid transfer.

An experiment was designed to try to detect low frequency transfer of virulence *in vivo*. Strain NCPPB 1001 was used as a donor; it is pathogenic and utilises octopine but is sensitive to rifampicin (25 μg ml^{-1}) and to streptomycin (500 μg ml^{-1}). Double mutation to antibiotic resistance occurs at a frequency of less than 2×10^{-10}. Strain K57 *rif–r str–r* was used as a recipient; it is non-pathogenic, unable to utilise octopine but is resistant to rifampicin and streptomycin. Suspensions of donor and recipient from 48-h cultures on yeast mannitol agar were prepared and mixed in the ratio of 10:1. There were 6×10^8 donor cells per ml. Separate suspensions of donor and recipient were also prepared. These three suspensions were used separately to inoculate tomato seedlings using 15 replicates per treatment. Each week for 5 weeks, three plants from each treatment were removed, the inoculated tissue cut out and macerated separately in 10 ml of sterile distilled water. The macerate (0.1 ml), both undiluted and diluted 10^{-3}, was transferred to agar plates and spread with an L-shaped glass rod. The basal medium contained, per l of water: K_2HPO_4, 10.5 g; KH_2PO_4, 4.5 g; $MgSO_4.7H_2O$, 0.2 g; $CaCl_2$, 10 mg; $FeSO_4$, 5 mg; $MnCl_2$, 2 mg; and agar (separately sterilised), 20 g. Separately sterilised octopine, 2 g; streptomycin, 0.5 g; actidione, 0.25 g and rifampicin, 25 mg per l were added just before the plates were poured. Actidione was added to prevent fungal contamination. Plasmid transconjugants which combine octopine utilisation of the donor and antibiotic resistance of the recipient grow well on this medium and can easily be distinguished from the 'ghost' colonies of the unconverted recipient. The donor strain is eliminated because it is sensitive to the antibiotics streptomycin and rifampicin. No transconjugant was detected (frequency $<10^{-5}$) 1 or 2 weeks after inoculation. Transconjugants were detected after 3, 4 and 5 weeks at a frequency per recipient of 4.0×10^{-4}, 4.8×10^{-3} and 3.7×10^{-2} respectively. The increase in the frequency of transconjugants with time is significant ($P = 0.011$ by the Kruskal Wallis one-way analysis of variance on ranks).

These results support the hypothesis that infrequent plasmid transfer occurs followed by an increase in the ratio of converted to unconverted recipients. This might be explained by the presence of octopine in galls induced by strain NCPPB 1001 (ref. 7). Converted recipients can utilise octopine and this might give them a biological advantage over unconverted recipients and explain the increase with time in the ratio of these two forms. If correct, perhaps transfer of virulence *in vitro* could be detected by exposing a mixture of donor and recipient to octopine.

We attempted to transfer virulence *in vitro*. Suspensions of donor and recipient were prepared as in the previous experiment. The bacteria in suspension were then deposited on Millipore filters (pore size 0.22 μm) which were then placed on the surface of the basal medium to which octopine (2 g l^{-1}) and actidione (0.25 g l^{-1}) had been added. Two filters from each treatment (donor alone, recipient alone and a mixture of donor and recipient at a ratio of 10:1) were transferred separately after 1, 2, 4 and 7 d to 10 ml of sterile water, the bacteria suspended and plated on the selective medium containing antibiotics. The donor was eliminated: the recipient by itself gave only 'ghost' colonies. The mixture of donor and recipient yielded transconjugants at each assessment, their frequency being 1.4×10^{-2}, 1.9×10^{-2}, 7.1×10^{-2}, and 2.5×10^{-1} after 1, 2, 4 and 7 d, respectively. Again there was a significant increase in transconjugant frequency with time ($P < 0.025$).

If transconjugants are detected because they are favoured by the presence of octopine, removal of octopine should drastically reduce their frequency. An experiment was designed to test this. Bacteria were deposited on filters, as in the previous experiment, but the filters were placed on three different media: (1) basal medium plus octopine plus actidione, (2) basal medium plus actidione and (3) basal medium plus arginine (2 g l^{-1}) plus actidione. Both donor and recipient can utilise arginine as a source of both carbon and nitrogen, whereas octopine (N^2–(D–1–carboxyethyl)–L–arginine) can be utilised as growth substrate by the donor only. The filters were removed after 3 and 7 d, the bacteria suspended in water and plated on the selective medium. Transconjugants were detected only when donor and recipient were exposed to octopine, their frequency being

2.2×10^{-3} after 3 d and 2.5×10^{-1} after 7 d. When octopine was omitted or replaced with arginine, frequency of transconjugants was less than 5.0×10^{-8} after 3 d and less than 1.5×10^{-8} after 7 d. These results further support the hypothesis that transconjugants are favoured by the presence of octopine. A possible interpretation is that octopine promotes plasmid transfer.

The octopine-utilising strains A6, B6 and NCPPB 4 were also used as donors with strain K57 *rif-r str-r* as recipient. After 5 d exposure to octopine in the basal medium recombinants were obtained at a mean frequency of 7×10^{-2}. Presumably the plasmid from nopaline-utilising strains could also be transferred and detected *in vitro* if nopaline, instead of octopine, were added to the basal medium. Unfortunately, nopaline is not commercially available and this restricts its use. But mutants of nopaline strains, constitutive for nopaline metabolism, can be obtained by plating a large number of cells on a medium containing octopine as the sole source of carbon and nitrogen[9]; these mutants can utilise octopine as well as nopaline. Three such mutants of strains C-58, K14 and K24 were selected and used as donors with K57 *rif-r str-r* as recipient using the conditions described above for successful transfer of virulence *in vitro*. Transconjugants were obtained at a mean frequency of 2×10^{-4}. This result indicates that the mutation to constitutivity is borne on the plasmid.

There is still a large group of pathogenic agrobacteria which have to be considered. These are biotype 2 pathogens[10]. They can utilise both octopine and nopaline but only nopaline utilisation is coded for by the virulence plasmid[4-7]. It is therefore impossible to select constitutive mutants for nopaline utilisation by plating these strains on octopine. Nopaline metabolism, however, is inducible; after it has been induced, nopaline strains can degrade octopine[9]. This characteristic was used to obtain transfer of virulence *in vitro* using the biotype 2 pathogens TT 133 and K27 as donors and K57 *rif-r str-r* as recipient. The same procedure as above was adopted except that nopaline (10 μg ml^{-1}), extracted from gall tissue[7], was incorporated into both media, in addition to the other constituents. This level of nopaline was sufficient to induce octopine utilisation. Transconjugants at a mean frequency of 4×10^{-6} were obtained. Although this frequency is much lower than that obtained with other donor strains, it is too high to be explained by mutation of wild-type donors to antibiotic resistance. It seems that most pathogenic strains of *Agrobacterium* can be used as donors to transfer the virulence plasmid to an efficient recipient *in vitro*.

In all the experiments described here, presumed plasmid transfer was detected by selecting recombinants which utilised octopine. At every assessment, 20 recombinants and 20 unconverted recipients were subcultured, purified and tested for pathogenicity. All transconjugants were pathogenic; no unconverted recipient was pathogenic.

In vitro transfer of the virulence plasmid of *Agrobacterium* has been achieved recently by other workers who used the fertility plasmid RP4 to promote transfer[5,6], but this and the following communication[11] are the first reports of plasmid transfer *in vitro* using wild-type donors or their spontaneous mutants.

Ti plasmids of *Agrobacterium* as conjugative plasmids

THE relationship of the plant-oncogenic properties of *Agrobacterium tumefaciens* to the presence in these strains of large plasmids (the Ti plasmids) has now been convincingly demonstrated in several ways: oncogenic strains cured of the Ti plasmid lose their oncogenicity irreversibly[1-3]; transfer of Ti plasmids to non-oncogenic plasmidless strains confers oncogenicity to these strains[3-7]. The first method used to transfer plasmids was based on observations made by Kerr[8,9], who had developed a method for the transfer of oncogenicity before the association of oncogenicity with large plasmids was known. It was later demonstrated that this transfer of oncogenicity was due to the transfer of the Ti plasmid[3,4]. These observations suggested that in certain circumstances the Ti plasmids could behave as conjugative plasmids in promoting bacterial conjugation and plasmid transfer. This paper and its companion[10] describe experiments confirming that suggestion, making use of the fact that the capacity of *Agrobacterium* strains to utilise the unusual amino acids octopine (N^2-(D-1-carboxyethyl)-L-arginine) or nopaline N^2-(1, 3-dicarboxypropyl)-L-arginine) is coded for by Ti plasmid linked genes[3,5-7,11], and indicate that octopine and nopaline may act in inducing plasmid transfer.

Conjugation experiments were performed with donor and recipient bacteria grown on YEB medium in a shaking waterbath at 28 °C for 12 h. The cells were collected and resuspended in λ-buffer. A mixture of about 10^4 donors and 10^8 recipients was filtered on Millipore filters (pore size 0.45 μm, diameter 25 mm) and the filters were incubated for various periods on solid media consisting either of YEB or octopine or nopaline agar. Filters were then removed and the cells were suspended in λ buffer. After dilution in λ buffer the cells were plated on selective agar media. Filters containing donor or recipient bacteria alone were also prepared and treated similarly.

In a first cross strain ACH-5 (ref. 12) was used as a donor: it is oncogenic, contains a single plasmid 60.6 μm long, utilises octopine but not nopaline as its sole N source and induces tumours which contain octopine but not nopaline. As a recipient we used strain C58-C1, *rif-r, ery-r*. This is a heat cured, non-onconegic, plasmidless derivative of the oncogenic nopaline strain C58 (ref. 4). It was made resistant to 100 μg ml^{-1} rifampicin and 150 μg ml^{-1} erythromycin by two separate spontaneous mutations. To eliminate the donor cells and select for octopine-utilising recipients the mixture from the filters was plated on the basal medium supplemented with 0.5% glucose, 100 μg ml^{-1} octopine, 100 μg ml^{-1} rifampicin and 150 μg ml^{-1} erythromycin. On this medium the donor cells alone did not form any colonies, whereas the recipient strain formed only 'ghost' colonies. When the filters with the mixture were incubated for 1, 4 and 7 d on YEB agar, no octopine-utilising recipients were detected, indicating that the frequency of such transconjugants was less than 1×10^{-8} in these circumstances. When the filters containing the same mixture were incubated for the same lengths of time on octopine (2 mg ml^{-1}) agar, octopine-utilising colonies were detected with frequencies per recipient bacterium of 5×10^{-4}, 1.5×10^{-3} and 6.4×10^{-3}, respectively. The results summarised in Table 1 demonstrate that all

Resistance to antibiotics was scored as growth on YEB medium containing the antibiotics. Sensitivity to the virulent phages of a typing set was scored as lysis or absence of lysis after spotting of about 10^7 phages ml⁻¹ on lawns of the tested strains in soft agar. The ability to utilise octopine or nopaline was scored by testing whether the tested strains could or could not form full colonies on octopine or nopaline agar. Exclusion of phage AP1 was scored as the absence of plaque formation by this phage on lawns of the tested strains. Oncogenicity was tested on sterile pea seedlings[16], Plasmids were isolated as supercoiled circular DNA molecules by ultracentrifugation[14] and their contour lengths were measured by electron microscopy[17]. Agrocin 84 sensitivity was assayed as described previously[18]. Restriction endonuclease digest fingerprints were obtained after digestion of the purified plasmid DNA with the *Eco*RI endonuclease[19] and separation of the fragments on Agarose slab gels[20]. YEB medium: 0.5% Bacto-Beef extract, 0.1% Bacto-Yeast extract, 0.5% peptone, 0.5% sucrose and 0.002 M $MgSO_4$, *p*H adjusted to 7.2. λ buffer: 0.001 M Tris-hydrochloride (*p*H 7.2), 0.01 M $MgSO_4$. Basal medium: 0.05 M K_2HPO_4, 0.05 M KH_2PO_4, 0.05 M $MgSO_4 . 7H_2O$, 2.5 × 10^{-4} M NaCl, 10^{-4} M $CaCl_2$ adjusted to *p*H 7.2 and 1.5% (w/v) agar (Difco). Octopine and nopaline agar: 2 mg ml⁻¹ of sterile octopine or nopaline separately sterilised and added to the basal medium before pouring plates.

the selected transconjugant colonies (C58-C1 (Ti-ACH5)) were indeed recipient cells and had acquired the Ti plasmid from the donor strain.

In a second cross, strain B6S3 (ref. 13) was used as a donor; this strain is oncogenic, contains two different plasmids with respective contour lengths of 59.0 ± 1.2 μm and 53.8 ± 0.9 μm. It utilises octopine but not nopaline as sole N source and tumours induced with this strain contain octopine but not nopaline. As a recipient we again used strain C58-C1 *rif-r, ery-r*. The cross was performed as described above. When the filters with the mixture of donors and recipients were incubated for 1, 4 and 7 d on the octopine (2 mg ml⁻¹) medium, octopine-utilising recipients were detected with frequencies of 2×10^{-6}, 1×10^{-4} and 2×10^{-4} respectively. As can be seen from Table 1 (C58-C1 (Ti-B6S3)) and Fig. 1, these transconjugant strains have acquired only one of the two plasmids present in the B6S3 donor strain. Indeed, the *Eco*RI digest fingerprint of the plasmid DNA in these transconjugant strains is identical to the *Eco*RI fingerprint of the plasmid DNAs from strain ACH-5 and from the transconjugants obtained with ACH-5 as donor. Furthermore, the fingerprint of the plasmid DNA from strain B6S3 contains as well as all the bands found in the plasmid of strain ACH-5 a number of extra bands. These extra bands are supposed to be derived from the second, so called x-plasmid in strain B6S3. Strain B6S3 must therefore harbour two different plasmids, only one of which is necessary to convey oncogenicity and the capacity to catabolise octopine to a recipient *Agrobacterium*. This plasmid has an identical *Eco*RI fingerprint to the single plasmid present in strain ACH-5.

When the filters with the mixture of donors and recipients were incubated for 1 and 7 d on YEB agar, octopine-utilising recipients were detected with frequencies of 2×10^{-4} and 3.8×10^{-6}, respectively. These colonies have been called C58-Cl *oct-u*(B6S3). As can be seen from Table 1, these are recipient strains that can grow on octopine and not on nopaline but they do not contain closed circular plasmid DNA nor can they induce tumours. Various methods[14] were used to look for plasmid DNA, and also for plasmids either smaller or larger than the donor plasmid; none was found. When used as donors in similar crosses with C58-Cl recipients resistant to 200 μg ml⁻¹ streptomycin and 100 μg ml⁻¹ spectinomycin these colonies were unable to transfer the octopine utilisation marker. It

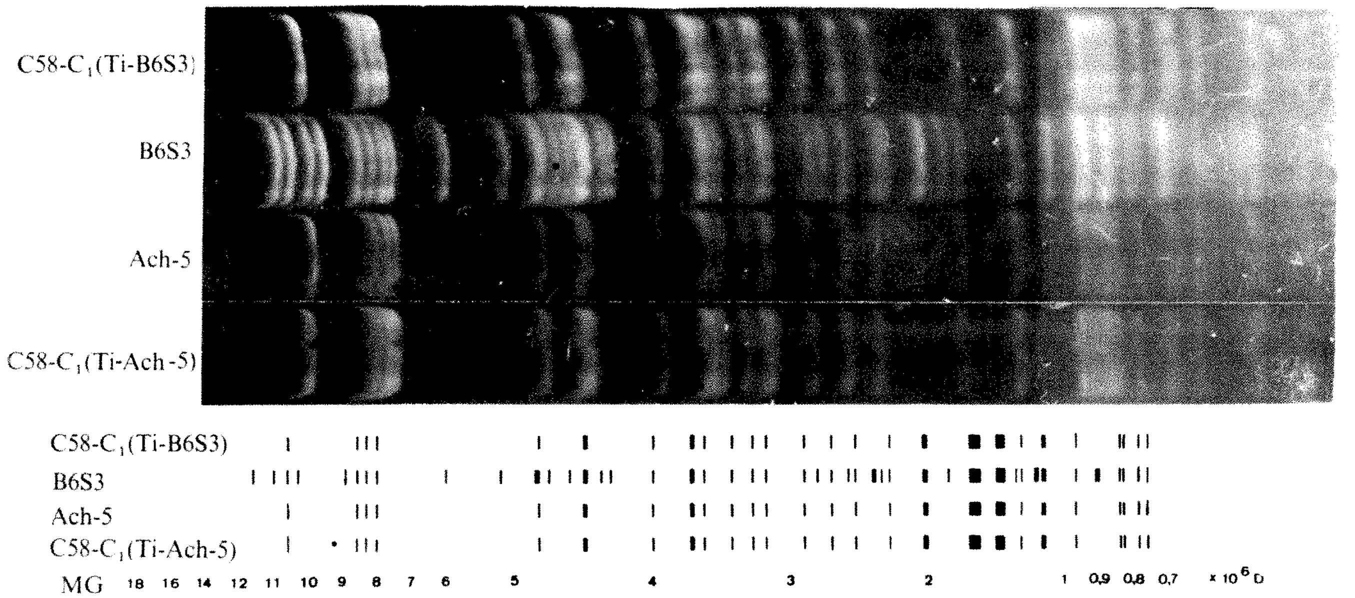

Fig. 1 Fingerprints of *Eco*RI digests of DNA from plasmids of donor and conjugant strains. The *Eco*RI enzyme was prepared according to Greene *et al.*[19]. Plasmid DNA of the indicated *A. tumefaciens* strains was purified on CsCl–ethidium bromide gradients, digested with *Eco*RI endonuclease and subjected to electrophoresis on 0.8% Agarose for 15 h at 2 V cm⁻¹ in the presence of ethidium bromide. The size of each fragment class was determined using *Eco*RI-treated λ DNA as the standard.

seems therefore that these strains have not acquired the whole Ti plasmid from the donor strain. The fact that such non-oncogenic, plasmidless octopine-utilising exconjugants could only be observed with strain B6S3 and not with strain ACH-5 as donor, could indicate that we are dealing here with a phenomenon similar to transduction. Indeed strain B6S3 is known to be lysogenic[13,15], whereas strain ACH-5 is not lysogenic. The main interest of these strains is that they indicate that the Ti plasmid genes that control octopine metabolism could be integrated into the chromosome of *Agrobacterium*.

A third cross was designed to test whether plasmids from nopaline-utilising strains also showed conjugative activity. As a donor strain C58 was used. This strain can degrade nopaline but not octopine and induces tumours that contain nopaline. It harbours a single plasmid 61.8 μm long. As a recipient we used again the C58-Cl *rif-r ery-r* strain. As in the first cross, nopaline-utilising recipients were observed when the filters were incubated on a medium containing nopaline but not when the filters were incubated on YEB agar. The frequency of occurrence of transconjugants was much lower, however, compared with those observed with octopine-utilising donors. Indeed, incubation of the filters on nopaline-containing medium for 1, 4 and 7 d yielded transconjugants with frequencies of 10^{-7}, 10^{-5} and 10^{-4} respectively. As can be seen from Table 1, these transconjugants are oncogenic and have acquired the complete Ti plasmid from the donor strain. The observations described above confirm and extend those described in the companion paper by Kerr *et al.*[10], and demonstrate that the Ti plasmids which determine oncogenicity in *Agrobacterium* strains are conjugative plasmids since transfer of intact Ti plasmids was observed by *in vitro* conjugation experiments. The possibility that the presence of the unusual, crown-gall specific, amino acids octopine and nopaline derepresses the genes involved in this transfer, must be considered seriously and would certainly explain Kerr's observations of *in planta* transfers[8,9].

An alternative explanation would be that the incubation on octopine agar in fact selects for rare exconjugants, increasing their number per recipient. This explanation, however, is unlikely, first, because rare exconjugants were not observed on media lacking octopine or nopaline (level of resolution better than 10^{-8}) and second, the doubling time of octopine-utilising exconjugants incubated on filters on octopine agar is about 3 h. The number of observed exconjugants after 24-h incubation of the filters on octopine agar (see also ref. 10) cannot therefore be explained by enrichment alone. The question therefore arises of whether a mechanism of induced plasmid transfer is involved in the transfer of plasmid-borne genes from the infecting bacteria to the plant cells.

We thank Drs A. Kerr and J. Tempé for discussion of the suggestion that octopine or nopaline is essential for Ti plasmid transfer. This work was supported by grants from the Kankerfonds van de ASLK and from the Fonds voor Kollektief Fundamental Onderzoek to J.S. and M.V.M. M.H. is a Navorsingsstagiair of the National Fonds voor Wetenschappelijk Onderzoek. A.D.P. is indebted to the Belgian IWONL for a fellowship.

Tissue enrichments and protein turnover measured with ^{15}N-glycine

VALUES for total body protein turnover (TBPT) measured in man using ^{15}N-glycine[1-3] are comparable with those obtained using ^{14}C-amino acids[4]. Because ^{14}C is radioactive it is of limited clinical use. The stable isotope ^{15}N has a potentially wider application, although its use has been restricted for technical and conceptual reasons[4]. When a tracer labelled with ^{15}N is used to measure TBPT the results are based on the enrichment of urea. This assumes that both urea and newly synthesised protein are derived from the same precursor N pool. Because urea is synthesised in the liver the enrichment of the precursor N pool for protein synthesis in the liver may determine the enrichment of urea. Thus the measurement of TBPT using ^{15}N-glycine may be weighted heavily by the rate of hepatic protein turnover[4,5]. Similar problems may arise when urinary ammonia is the end product (M.H.N.G. and J. C. Waterlow, to be published). The extent of labelling of the precursor N pool is affected by at least two factors. First, after infusion of a ^{14}C-amino acid, its specific radioactivity at plateau is lower in tissues than in plasma[6-8], due to dilution with unlabelled amino acid derived from intracellular protein breakdown. This is termed internal recycling and also applies when ^{15}N-glycine is infused. Second, when ^{15}N-glycine is infused, extensive rapid intracellular transamination occurs especially in liver and kidney, so that the ^{15}N is distributed to other amino acids, which will have a higher enrichment within the cell than in the plasma. Thus, depending on the balance between internal recycling and transamination, the intracellular enrichment of amino acids may be greater or less than the plasma enrichment. To investigate this problem we have infused ^{15}N-glycine, and measured the enrichment of α-amino-N urea-N and

Table 1 Enrichments of N compounds in rat rissue after constant infusion of ^{15}N-glycine

Tissue	α Amino-N	Urea-N (atoms % excess)	Ammonia-N
Whole blood	0.172 ± 0.017	0.118 ± 0.006	0.073 ± 0.011
Liver	0.296 ± 0.019	0.132 ± 0.004	0.134 ± 0.004

ammonia-N in various tissues. The TBPT calculated from the liver urea-N enrichment gives a value which we consider representative and which agrees with published values based on ^{14}C.

Male albino rats weighing about 390 g were infused through a tail vein with a solution of ^{15}N-glycine (97 atoms % excess, Prochem BOC, London) at a rate of 0.1239 mg ^{15}N per h for 6 h. The rats were then decapitated and whole blood was collected in cold 10% (w/v) trichloroacetic acid (TCA). The liver, kidneys, quadriceps muscle and brain were homogenised in cold TCA. After centrifugation the supernatants were extracted twice with ether and alkalinised with sodium hydroxide in a Leurquin apparatus[10]; the ammonia produced was collected in 0.1 N sulphuric acid by aeration. Urea in the NH_3-free extracts was converted to ammonia by urease (Type III Sigma) at *p*H 5.6 and collected by aeration. Amino-N was extracted from the ammonia-free and urea-free extract by the method of McFadyn[11]. N-enrichment was measured in a double collector mass spectrometer (602 VG Micromass) after reaction of the ammonium sulphate with sodium hypobromite in a vacuum. TBPT was calculated according to the method of Picou and Taylor-Roberts[1]. Significance was tested by the paired *t*-test.

Table 1 shows the enrichment of the three nitrogen compounds in the various tissues. The hepatic α-amino-N enrichment was nearly twice that in whole blood. The enrichment in renal α amino-N was significantly less than that in liver and greater than that in whole blood. This indicates that transamination was extensive in these organs and was a more important determinant of α-amino-N enrichment than internal recycling. The enrichment of α-amino-N was very much lower in brain than in other tissues studied. This is possibly due to a low rate of uptake of glycine by the brain with extensive internal recyclng. Enrichments of α amino-N in muscle and whole blood were the same. There was no significant difference between urea enrichments in liver and kidney. Urea is first synthesised in the liver and then mixes with urea in other tissue pools, so urea samples isolated simultaneously from liver and kidney are originally synthesised at two different times. Since hepatic and renal urea-N have the same enrichment an isotopic steady state must have been achieved between these two pools. The lower enrichment of urea-N in muscle suggests that the muscle pool has not yet reached isotopic equilibrium with the liver pool at 6 h. Unequal enrichment of plasma and erythrocyte urea-N may explain why the enrichment in whole blood was lower than that in the liver and kidney.

There was no significant difference between liver and kidney ammonia-N enrichment or between ammonia-N and urea-N enrichment in these two tissues. Therefore TBPT can be calculated for each rat from the hepatic urea-N and renal ammonia-N data. The results show that there is no significant difference between values for TBPT based on the two excretory products. Furthermore, these results agree closely with those obtained after infusion with ^{14}C-labelled amino acids (Table 2). This substantiates the validity of both methods and suggests that the highly enriched α amino-N in liver, which was not reflected in hepatic urea-N values, does not unduly influence TBPT results calculated from urea-N data.

The total α amino-N of the body does not form a single homogeneous pool. After an infusion of ^{15}N-glycine the ^{15}N label will be distributed to amino acids in a complex way depending on the size of the pools, their varied metabolism and differing turnover rates. Thus it is difficult to interpret or predict the enrichment of total α amino-N in any tissue. Nevertheless, the extremely high enrichment of hepatic α amino-N and the less highly enriched α amino-N in muscle, kidney and blood raises the question of the origin of urea-N. The data obtained show that none of the tissue pools of α amino-N can be identified as the single precursor for urea synthesis. The method of measuring TBPT, however, does not make any assumptions about the precursor enrichment for either urea or protein and does not require this enrichment to be measured. The method requires only that the nitrogen originating from glycine contributes to both protein and urea in the same ratio as the total α amino-N contributes to protein or urea. This assumption is supported by the close agreement between results obtained by ^{14}C and ^{15}N-glycine measurements, and between ^{15}N-glycine and ^{15}N-egg protein measurements[2].

If urinary ammonia-N enrichment is shown to be the same as renal ammonia-N enrichment, then urinary ammonia-N enrichment could be used to estimate TBPT in man. This would shorten the time required to reach plateau considerably and also simplify sample analysis.

We thank the Wellcome Trust for support, Mrs L. Charley for technical assistance, Professor D. Picou for comments and the MRC for the mass spectrometer.

reviews

Functional biology of the mollusca

R. D. Purchon

Living Marine Molluscs. By C. M. Yonge and T. E. Thompson. Pp. 288. (Collins: London, 1976.) £6.00.

BEAUTIFULLY illustrated with sixteen plates (eight in colour) and with 162 informative line diagrams, this inexpensive book fills a major gap in libraries. It will be invaluable to university students; malacologists and palaeontologists professionally concerned with understanding functional morphology and the principles of molluscan evolution; conchologists; and enthusiastic amateur shell collectors.

The text, arranged in eighteen chapters all of a convenient size, is an easily understood narrative reviewing the functional biology and evolution of all the more important molluscan taxa, on a global scale. There is also a wealth of minor detail regarding the species of British marine mollusca.

After a brief introduction, chapter 1 is devoted to an historical review of molluscan studies to the present day. It remains for the reviewer to emphasise that the past half century has seen an explosive growth in the study of the functional biology of molluscs, to which no-one has contributed as extensively as has the senior author of this book.

Chapters 2, 3 and 4 deal with basic features of molluscan organisation and classification, and with the chitons which, with their eight overlapping shell plates and muscular foot, are adapted for movement over irregular hard surfaces. Chapters 5–9 concern the Prosobranchia, dealing successively with "The first gastropods"; "Limpets and top shells"; "Mesogastropods" (which require two chapters); and with "Neogastropods". Here is a wealth of well-explained functional biology and ecological detail. These chapters portray the evolutionary plasticity of the Prosobranchia, and the resourcefulness of the Mesogastropoda in particular.

The next two chapters concern "Opisthobranch sea snails", and "Sea slugs". Reduction of the shell here leads to alternative chemical and biological protection against predators. After lightening, or loss, of the shell several lineages have independently acquired the ability to swim, the better to escape from their enemies. We can appreciate something of the grace and beauty of these delightful animals from the excellent line and stipple drawings here.

Title page of first book devoted entirely to molluscs

By Filippo Buonanni (Rome, 1681)

Five and a half chapters are assigned to the Bivalvia, beginning with an account of the origin of primitive bivalves from a generalised molluscan ancestry, and covering the general organisation and mode of growth of bivalves. In "Evolution and adaptation of bivalves" we see a transition from deposit-feeding protobranchs to suspension-feeding lamellibranchs, with elaboration of ctenidial ciliary sorting mechanisms. These lamellibranchs exploit every possible aquatic habitat and mode of life, as is shown in chapters 14–16: byssal attachment to hard surfaces, with the adoption of heteromyarian or monomyarian form; swimming; shallow or deep burrowing in sediment, with a return to deposit feeding in the Tellinacea; commensalism; and boring in rock and timber by pholads and shipworms.

Chapter 17, "Anomalous bivalves and scaphopods", deals first with the Anomalodesmata, which lack hinge teeth and in some of which there is a lithodesma. The Verticordiidae indicate a transition from filter feeding to a scavenging or carnivorous habit, as also in the related Septibranchia. This was a necessary pre-adaptation towards life in abyssal sediments. Mention is made of the Watering Can Shell, *Penicillus*, which calls for a special effort by functional morphologists, who happen to be well-placed in the Indo–Pacific Region, to elucidate the general biology and growth processes of early stages of this puzzling bivalve.

The Scaphopoda are shown to be either microphagous (*Dentalium conspicuum*), or carnivorous (*D. entalis*).

Chapter 18, "Cuttlefish, squid and octopus", relates the mantle cavity of these actively swimming molluscs to those of other molluscan classes. Attention is given to newly gained knowledge of the biology of the Pearly Nautilus, which moves slowly in moderately deep waters. Transition from ciliary to muscular ventilation of the mantle cavity permitted fast swimming, and required a high metabolic rate. This permitted the exploitation by cephalopods of waters from just above the seabed to the surface of the sea. In such pelagic hunters the statocysts, eyes, and brain are well developed, as also the tactile sense in octopods, which have secondarily returned to the seabed. A brief account is given of learning and memory in the octopus, and how knowledge of this has been gained by simple experiments.

The substance of the book is surveyed in an Epilogue. The mollusca arose with the contrasted advantages accruing from a bilaterally symmetrical body and a radially symmetrical protective shell; these, with the versatile radular apparatus, provided a basis for diversification to suit widely different habitats and modes of life. By acquisition of neutral buoyancy and muscular jet propulsion the cephalopoda outstripped all other invertebrates and now compete on equal terms with the marine (but not freshwater) Teleostei.

Erato voluta (Fig. 34, p86), until recently regarded as a cypraeid, should be assigned to the family Eratoidae together with the genus *Trivia*. *Xylophaga* (p218) is reported as being unable to swallow fragments of the wood through which it bores, but this is not so; it has a moderately large caecum which is normally packed with wood fragments.

There is a useful list of recommended books for further reading, and there is a thorough index. Typographical errors are rare. □

R. D. Purchon is Professor of Zoology at Chelsea College, University of London, UK.

Chromosome studies in cancer cells

Cytogenetic Aspects of Malignant Transformation. (Experimental Biology and Medicine: Monographs on Interdisciplinary Topics, Vol. 6.) By N. B. Atkin. Pp. iii+168. (S. Karger: Basel, London and New York, 1976.) SFr/DM74.

THIS book is a critical review of the present state of chromosome studies in cancer cells by an author who has worked on these problems for very many years. Essential concepts relating to chromosome changes in malignant transformation are old and represent views which are now 'rediscovered' with more precise tools. In his evaluation of new evidence, the author draws on substantial material of his own, and the book therefore gains a particular authority. Such studies are *central* to the cancer problem, more so than many erudite and sophisticated lines of research, intellectually more favoured by grant-giving authorities. The new evidence clearly bears out that chromosome changes are nonrandom, clustering on particular chromosomes; but many patterns are not yet discernible at histological and biochemical level, although such distinction must be present.

Some expected conclusions are not drawn by the author. The monoclonal nature of neoplasms sets a low limit to the number of cells capable of forming a clone in a tissue, the target cells for transformation. Other general principles seem to emerge. With a primitive stem cell transformation comes tumour-specific numerical chromosome imbalance, with a more derived stem cell transformation, single gene effects, that is, balanced translocations, and low numerical variation.

It may be that transformation is a process by which a clonogenic cell takes a retrogressive step in its phylogenetic pathway, thereby gaining a proliferative advantage over other cells. Further transformation often occurs within the clone. This study of 'embryogenesis in reverse' represents a formidable task, not likely to be quickly solved unless supporting disciplines work with these ideas in mind.

Membrane separation

Membrane Separation Processes. Edited by P. Meares. Pp. ix+600. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl. 250; $96.25.

MEMBRANE separation processes, despite a long history, can only recently be said to have reached a stage of development where large scale practical applications are possible. At the same time, as a result of very many basic researches, the physics and chemistry of membrane processes have been clarified and a general formulation in terms of irreversible thermodynamics has been developed. It is therefore timely that a monograph on the theory and practice of membrane science should have appeared, in which actual and potential applications have been particularly emphasised.

The book is a cooperative effort to which well-known specialists in various technically significant areas have contributed. Such texts have both advantages and disadvantages—expertise in every topic covered in some, but some omissions, overlap and unevenness in others. This presentation, under the editorship of Professor Meares, has had considerable success in minimising the disadvantages, and the contributors have ensured a high standard in the areas chosen.

The coverage can best be seen from the following chapter headings: the physical chemistry of transport and separation by membranes; liquid permeation through polymers; ultrafiltration; reverse osmosis in desalination; hollow fibres in reverse osmosis, dialysis and ultrafiltration; electrodialysis; piezodialysis; gas separation by selective permeation; hydrocarbon separation by liquid membrane processes; enzyme membranes; separators and membranes in electrochemical power sources; ion-selective membrane electrodes; treatment of aqueous wastes and foods by membrane processes; and biochemical applications of membranes.

The book is well produced despite some printing errors, such as a mix-up in the middle of p201 and a misspelling of "repetitive" in the diagram on p94 and elsewhere. The contributors and editor are to be congratulated on a useful and comprehensive task well completed. The price of this book has unfortunately been set so high that many potential purchasers may be deterred and some libraries will also need to consider whether their funds permit them to buy it.

Cyano complexes of transition metals

The Chemistry of Cyano Complexes of the Transition Metals. (Organometallic Chemistry: A Series of Monographs.) By A. G. Sharpe. Pp. xi+402. (Academic: London and New York, 1976.) £10.40; $26.25.

THE publication of a comprehensive and up-to-date review of the cyano complexes of the transition metals is particularly timely. There is currently a rapidly growing interest in a whole new range of the related organic isocyano metal complexes, and it is appropriate that this volume indeed appears as a member of the excellent series of monographs on organometallic chemistry, edited by Maitlis, Stone and West.

Although the study of the metal cyano complexes goes back to the early eighteenth century, they continue to be a source of interest and research. Further, they present some of the most elegant examples for the teaching of the main principles of the structure and theory of the coordination complexes of the transition metals.

An introductory chapter deals with the general aspects of the cyanide ion along with the relevant structural, spectroscopic, thermodynamic and kinetic background. The rest of the book deals essentially with factual knowledge of the cyano complexes by individual groups in the Periodic Table, from the lanthanides to the copper and zinc groups.

The past fifteen years have seen a considerable growth in the literature of these complexes, and the author has surveyed this very extensive area with remarkable thoroughness. He does not, however, hesitate to draw attention to scientific results that he regards as either inconsistent or possibly unreliable.

The book contains over 1,800 references to the chemical and physical literature, but only a very brief subject index. Each chapter is, however, so consistently organised that I found little difficulty in finding what information, if any, was available about any particular cyano metal complex system.

Most organometallic and inorganic chemists will want this book on their shelves, not only as a valuable source of reference, but also as a pointer to many intriguing potential research areas.

WILEY
INTERSCIENCE

ESSAYS IN NEUROCHEMISTRY AND NEUROPHARMACOLOGY Vol. 1

edited by **M.B.H. Youdim,** *MRC Clinical Pharmacology Unit, Radcliffe Infirmary, Oxford;* **W. Lovenberg,** *National Heart and Lung Institute, Bethesda, Maryland;* **J. R. Lagnado,** *Department of Biochemistry, Bedford College, University of London,* and **D. F. Sharman,** *Institute of Animal Physiology, Babraham, Cambridge.*

These essays have been written for postgraduate students and researchers who wish to familiarize themselves with current specific problems in neurochemistry and neuropharmacology. The level of presentation is such that the essays can be understood by advanced undergraduate students in biochemsitry, physiology and pharmacology. Each contribution is readable as an essay rather than as a review, and provides factual information to support or reject current theories. In summarizing, the authors state their own views on the trends for future research.

0471 99424 3 208 pages Jan. 1977
£19.90/$19.50

ADVANCES IN MODERN TOXICOLOGY Vol. 1, Part 1: New Concepts in Safety Evaluation.

edited by **M. A. Mehlman,** *National Institute of Health;* **R. Shapiro,** *National Institute of Environmental Health Sciences,* and **H. Blumenthal,** *Food and Drug Administration.*

Explores new and dynamic approaches to public health and safety. Discusses the effects of chemical interactions, methodological and conceptual approaches to safety evaluation, the use of pharmacokinetics in assessing potential chemical hazards, metabolism and biochemical toxicity, and transplacental toxicity.

0470 98919 X 476 pages December 1976 £18.90/$31.00

Published by Hemisphere Publishing Co., and distributed by John Wiley & Sons Ltd.

THEORY AND APPLICATIONS OF MOLECULAR PARAMAGNETISM

edited by **E. A. Bordreaux,** *University of New Orleans,* and **L. N. Mulay,** *Pennsylvania State University.*

A thorough and lucid treatment of the basic theory of paramagnetic phenomena from both the classical and quantum mechanical approach. For each class of compounds, appropriate details of descriptive and mathematical theory are given before proceeding to applications.

0471 09106 5 522 pages July 1976 £26.50/$44.75

ELECTRON SPIN DOUBLE RESONANCE SPECTROSCOPY

by **L. Kevan,** *Wayne State University,* and **L. D. Kispert,** *University of Alabama.*

Explains, at an introductory level, the basis behind electron nuclear double resonance (ENDOR) and electron-electron double resonance (ELDOR) spectroscopy and its application to organic and biological free radicals.

0471 47340 5 438 pages July 1976 £19.10/$32.25

TOPICS IN ENZYME AND FERMENTATION BIOTECHNOLOGY

Vol. 1

edited by **Alan Wiseman,** *Department of Biochemistry, University of Surrey.*

This volume surveys the important areas of current interest and development in the manufacture and use of enzymes and other proteins by fermentation procedures using micro-organisms. This publication is the foundation volume in a new "open-ended" series which aims to provide a balanced and up-to-date presentation of the new information available on specialist topics in enzyme biotechnology and fermentation biotechnology, with particular emphasis on the interdisciplinary nature of enzymes and their production by fermentation processes.

085312 051 X 192 pages Jan. 1977
£10.50/$19.95

PEPTIDE SYNTHESIS 2nd Ed.

by **M. Bodanszky,** *Case Western Reserve University;* **Y. S. Klausner,** *Hebrew University of Jerusalem,* and **M. A. Ondetti,** *Squibb Institute for Medical Research.*

A critical study of the subject designed to help scientists who have some training in organic chemistry, to understand the synthesis of biologically active peptides. Detailed descriptions make this a practical tool in the laboratory. (Interscience Monographs on Organic Chemistry).

0471 08451 4 224 pages December 1976 £15.00/$24.80

PHONONS AND RESONANCES IN SOLIDS

by **B. Di Bartolo,** *Boston College,* and **R. C. Powell,** *Oklahoma State University.*

Deals with the thermal vibrations of crystalline solids and their effects on the spectra of these materials. Emphasizes symmetry considerations (group theory) and experimental techniques.

0471 21275 X 534 pages June 1976 £17.35/$29.10

GAS DYNAMICS Vols. 1 and 2

by **M. J. Zucrow** and **J. D. Hoffman,** *both of Purdue University.*

A detailed introduction to the science of gas dynamics with extensive applications to problems in engineering. Uses a classical approach and presents numerical techniques to analyze the flow of imperfect gases. Numerous worked examples in SI units illustrate the theoretical developments for both perfect and imperfect gases. Vol. 2 emphasizes multi-dimensional flows.

0471 98440 X Vol. 1 782 pages Sept 1976 £20.15/$36.75
0471 01806 6 Vol. 2 In Press.

New Books in Molecular Biology

Biomedical Applications of Immobilized Enzymes and Proteins

edited by **T. M. S. Chang**
McGill University

This two-volume work provides a comprehensive survey of the state of research on the uses of immobilized enzymes and proteins in medicine. The first volume is devoted to the multiplicity of current and future therapeutic applications, including the feasibility of immobilizing various enzymes and proteins for use in specific treatment regimes. Volume 2 discusses the applications and prospects for these substances in diagnosis and public health as well as the techniques used in clinical and preventive medicine.
Volume 1: approx. 475 pages, illus., $53.40/£28.04
Volume 2: approx. 400 pages, illus., in preparation

Purine Metabolism in Man—II

Regulation of Pathways and Enzyme Defects
edited by **Mathias M. Müller** and **Erich Kaiser**
University of Vienna, Austria
and **J. Edwin Seegmiller**
University of California, San Diego

The first volume in a two-volume set aimed at consolidating our present understanding of the mechanisms involved in the synthesis and degradation of purines, this book focuses on the aberrations produced in the regulation of these processes by well-characterized defects in purine metabolism. Volume 76A in the Advances in Experimental Medicine and Biology series.
approx. 670 pages, in preparation

The Structure of Biological Membranes

edited by **Sixten Abrahamsson** and **Irmin Pascher**
University of Göteberg, Sweden

This outstanding volume brings together leading scientists from around the world to discuss the structure and function of biological membranes. They define the most urgent problems that have yet to be solved, providing an expert summary of current knowledge in this dynamic field of research. Volume 34 in the Nobel Foundation Symposium series. approx. 580 pages, $59.40/£31.19

Methods of Protein Separation

Volume 2
edited by **Nicholas Catsimpoolas**
Massachusetts Institute of Technology

Methods of Protein Separation presents a comprehensive account of the advantages and limitations of the most modern techniques for the separation, identification, and characterization of proteins. Topics covered in Volume 2 include scanning gel chromatography; analytical and preparative polyacrylamide gel electrophoresis (PAGE); determination of molecular weight and radius by gel filtration, PAGE, and PAGE in sodium dodecyl sulfate; zone electrophoresis, isoelectric focusing and displacement electrophoresis; hydrophobic adsorption chromatography; and sievorptive chromatography. A volume in the Biological Separations series.
326 pages, illus., $35.40/£18.59
also available
Volume 1: 281 pages, illus., $33.00/£17.33

Methods in Membrane Biology

Volume 8
edited by **Edward D. Korn**
National Heart and Lung Institute

Volume 8 of this dynamic series discusses chemical and innovative physical methods for characterizing membrane lipids, the use of organic solvents for separating membrane components, chemical synthesis of stereospecific lipids, and the application of electron paramagnetic resonance spectroscopy to the study of membranes. Emphasis is placed on the interpretation of results and on the applications, limitations, and theoretical basis for each method. 368 pages, illus., $39.00/£20.48

Membranes, Ions, and Impulses

edited by **John W. Moore**
Duke University Medical Center

This volume in honor of Kenneth S. Cole expands upon his pioneering research in membrane biophysics. Outstanding contributors present the latest advances in the areas of Cole's most significant discoveries in membrane capacitance and conductance. There is also extensive coverage of new areas of membrane research, including the measurement and analysis of fluctuation phenomena and uses of the voltage clamp in cells other than the squid giant axon. Volume 5 in the FASEB Monographs series. 195 pages, illus., $23.40/£12.30

Synaptic transmitter substances

Neurotransmitter Amino Acids. By Neil Davidson. Pp. viii+179. (Academic: London and New York, 1976.) £5; $12.75.

In the past ten years there has been a rapidly growing interest in certain amino acids such as GABA, glycine and glutamate which are now generally believed to be important synaptic transmitter substances in the vertebrate central nervous system. Neil Davidson has undertaken the formidable task of writing a short book in which he aims to cover all aspects of neurobiology relevant to these amino acid transmitters.

The three opening chapters, which together occupy just over two-thirds of the book, provide an excellent account of the evidence that glutamate and aspartate, glycine, and GABA, are central transmitters. The references are usually well chosen but it is surprising that there is no mention of *N*-methobicuculline or the immunohistochemical localisation of glutamate decarboxylase (GAD). The latter omision is particularly surprising since the localisation of GAD is potentially a valuable method of identifying GABA-operated synapses.

The author is at his critical best when discussing problems of electrophysiology and particularly the interpretation of experiments in which drugs are applied to neurones by iontophoresis. More neurochemical problems involving subcellular distribution, autoradiography and uptake, however, are not so critically assessed. For example, the author suggests that the presence of a high affinity uptake mechanism is a criteria for an amino acid transmitter, a view against which there is now much evidence.

There is an adequate chapter on taurine but the account of amino acids in retinal neurotransmission is rather disappointing. The role of GABA in the retina is discussed but taurine, glutamate and aspartate are barely mentioned, although there is much inferential evidence that they may be retinal transmitter substances.

The last two chapters provide an excellent account of the possible role of amino acids in presynaptic inhibition and a review of the behavioural and clinical correlations in studies of the neurotransmitter amino acids.

The book has a rather large number of typographical errors but of more consequence is the use of a bewildering number of units. For example, the concentrations of amino acids are expressed in at least five ways making ready comparisons difficult. It would be helpful if in future editions the author would recalculate amino acid levels in one unit such as μmol g^{-1}. These are, however, minor criticisms, and the author is to be congratulated on producing a very readable introduction to amino acid transmitters. This book will be of great value to both undergraduate and postgraduate students, and I suspect that many involved in research on amino acid transmitters will keep a copy of this book readily available.

M. J. Neal

M. J. Neal is a Senior Lecturer in Pharmacology at The School of Pharmacy, University of London, UK.

Gerontological observations

The Ageing of Connective Tissue. By David A. Hall. Pp. vi+204. (Academic: London and New York, 1976.) £4.80; $10.50.

Over the past decade considerable advances have been made in our understanding of the biosynthesis and structure of the components of connective tissue. The deterioration of connective tissue is an obvious fact of ageing, and connective tissue biochemists should be encouraged to apply this new fundamental knowledge and accelerate the emergence of gerontology from its classical descriptive phase. Certainly it is becoming increasingly obvious that any breakthrough in the understanding of ageing can only come from studies at the molecular level. Dr Hall has therefore chosen his time well to write his monograph.

The book is well organised to provide the reader firstly with a brief resumé of the current theories of ageing and then with an overall view of the breadth of involvement of connective tissue components in various tissues, starting at the macroscopic level and working gradually down to the complex molecular level.

The book does, however, contain a number of errors, some obvious and some not so: for example, the gal–glc disaccharide is stated as being attached to hydroxyproline instead of hydroxylysine; the statment that $(\alpha 2)_3$ exists in tissues; the stated presence of hydroxylysinonorleucine in elastin; and a number of incorrect cross-link formulae. There are also a number of surprises: for example, quotation of the old, unconfirmed observation that cellulose is present in older human skin; the electron micrograph picture of metacollagen (thermally denatured skin collagen); the considerable over-emphasis on pseudo-elastin (an unfortunate name, since it is surely no more than highly cross-linked impure collagen). The statement that elastase, a serine protease similar to chymotrypsin, has no effect on collagen is incorrect, a fact which throws some doubts on the conclusions drawn from these experiments.

I did not, therefore, feel that the promise of the first half of the book was fulfilled when the biochemical basis of the age changes was discussed. More importantly the emphasis in this part of the book on old unconfirmed and often confusing work, together with the numerous errors of fact that have been overlooked, mean that the book has to be read with considerable wariness. This is particularly important since the stage is now set—and Dr Hall has played no small part in this—for some critical studies on the role of connective tissue in the ageing process. Despite these reservations, it is hoped that this compact and inexpensive book will engender the right kind of enthusiasm for establishing the biochemical and molecular basis for gerontological observations.

Multitude of fishes

Fishes of the World. By J. S. Nelson. Pp. xiii+416. (Wiley-Interscience: New York and London, October 1976.) $31.85; £18.50.

MODERN estimates of fish abundance have reached 30,000 species, although the present author arrives at a conservative and precise 18,818. Nowadays, to encompass the fishes even at family level is a daunting task, further complicated by much revision of their higher classification within the past fifteen years.

The purpose of this book is "to present a modern introductory systematic treatment of all major fish groups", the basic units being all extant, and selected extinct, families of fishes, from jawless ostracoderms to choanate crossopterygians. As a preliminary, protochordates and even conodonts are also discussed. The family category is, of course, a subjective taxon, but the author is not extravagant by previous standards in recognising 450 of these in 46 orders of true fishes. Overall classification follows accepted recent schemes, although more radical alternatives are mentioned. Each family receives a common name, a concise statement of distribution, essential diagnostic features, sometimes further division into subfamilies, and biological notes when of better known status. A line drawing of a typical species is provided for most families. Appendices contain a simplified classification and a series of 45 world distribution maps. A useful bibliography of about 600 references (though none more recent than 1973) and a systematic index, complete the work.

This is a pleasing book, not only in much of its content but also in typography, format and illustration. Factual coverage for each family is necessarily brief, but random consultation proved consistently successful even for such diverse forms as *Schindleria* (the lightest vertebrate), parasitic eels (Simenchelyidae), the dreaded candiru (Trichomycteridae), and Baikal oilfishes (Comephoridae). Treatment of the gobioid fishes—representing perhaps one-tenth of all living teleosts—seems restrained and practicable in comparison with more frenetic and provisional specialist schemes.

Among shortcomings, fossil groups receive uneven and often perfunctory attention, out of keeping with current efforts to integrate classification over the entire time range of fishes. A work for general reference also needs a synopsis of fish anatomy, especially osteology, to explain diagnostic characters, perhaps replacing much of the rather generalised introduction and the 24 pages devoted to maps. Use of recognised terminology for faunal complexes could have given a more precise and biologically significant statement of family distribution. Finally, comparison with a recent Russian work by Lindberg, also entitled in translation *Fishes of the World,* and involving the same publishers, emphasises the absence of a key to families from Nelson's account. Keys are not only altruistic but also cathartic against taxonomic subdivision. In a number of ways, by accident or design, the two monographs are unfortunately complementary rather than competitive and it is a pity that a little more on bones, fossils, and identification could not have been included between the relatively expensive covers of the one now reviewed.

P. J. Miller

P. J. Miller is a Lecturer in Zoology at the University of Bristol, UK.

Radioimmunoassay

Radioimmunoassay of Biologically Active Compounds. By C. W. Parker. Pp. xiv+239. (Prentice-Hall: Englewood Cliffs, New Jersey, 1976.)

RADIOIMMUNASSAY is a technique the possibilities for which were realised, at least partly, by endocrinologists a good many years ago. They are, however, far wider than is even now recognised. In principle any soluble substance with which a specific antibody can react is capable of being estimated at the nanogram level or better, even in the presence of large quantities of nonspecific material. At one extreme, therefore, proteins, which are intrinsically immunogenic, and at the other simple chemicals, such as drugs which can be stably attached to 'carrier' proteins and made immunogenic, are open to estimation in grossly heterogeneous mixtures, such as serum and crude tissue extracts. The intermediate group, the medium sized polypeptides of about six to about fifty residues—a group which includes many important hormones—is in fact the trickiest problem. But essentially the problem boils down to good chemistry, so as to attach one's substance undamaged and the right way round; and competent immunology, so as to raise antibodies of—and this is not always so easy—satisfactorily high affinity: which just means that the antigen–antibody complexes must remain bound even at very high dilution. The sensitivity of the test—that is, the smallest concentration per millilitre which can be quantitated—is directly dependent on the affinity attained.

The great strength of this book, which can be recommended without reservation, is that Dr. Parker has realised that the principles and practice of immunogen preparation and of immunisation are in importance equal to or greater than, the details of the actual tests, so that the former are considered at length and with invariable common sense. He treats clearly, thoroughly and from first principles problems of affinity and of cross-reactivity, and of factors in tissue extracts or serum such as degradative enzymes, which may affect assays. He also refers to methods alternative to the standard ones—for example when dealing with the separation of free from antibody-bound antigen, he considers chromatographic or molecular sieve separation as well as the more conventional salt-precipitation or double-antibody techniques.

There are two techniques related to radio-immunoassay which may be of increasing importance in the future, to which some but no very extensive reference is made. These are the use of endogenous blood or cell receptor proteins instead of antibody, and the method known affectionately as Eliza, the enzyme-linked immunoassay. About the first, the general conclusion is that it is usually easier to raise an antibody than to purify a specific receptor protein: I would suggest, however, that in some cases—using, for example, suspensions of cultured cells or blood leukocytes—a highly sensitive assay might be contrived for quite small radiolabelled substances, which might be difficult by any other method. As far as Eliza goes, since this involves an antibody, practically everything in this book is as applicable to it as it is to a radioimmunoassay. The great advantage claimed for Eliza is that it is not dependent on a large and expensive counter which is always breaking down, but on a simple colorimeter. The whole question is whether an enzyme assay ending in a coloured product (generally using peroxidase or alkaline phosphatase) can be made as sensitive as a count of radioactivity. The evidence is, rather surprisingly, that under favourable circumstances it can.

This book is the most intelligent one which I have met for developing and advancing the subject; it cannot fail to be of continuing importance in biology and medicine.

Choosing the top people

It is taking some time to find a successor to Sir Sam Edwards as chairman of the UK Science Research Council (SRC), the body that oversees the spending of an annual £100 million on research projects in universities, institutions and international laboratories. Sir Sam returns to the academic world in October and although feelers have been put about for several months and several people have been approached through the Department of Education and Science, it seems that no one has yet given a favourable reply.

The job is not without its attractions, because even in these days of cash limits it is still possible to pursue modest initiatives rather than simply shore up the *status quo*; indeed in some ways the power may be greater than before in such matters as postgraduate education, where the universities certainly take more note of SRC's influence and views than in more affluent times. The chairman's job could not really be said to be a post with great appeal to those who have already made their name on the scientific-political scene; strange, then, that one or two of those to whom early feelers went out were people exactly in this category. Maybe commonsense has prevailed—there are several others now being mentioned who have still a name to make; it is surely desirable that with so few scientists privy to the London political scene an imaginative choice should be added to their ranks.

The problem confronting many in this category, however, is what to do after a spell at SRC. If a professorship is resigned at the age of 45, will another professorship or university post conveniently appear at 50? If such prospects look bleak, is it possible to keep in touch with the academic world by spending a day or two every week back at the bench and giving SRC three or four days a week? If the chairman finds public service appealing, will opportunities open up for a now-experienced scientist-politician to be employed in ways that are not trivial? Would a chairman with appropriate leanings be able to find a satisfying post in industry?

That these questions have to be posed seriously and are undoubtedly running through the minds of several people interested in this appointment shows how depressingly rigid career structures can be in Britain for senior people of high competence. The last thing that those of ability should have to do is to cling to tenured posts for fear of loss of income or serious erosion of pension; the country surely needs such people to circulate freely and to be able to put their well-experienced minds whole-heartedly to new tasks, probably administrative more than scientific, right into their sixties. There is a serious danger that by consistently failing to encourage free flow between industry, government and the academic world, Britain is wasting much of its senior intellectual resources; the appointment at SRC is just one instance of the sort of dilemma that faces those who genuinely wish to be mobile.

If a top British post in science policy is discussed discreetly by a charmed circle and names are mentioned only on promises of infinite discretion, to preserve the sensibilities of candidates, no such inhibitions seem to surround the procedure of appointing a Presidential Science Adviser in the United States. For weeks before the appointment is made names are quite openly mentioned as the pros and cons of various candidates are widely discussed. The assumption is, presumably, that aspirants to life in the public eye had better get used early on to being talked about, and that it is better to search out any rational opposition to candidates while there is still time.

Which is the better way of doing things? British concern to protect the individual or American wide exposure? Obviously the question cannot be answered in isolation from recognition of a totally different political and even cultural environment. But even so, there do seem ways in which the appointment of a few of Britain's top science-policymakers could be coupled with much more open consultation, so that the announcement does not come as a complete surprise to virtually all scientists and the name is not greeted with expressions of complete ignorance. This is a matter on which the Department of Education and Science should try to force the pace—they would find mild dissatisfaction with the present system of appointments and a general enthusiasm for more open government amongst scientists. ☐

European energy: where now?

Chris Sherwell looks at the immediate prospects for European energy policy with Britain in the Council chair

ASK almost anyone about energy policy in the European Community and the response, when it is not a blank stare, usually reflects deep-seated disillusion. There is no energy policy, some will imply, and there won't be one that is coherent until someone decides how much of what fuels will be needed for what purposes at which points in the future. Others say that only a policy of fully developing all possible sources of energy will fuel Europe's future growth—which, they may add, is what it is all about.

One thing is certain: the future, like nostalgia, is not what it used to be. Hence the gloom. The OECD's recent *World Energy Outlook*, for example, projecting supply and demand to 1985, pointedly urged industrialised countries to adopt more vigorous energy policies. The EEC experience certainly doesn't augur well. Francois Xavier-Ortoli, the outgoing president of the European Commission, said as much when he spoke disparagingly of the "feeble" European response to calls for a common energy policy. His successor, Roy Jenkins, stressed only last week the need to develop a coordinated policy. And the outgoing EEC Energy Commissioner, Henri Simonet, has said that EEC governments have accomplished "virtually nothing" on energy.

The theme is not always so general. Guido Brunner, the Research Commissioner who has now also taken on the energy portfolio, appealed to Britain a fortnight ago to shift position on the specific issue of the proposed Euratom loans plan; he wants a move on the sensitive issue of a minimum safeguard price for oil (msp) as well. Simonet himself has said that until the Community rids itself of "the ball and chain" of a floor price and gave a go-ahead on Euratom loans it would not be able to develop a policy for boosting alternative energy sources.

Dispelling the log-jam

Now there are hopes that the log-jam may begin to be dispelled. Mr Brunner's appeal followed a series of meetings held in various European centres by Mr Anthony Wedgwood Benn, the UK Secretary of State for Energy, who now holds the chair of the Council of Ministers because it is Britain's turn under the six-month rotation scheme which the Community operates. Mr Benn's purpose was to learn the objectives of EEC members over the period until July (when Belgium takes over), and to discuss the ways the Council worked.

The date of the first Council meeting under Britain's chairmanship is tentatively set for 4 April. The issues it confronts extend beyond the msp and Euratom loans into the broad nuclear field and into the area of fusion and the Community's JET project as well. On all these matters progress will have been hamstrung for a year to eighteen months by the time the Council meets.

Mr Benn freely acknowledges that the Community has been unsuccessful in energy policy thus far. In an exclusive interview with *Nature* last week, he described the approach as "too scholastic", with too many people in offices with computer forecasts operating too much from the centre: officials should be made more responsive to politicians, whose shoulders must bear more responsibility.

In Europe, he says, "everything becomes a package deal" and he doesn't want a "haggling relationship". Rather, he wants a realistic one in which the needs of each country, which aren't identical, are taken seriously. The aim is to "harmonise interests", but there is no point in pillorying a country because it can't move. There should be a search for areas of common interest on which people could build a consensus.

Mr Benn says this view is shared by his European colleagues, being more open, more "discussive" and a move away from judging policy by the number of regulations or directives it produces. In energy matters decisions were not always clear and could not always be taken quickly. No policy sticks, he says recalling the Concorde experience, if it isn't also acceptable to public opinion. An energy policy which makes sense will be put together "bit by bit". And it will fall "far short of any 'federal control' of European energy; I think that is absolutely out".

It is on these lines that Mr Benn wants his Council presidency to be judged. How any success he achieves will manifest itself in the realm of decisions, though, is another matter. He is reluctant to put priorities on the solution of the many long-standing energy questions facing the Council this year: "We'll have to make progress as and when we can", he states, "and I don't want to set myself a target for a particular decision and then have every meeting which doesn't quite realise it written off as a failure".

Keystone

Mr Benn: breaking the log-jam?

Range of problems

A glance at the topics due to come up during Britain's presidency reveals the problems. They range from the barely answerable, like the rational use of energy, to the arguably unresolvable, like the protection and promotion of investment. It is the latter question which focuses upon the highly controversial issue of the msp, the background to which highlights the sort of difficulty the EEC faces.

Irrelevant symbol or careful calculation, the msp's purpose is to make investment both in the North Sea and on alternative energy sources worthwhile. Britain thinks the msp was agreed by the Community at the end of 1975 when Britain dropped her claim, as EEC's only energy exporter, to speak independently of the Community at the upcoming 'north-south' conference. And most members of the International Energy Agency (IEA), the OECD agency based in Paris, have agreed on the idea. But France—not a member of the IEA because, in her view, it encouraged confrontation with the major oil producers—has firmly resisted an msp, insisting, like Mr Simonet recently, that only an investment guaranteeing mechanism was agreed.

No one disputes that the msp issue is politically linked to the issue of the Euratom loans, a scheme under which construction of nuclear power stations might go ahead more fluidly by permitting a Community contribution. Germany and France, with their large nuclear programmes, would both benefit by it. Mr Benn himself says he was mandated twelve months ago to agree to a package in Brussels involving both these items. But there was no progress on the msp. EEC countries agreed in principle to the loans scheme, but Britain refused to sanction its implementation without agreement on the msp, even though she had no objection to it and actually stood to benefit by it. The two matters have remained inextricably linked ever since.

There is a parallel linkage in the

EEC Research Council, now chaired by Mr Gerald Kaufman from the UK Department of Industry. Its inability to agree on a site for JET, the Community's fusion project, has held up implementation of the four-year joint research programme, most recently because of French insistence that the site be at CERN if not in France itself. The two main contenders are Garching in Germany and Culham in Britain.

The possibility that, with the appointment of Mr Brunner as both Energy and Research Commissioner, these two sets of linked issues might themselves become linked is not being talked about openly. But Mr Benn, while pointing out the division of responsibilities between the two Councils, does stress that he is taking a close interest in the subject and affirms that the project is not dead. He could conceivably argue that JET is now to be seen as an energy matter rather than a research project. But for the moment he merely continues to emphasise Britain's view that the Culham site is the most suitable.

JET domino

In a sense JET is a vital domino in the efforts to stimulate some movement on European energy. Britain for one might find it more difficult to posture over certain aspects of policy if she won JET, although she is highly unlikely to relinquish her self-styled role of remaining Europe's energy equivalent of a 'bread basket' by surrendering sovereignty over North Sea oil and gas.

Yet this idea has been publicly canvassed. It was Mr Simonet's view at the end of his tenure that Britain should invite other EEC members to join in North Sea exploitation in return for the guaranteed European market she wants even if prices fall: in other words, access to the goods for access to the market. Mr Benn is fiercely resistant to that suggestion.

He also resists the notion of dealing with one type of energy investment, in nuclear power for example, without dealing with support for other types. To him there is no trade-off to be made: if Europe is to reduce its dependence on imported energy to some 50% by 1985—its intended (if receding) goal—all energy investment must be stimulated.

But even while the haggling goes on over the msp and Euratom loans, the fact remains that Europe will still be the world's largest energy importer in 1985. That, indeed, is why some people say that Europe's nuclear policy, of which the Euratom loans are just one facet, is the most crucial aspect of its energy policy and one which simultaneously offers the best prospect of European cooperation.

The Commission is concerned that the projected nuclear future is now a mere shadow of what it was: the optimistic forecasts of 200 GW of nuclear power by the mid-1980s were reduced to 160 GW some time ago, and according to Simonet the Community would now be lucky to reach 90 GW by then. The problems here, however, stretch beyond mere construction of nuclear power stations.

The EEC countries, all members of Euratom, have so far failed to resolve the now long-standing problem posed by France, which has not signed the Non-Proliferation Treaty, regarding the arrangement for IAEA inspectors to check nuclear installations. France fears IAEA safeguards will be imposed without her consent; her Euratom partners fear she will escape the safeguards they face. One by-product: without agreement on safeguards, a threat to future supplies of enriched uranium from abroad—at a time when at least one of the two European enrichment consortia, Urenco, is facing increasing difficulty.

The issue of reprocessing is still to come on the European front, although reassessment of the matter by the new Carter Administration could have implications for any European intention to reprocess spent fuel on an international basis. Mr Benn hopes to go to the United States to discuss such matters while Council president, although as a UK minister. But the subject of nuclear fuel supply and the nuclear fuel cycle is only slated to come up in the Council in the second half of 1977.

The work programme for Britain's half of the year includes the subjects of oil refining policy, security of oil stocks, the stockpiling of coal and the use of it in power stations. The Council under Mr Benn may not manage to embrace all these matters as well as make progress on the immediate decisions in the two meetings provisionally planned for April and June.

Past experience of the Council certainly does not offer a happy prognosis. But perhaps the man temporarily at the top can remedy that and confound his critics at the same time. It would indeed be ironic if it was Mr Benn who finally did most to promote European cooperation. That is what is now needed. Matters have reached the stage when the degree to which the old Europeans take Britain seriously over energy policy, and *vice versa*, is now to be determined. ☐

USA

An unprecedented debate

Colin Norman reports from Washington on the continuing discussions about genetic manipulation experiments in the United States

AFTER seven months of intense and at times acrimonious debate, the City Council of Cambridge, Massachusetts, last week lifted a moratorium it had placed on some uses of the controversial recombinant DNA genetic engineering technique at Harvard and Massachusetts Institute of Technology. Acting on the advice of a citizens' review board, the council has decided to allow the research to go ahead in Cambridge under strict safety controls and under the watchful eye of a committee of the city's residents.

While the debate in Cambridge has been coming to a resolution, however, it has been picking up momentum in many other parts of the United States. A debate without precedent, it is leading in many cases to an unusual degree of citizens' involvement in the conduct of academic and industrial research, and in the view of many could have a profound influence on future relationships between universities and their surrounding communities.

The following are some of the more important developments which have occurred over the past few weeks.

● **New York.** Legislation to control recombinant DNA research throughout New York state is expected to be introduced into the state legislature this week.* If passed unchanged, it could result in the most stringent controls so far adopted anywhere in the United States.

The legislation is a direct result of a public hearing called last October by the State Attorney General's Office, and the bill was drafted by Deborah Feinberg, an aide in the Attorney General's environmental health bureau. The legislation would essentially require that all academic and industrial research laboratories planning to conduct recombinant DNA experiments must apply for a licence from the state Department of Public Health. The Commissioner of Public Health would be empowered to draft state-wide regulations, based on the NIH guidelines but with additional enforcement provisions. Health monitoring of laboratory personnel would be required, for example, and applicants for licences would have to describe their proposed monitoring procedures. The health department would also be given power to inspect all facilities conducting recombinant DNA experiments, to ensure that the regulations are being followed. Violations could result in a fine and suspension of the licence.

In a 60-page report accompanying the bill, Feinberg recommends that most recombinant DNA experiments should be conducted in moderate containment laboratories (P3 laboratories under the terms of the NIH guidelines), at least until the potential hazards have been better evaluated. "If it then seems safe and appropriate", she suggested last week, "they could be lowered to P2 or P1". The report is advisory, however; the bill requires the health department to set containment levels for classes of experiments.

- **California.** Two committees of the California state assembly, the health committee and the committee on energy, environment and natural resources, have been holding public hearings on recombinant DNA at which a number of prominent opponents and proponents of the research ("the recombinant DNA travelling road show", one wit has described them) testified. A bill, drafted by Marc Lappé, an official in the state health department, is under consideration by the committees, but it has not yet been introduced into the legislature.

Lappé said last week that he expects the legislature to approve legislation later this year which would at least make the NIH guidelines applicable to all facilities conducting recombinant DNA research in California. Like the New York legislation, the California bill is also expected to include provisions for health monitoring of laboratory workers and enforcement by the state government. In addition, Lappé said that the bill now under discussion would require principal investigators to obtain informed consent from other laboratory personnel taking part in recombinant DNA research.

- **Cambridge.** The widely-reported debate over recombinant DNA research in Cambridge is largely responsible for sparking the interest of other city and local governments in the issue. The city council last July imposed a three-month moratorium (later extended to seven months) on P3- and P4-level experiments at Harvard and MIT, and established a committee of Cambridge citizens to recommend the conditions, if any, under which such research should be permitted in the city. Last month, the committee suggested the P3-level work should be allowed to go ahead in accordance with the NIH guidelines, but with some added precautions. All P3 experiments should be conducted on crippled microorganisms, for example, there should be health monitoring of laboratory workers, and a committee of Cambridge residents should be established to oversee the work, to ensure that the regulations are followed.

Last week, the council rejected, by a vote of 6 to 3, a resolution proposed by Mayor Alfred E. Vellucci to prohibit all P3- and P4-level experiments in Cambridge, and it then voted to implement the committee's recommendations. The vote, which essentially incorporated the recommendations into city ordinances, was widely regarded as an acid test of public acceptability of recombinant DNA research.

- **Princeton.** Events at Princeton University provide a unique, and in some respects, exemplary record of cautious debate and discussion before proceeding with recombinant DNA research. Nobody at Princeton was involved in developing recombinant DNA techniques, and thus no experiments were under way there before the national debate began. Last year it was decided no recombinant DNA experiments should be permitted at Princeton until the matter had been fully discussed.

Last September, the university established a special biohazards committee, under the chairmanship of ecologist Robert May, to recommend a policy for the university. The committee, which consisted of three biologists and seven people from other disciplines, unanimously approved a report last December which essentially states that the research should be permitted at Princeton, subject to controls more strict than the NIH guidelines. It suggested, for example, that no P4-level work be permitted, that the NIH guidelines be used as a minimum set of requirements for containing modified microorganisms, and that any P3 laboratories built at Princeton should meet more stringent standards.

The report then went to the University Research Board, which endorsed it unanimously and passed it on to the university's President. He took it to the Council of the Princeton University Community, a group consisting of undergraduates, graduate students, faculty and alumni, which also endorsed it unanimously. The President, William G. Bowen, intended to take the report to the university's trustees, the top governing body, at the end of January, but in the meantime, the local community was brought in. A public meeting organised by officials from the university and from the local township and borough was held to discuss the report, as a result of which a citizens' committee has been established to review the proposals. Bowen is expected to await the findings of that committee before taking the report to the trustees.

- **San Diego.** After the debate erupted in Cambridge, Mayor Pete Wilson of San Diego invited officials of the University of California at San Diego to meet with him to discuss their plans for conducting recombinant DNA experiments. They informed him of their intent to construct a P3-level laboratory in the new medical school, and invited an aide to the Mayor, Mike Madigan, to sit on the university biohazards committee. Subsequently, the city also established a citizens' committee to review the matter. The committee conducted about six months of hearings, taking testimony from a variety of people from around the United States, and it issued a report last month which is expected to be debated by the city council in the next couple of weeks.

The committee intentionally steered clear of recommending whether or not the work should be allowed to proceed at the university, since the city has little formal jurisdiction over the university. It recommended, however, that more citizens be brought on to the biohazards committee, urged the university to disseminate information on its plans for recombinant DNA research, and suggested that health monitoring of laboratory workers be undertaken.

- **Ann Arbor.** An intense internal debate took place at the University of Michigan last year over plans to conduct recombinant DNA research there. The university planned to construct P3-level facilities for recombinant DNA research, and it established a committee to review the biological hazards and a second committee, consisting of non-biologists, to look into the social and philosophical implications.

After an extended debate, the committee of non-biologists recommended, with one dissent, that the university should go ahead with its plans, and the Board of Regents, the university's governing body, subsequently endorsed the recommendation by a vote of 6 to 1.

- **Bloomington.** A public hearing was held last year by an environmental committee appointed by the Mayor of Bloomington, Indiana, to review plans by the University of Indiana to construct a P3 laboratory for recombinant DNA research. The council has so far taken no action, however, and an aide to the Mayor said last week that city officials plan to keep an eye on events, but no city-level regulation is anticipated at present.

- **The federal government**. Much of the concern which has been expressed

---

An oversight meant an error in "Carter's energy problem" (3 February, page 398–399): $31,400 million and $42,000 million should have read $314,000 million and £420,000 million, and 100 million and 300 million should have read 1,000 million and 3,000 million. Our apologies.

in state and local debates on recombinant DNA research stems from the fact that the NIH guidelines do not apply to industry, and are not backed by any enforcement mechanism. In that regard, a little-known committee, established last year by President Ford, could prove influential. The committee, which consists of representatives of a variety of federal agencies, is looking into ways to extend the NIH guidelines to cover all recombinant DNA research in the United States. The committee, which meets in closed sessions, is expected to issue recommendations in mid-March.

According to one participant, a broad consensus has been established in the committee that the NIH guidelines should be transformed into enforceable regulations, but it seems that no existing agency has the power to enforce them. For obvious reasons, NIH doesn't want to be placed in the position of both supporting and regulating the research, and the committee is now debating whether to recommend that several regulatory agencies be given the responsibility jointly, or whether to recommend that Congress should pass legislation to give the authority to a single agency. The basis of the regulations, in any case, will be the present NIH guidelines.

In the meantime, a bill was introduced into both the House and the Senate last week to establish a federal licensing scheme for recombinant DNA research, which would apply to both industrial and academic research. Drafted by Senator Dale Bumpers of Arkansas, the legislation is designed to enforce the NIH guidelines as a bare minimum. When he introduced the bill, Bumpers said that if he had his choice, "there would be a moratorium declared right now on all recombinant DNA research". Senator Edward Kennedy's health subcommittee is expected to hold hearings on the bill early in April, after the inter-agency committee has issued its proposals.

Underlying a good deal of the concern is a deep suspicion of what industry is intending to do with recombinant DNA technology, and those suspicions have surfaced dramatically in the past couple of weeks following the publication of a proposal by the Department of Commerce to expedite patent applications involving recombinant DNA techniques.

The proposal, drafted by Assistant Commerce Secretary Betsy Anker-Johnson, would require patent applicants to state that they will abide by the NIH guidelines, though they would be permitted to "include an explanation of any deviations (from the guidelines) considered essential to avoid disclosure of proprietary information". That exemption has attracted criticism because it would allow industrial companies to proceed with their research without notifying anybody.

Such criticism last week prompted Joseph Califano, the new Secretary of Health, Education and Welfare, to ask Secretary of Commerce Juanita Kreps to withdraw the proposal. Dr Anker-Johnson pointed out in a telephone interview last week, however, that the proposal in fact forces industry to disclose more information than it is required to under existing regulations. Further disclosure could result in loss of patent rights in many countries which preclude the award of patents on processes for which there has been any prior disclosure. ☐

CANADA

Guidelines recommended

Canadians are now discussing guidelines for recombinant DNA experiments. David Spurgeon reports

An ad hoc committee of Canada's Medical Research Council has presented its recommendations on guidelines for handling recombinant DNA molecules. The guidelines are similar to those adopted by Britain and the United States, although they are designated differently, but they go further in that they include guidelines also for experiments involving animal viruses and cells.

The committee's report was made public recently in a press conference held by the MRC, which is the federal granting agency for medical research in the universities. If adopted, the guidelines will apply to all MRC grantees, but not to industry. A federal interagency committee has been studying the question as it applies to industry. Dr G. Malcolm Brown, the MRC president, said the ad hoc committee's recommendations would be discussed at a meeting of the council near the end of February, when they could be approved, rejected or modified It is considered almost certain, however, that the council will accept them.

The recommendations were drawn up by a group that included researchers in the appropriate fields and also a member of Queen's University's law faculty. The committee also included a member of the Defence Research Establishment, a member of the University of Alberta's pediatrics department and an observer from the National Research Council.

The Chairman of the committee was Dr Louis Siminovitch, chairman of the department of medical genetics at the University of Toronto and geneticist-in-chief at the Hospital for Sick Children. Dr Siminovitch was influential in the MRC decision to include animal viruses and cells in the committee's terms of reference.

At present, no research involving recombinant DNA is being conducted in Canada, but some experiments have been proposed. A total of one-sixth of MRC's grants could be affected by the proposed guidelines, totalling about $8–10 million a year, because of their effect on animal viruses and cells.

The earliest the recommendations could be put into effect would be April 1, according to Dr Brown, but Dr Siminovitch said many precautions have already been introduced. If the guidelines are approved, the MRC will insist that all recommendations for laboratory safety are carried out before granting funds. The mechanism for enforcing guidelines is thus similar to that adopted in the United States, though different from that in Britain.

The guidelines themselves provide for six levels of containment, ranging from a statement of good microbiological laboratory practice (level A), plus suitable containment measures for agents of no known or potential risk, to requirements for very hazardous materials, such as the virus that causes lassa fever (level F). The technique and equipment described cover all aspects of laboratory research, including the design of laboratories, treatment of effluents, protective clothing and handling of animals.

In the section on recombinant DNA molecules, biological containment methods involving the use of strains of viruses and bacteria that have been altered so that they will not survive outside the laboratory, are included. In the section on cells and viruses, viruses known to cause infectious diseases, and those known or thought to be associated with cancer, are classified according to risk on the basis of their infectivity for man, and also for animals, the severity of the disease they cause, and the range of animals they can infect. Various factors, such as the type of cell, culture conditions, and the manipulations involved, are used to assign the various experiments with animal cells in culture to the containment levels described. Three levels of responsibility are described: the principal researcher, the institution where the work is performed, and the MRC. The chief responsibility lies with the principal investigator.

In its report, the ad hoc committee attempted to relate its proposed standards to those of the US National Institutes of Health and the UK Working Party on the Practice of Genetic Manipulation. "Level A requires no special design features beyond those suitable for a well-designed laboratory," the report said. The level is similar to the NIH's P1, but less stringent than the UK's Category I.

Level B requires a ventilated cabinet and is similar to the NIH P2 and the UK Category I. Level C requires a segregated room or cubicle from which all air is exhausted directly to the outside or is recirculated after passage through a high efficiency particulate air filter. In addition, all air exhausted from protective hoods must be passed through a HEPA filter. This level is more stringent than the NIH P2, less stringent than NIH P3, and similar to UK Category II.

Level D requires a directed airflow through the entire laboratory and thence directly to the outside. All exhaust air must be filtered through a HEPA filter. This level is similar to NIH P3 but less stringent than UK Category III. Level E requires the addition of an air lock, a Type III biological safety cabinet, an emergency plan and alarm system, and a safety cabinet outside the laboratory area. It is more stringent than NIH P3 and similar to UK Category III.

Finally, Level F calls for an isolation unit geographically separate from other areas. This separation may be by means of a separate building or by a separate air system in a multipurpose building. It is the equivalent of NIH P4 and UK Category IV.

A number of experiments with uncharacterised or partially characterised DNA are forbidden at present:

- The deliberate creation of recombinant DNA expected to make harmful products, such as plant pathogens of increased virulence.
- The deliberate release into the national environment of an organism containing recombinant DNA.
- The use of recombinant DNA to transfer drug resistance to microorganisms not known to acquire it naturally, if such transfer could compromise the effective use of the drug in human or veterinary medicine or agriculture.

Other experiments are to be individually assessed by the MRC to determine whether they should be allowed to proceed and, if so, what containments are necessary. These include etiological agents that may pose a special hazard because of particular reasons (that is, that they do not occur in Canada); plants, animals or insects that are either poisonous or whose entry into Canada requires a special permit because of pathogenicity; and all viruses that require containment levels above B.

The report pointed out that guidelines would require periodic review in the light of new information, and that there would still be experiments for which guidelines do not provide explicit containment requirements. For these reasons, the committee proposed that the council set up a standing committee to review the needs and advise the council. □

BRITAIN

Windscale: no escape

No development connected with the Windscale plant operated by British Nuclear Fuels Ltd (BNFL) now escapes national headlines. Chris Sherwell outlines some of the latest problems

WINDSCALE remains in the front line of an increasingly controversial debate over nuclear power in Britain. What encouragement there was last week for BNFL came in the House of Commons, when at the end of a second reading debate on the Nuclear Industry (Finance) Bill a vote was recorded of 196 to 22 in favour. Among other things, the bill provides for an increase from £75 million to £300 million (£500 million by order of parliament) in the limits of the capital which BNFL can raise with government backing

BNFL is reluctant to place any interpretation on the vote for the bill or on its content, but late last year, when expansion at Windscale came under heavy scrutiny, Mr Con Allday, BNFL's managing director, did draw encouragement from the support which he said the existing guarantees represented.

In the House last week, Mr Anthony Wedgwood Benn, the Secretary of State for Energy, implied that the bill was at least a case of prudent preparation. Although he was at pains to stress that the authority provided by the bill would not become operative without planning authority for the expansion, he said it was important that the company should be able to keep open with its customers the option of undertaking reprocessing business should that authority be forthcoming.

On both these aspects there have been some further developments recently. It was just before Christmas that Mr Peter Shore, the Secretary of State for the Environment, announced that BNFL's application to build its proposed oxide fuel reprocessing plant would require the sanction of a public inquiry. Mr Shore also indicated that such a procedure would be unlikely in respect of applications for Magnox fuel facilities and for proposed research projects.

BNFL has since submitted a separate application for the latter expansion to Cumbria County Council, but by last week had yet to announce that it proposed to go ahead with the oxide plant application.

On the related matter of the need for BNFL to keep its options open with its customers, the possibility has now emerged that, when it makes its application, BNFL will split it in two, one asking for permission to build the reprocessing plant itself, and the other seeking permission to construct ponds in which oxide fuel might be stored pending reprocessing. Whether the latter proposal could be sanctioned without an inquiry is not clear, since no one is actually admitting that it is under active consideration. But in the House Mr Benn did manage to give a hint on the matter.

Responding to a question on the building of storage ponds, he said that it was necessary for the company to take discussions to the point of concluding provisional contracts, and that he was having discussions with BNFL "about procedures along these lines". It is thought that this might be a way for BNFL to give additional assurances to the Japanese, at the moment the most important overseas customers. A high level delegation from Japan was in Britain last week for talks with the Departments of Energy and the Environment, with BNFL and with the Cumbria County Council.

Whether the whole issue remains one for the relevant British and Japanese authorities alone, however, is another question. The United States, as supplier of nuclear fuel for stations in Japan and other countries, is in a position to exercise a veto over what happens to spent fuel earmarked for reprocessing.

BNFL are not prepared to comment on this authorisation procedure, which derives from the requirement that any transfer of fissile material of US origin between two countries outside the USA needs the approval of the US Energy Research and Development Administration. US policy thus far has been to authorise the transfer of spent fuel for reprocessing, but the UK Department of Energy says it "may well be" that as part of the US review of non-proliferation policy "further consideration will be given to the conditions under which authorisation is given". According to the *Times*, negotiations between British and the USA on the matter have made little progress so far.

Important as this is, though, the most immediate of Windscale's problems last week appeared to be the continuing stalemate it faced in an industrial dispute which began on 25 January and which coincided awkwardly with the Japanese delegation's visit. Changing room attendants went on strike over a claim for increased allowances for working in an active area. Other workers were laid off as a result, and the strike spread, eventually affecting some 3,000 workers. After 11 days, during which reactors had been shut down and special safety procedures adopted, workers rejected a peace formula; last week no further efforts were being planned to solve the dispute, which was costing BNFL some £14,000 a day in lost revenue.

Meanwhile, worries over the health of workers at Windscale have revived. The deaths of two Windscale workers apparently suffering from cancer-related diseases have been the subject of separate inquests; open verdicts were recorded. Difficulties over secrecy being faced by BNFL lawyers handling two other cases, involving families of Windscale workers who died of cancer-related diseases, are thought to be partly responsible for last week's publication by the National Radiological Protection Board (NRPB) of a paper by Dr G. W. Dolphin, its Assistant Director (Research and Development).

The long-promised paper is substantially the one produced in September 1975 comparing the numbers of observed and expected deaths at Windscale from various cancers. It concluded that the difference was insignificant, but was much criticised, notably by the Flowers Commission on nuclear power and the environment, particularly in being limited only to those actually employed at Windscale.

With the aid of an independent consultant epidemiologist, Dr Peter Smith, BNFL is now to conduct its own two-year study of all 20,000 workers who have been employed at Windscale for any period of time in the past. Its findings will be lodged in a registry of radiation workers which the NRPB has established to produce a long-term study of those exposed to radiation. ☐

USSR

The web of 'secrecy'

Vera Rich reports on the case of Dr Naum Salanskii, now facing problems in seeking to emigrate from the USSR

THE prospect that this year's Diamond Jubilee of the October Revolution might be marked by a spirit of amnesty and a relaxation of pressure on dissidents and minority groups is beginning to look less realistic. A vicious attack on Andrei Sakharov in the embassy 'hand-out' publication *Soviet News*, the arrest of members of the 'Helsinki monitoring group' (including physicist Yurii Orlov and science-fiction writer Mykola Rudenko), and now the peculiar case of Dr Naum Salanskii in Vil'nyus, all indicate an intensification rather than a relaxation of pressure.

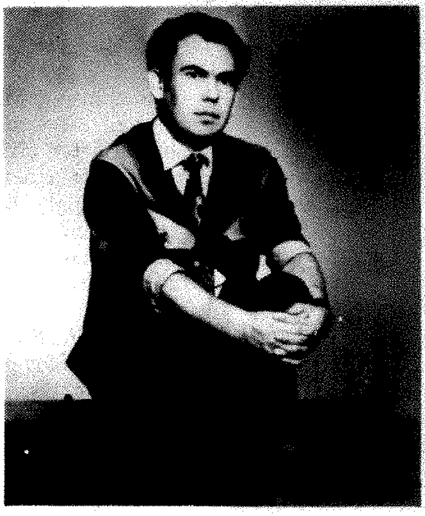
Dr Salanskii, formerly a laboratory head at the Institute of Physics of the Siberian Branch of the Academy of Sciences of the USSR, applied in 1975 to emigrate to Israel and was, according to standard Soviet practice, dismissed from his post. Before leaving the institute, however, he managed to obtain a document signed by the Director of the Institute, Professor I. A. Terskov, which stated unequivocally that "all the works by N. Salanskii were published at home and abroad in journals and other *non-secret* publications".

Dr Salanskii was nevertheless refused permission to emigrate, and on the grounds of his "secret work". With Professor Terskov now retired, Dr Salanskii found it impossible to get the new Director, Professor Pershov, to confirm his predecessor's assessment. While awaiting permission, Salanskii, like so many refusniks, became associated with Mark Azbel's illicit seminars. At the end of December 1976, when the authorities broke up the attempt of the seminar group to hold a three-day symposium on Jewish life in the USSR, several members were held for a time by the police. In Salanskii's case the matter is being taken further.

According to official statements, Salanskii is being investigated on the charge of having "slandered Soviet policy regarding the Jewish minority". The issue of secrecy also occurred several times during interrogations. On one occasion an investigator, Bakuchornis, told him that he had written to Salanskii's old institute enquiring about the alleged secrecy of his work and had already received a reply. On another occasion he was told by an official of the Central Committee of the Lithuanian Communist Party that no such enquiry was ever made nor had a reply ever been received since 'criminal proceedings' had been started. "This seems rather strange", Salanskii commented, in a telephone conversation last week; "first they said that enquiries had been made and a reply received, and suddenly all this has disappeared".

Salanskii is still trying to discover details of the accusation, and has asked the investigator to explain the policy of the USSR towards the Jewish minority which he is alleged to have slandered. According to Salanskii, the investigator said he was not an expert in this field and must look it up in a book. "It seemed very odd to me," says Salanskii, "that he has been working on my case for seven weeks, but still is unable to explain the accusation. As I do not know the essence of the case, I am in the meantime writing the history of my application for emigration [by way of a defence]. If I am taken to court, I will be handed the accusation just before the proceedings begin, so that I cannot prepare a defence."

Salanskii's case is noteworthy for several reasons. Isolated as he is in Vil'nyus, he does not have the moral support which one finds, for example, among the Moscow group of refusniks. And the issue of 'secrecy' has once again raised its bureaucratic head, but in this case it is not only the nature of Dr Salanskii's former work which is considered a secret, but apparently the charges against him too. An early decision has been promised as to whether the charges will be taken to court, dropped, or retained for further investigation—provided, of course, that the outcome of that decision is not itself considered an official secret. ☐



Naum Salanskii

IN BRIEF

Threat to Polish physicist

Miroslaw Chojecki, a Polish physicist and active participant in the unofficial Workers' Defence Committee, has been threatened with arrest. Chojecki, who was dismissed last December from the Nuclear Research Institute at Swierk, has been collecting materials on alleged police brutality and abuses of power in connection with the Radom and Ursus disturbances last June. On 12 February, he sent a memorandum to the Sejm (Parliament), to the Council of State, and to leading journals demanding that the Sejm should appoint a committee to investigate these abuses. Three hours later he was called to the office of the Chief Prosecutor and told that unless he withdrew the memorandum he would be charged and arrested.

The Workers' Defence Committee, set up last September, includes a number of scientists. Among the many recent letters of protest sent to the Sejm, one is from 13 scientists, another by 170 intellectuals, including some 30 scientists, and a third is from 28 professors, 14 of whom are either members of the Polish Academy of Sciences or else working at Institutes of the Academy.

Science adviser tipped

More than three weeks after President Carter's inauguration, vacancies still abound in the federal science agencies, and the most important post, the president's science adviser and head of the Office of Science and Technology Policy, was the only top White House job unfilled by the end of last week. There have, however, been some recent signs of movement. Several candidates were said to be under serious consideration for the science adviser's post last week, and the leading contender was rumoured to be Frank Press, head of the Department of Earth and Planetary Sciences at MIT.

Well regarded in science policy circles, Press was a member of the president's science advisory committee and a delegate to the test ban talks in the early 1960s. He is now a member of the national science board and chairman on the National Academy of Sciences' Committee on Scholarly Communication with the People's Republic of China. Though White House sources cautioned last Friday that Press's appointment was not cut and dried, an indication of high level interest is the fact that Press met with Carter for about half-an-hour last week.

Minister's vaccine statement

Ten days after an announcement that the UK Health Service Commissioner

Hard selling bugs

BACKGROUNDER

"Bugs by the bushel" read the headline to an item in the latest issue of the Pharmaceutical Society's journal, referring to an advertisement that appeared in *Nature* late last year. The advertisement itself, placed by the Ministry of Defence's Microbiological Research Establishment at Porton Down, was headlined "Bacteria by the Kilogram" (November 11, 1976—Cover 3). The journal had expressed concern that terrorists might acquire dangerous bugs.

A London evening newspaper picked the story up and ran it on the front page. The national dailies, ranging from the *Times* to the *Daily Mirror*, gave it prominence the following day, the *Times* on its front page. A spokesman from the Pharmaceutical Society was quoted as saying that all the bacteria named in the advertisement were very dangerous toxins, no less.

An MP who found the matter "outrageous" arranged to ask a question in the House of Commons about the offer. A junior minister, Mr John Gilbert, duly reported the same day that the sale of bacteria for civil research requirements was not a new departure for the MRE, though the offer by means of advertising was. And the storm seemed to pass.

What was the fuss about? The Pharmaceutical Society journal article focuses strongly on the implications of a particular section of the advertisement. Three words, in fact, saying that the MRE can supply the products advertised "to any destination". This does look worrying when the products include "toxic proteins" and "animal viruses", and when the MRE says, "We also grow new strains for research workers—if you have a requirement please ask if we can help". Small wonder, it seems, that others should latch on to the journal's worry about terrorists.

Mr Gilbert did have some comforting words in the Commons, however. The bacteria weren't dangerous pathogens. They were sold solely for research. And the phrase "to any destination" was there, he said—this, the catch-all British legitimation — to make it clear that export inquiries were welcomed.

Mr Gilbert also assured the Commons that the only bacterial species mentioned which could be conceivably harmful to humans were supplied only to bona fide customers at recognised laboratories or research institutes. They were dispatched in full conformity with international regulations.

The harmless species advertised included *E. coli*, found in the human gut, and *B. stearothermophilus* and *T. equaticus*, which are soil and water bacteria that do not infect man or animals. Researchers need bacteria in large quantities for the extraction of even small amounts of various microbial proteins. The MRE has the time, expertise and facilities to grow them.

Indeed, the MRE has recently expanded its Microbial Research Products Division to meet the growing demand for a wide variety of microbial products, in particular the restriction endonucleases — enzymes which snip DNA at precisely specified sites and which are now essential tools for recombinant DNA work and to generate DNA fragments for cloning. The MRE also has a contract service for researchers needing large quantities of particular bacteria.

What makes the latest development newsworthy is, as Mr Gilbert implied, the *Nature* advertisement. The Ministry of Defence decided last year that it will no longer meet the cost of providing facilities and staff at the MRE for the non-military work it does (military-related work is being transferred to the nearby Chemical Defence Establishment). That means researchers in microbiology in Britain stand to see the only facility of its type go to seed unless it can stand on its feet outside the Ministry of Defence. So to drum up business, the MRE has started advertising.

is to take up the cases of four children said to have suffered brain damage after whooping cough vaccinations, the UK Social Services Secretary, Mr David Ennals, last week told the House of Commons that despite their case he could not consider claims for vaccine-damaged children in isolation ahead of a Royal Commission report on liability and compensation for personal injury.

He expressed concern at the 60% fall in whooping cough vaccinations over the past three years, and added that the government's adviser on immunisation thought the policy of offering whooping cough vaccine should not be changed as the benefits far outweighed the risks.

UK coal report

With the help of continuing high inflation and a disappointing productivity performance the costs associated with expanding coal production in Britain to 135 million tons a year by 1985 have more than doubled from £1,400 million three years ago to £3,150 million. However, the British coal industry's tripartite group, embracing the government, the National Coal Board and the unions, shows no signs of changing the emphasis accorded to coal in the country's energy strategy. In its third report (*Coal for the Future*, free from the Department of Energy) updating progress on the ambitious 1974 "Plan for Coal", the group stresses the importance of research and emphasises the role for UK coal in EEC energy policy.

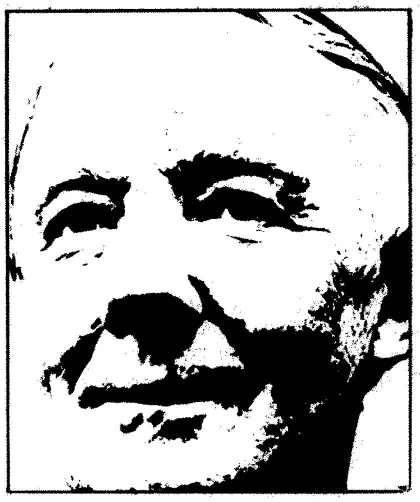
Energy unit set up

The UK Science Research Council has set up a support unit at its Rutherford laboratory to assist the energy research it funds at universities and polytechnics. Known as the Energy Research Support Unit (ERSU), it will also conduct feasibility studies for proposed projects and undertake necessary development work for industry to adopt research programmes.

Orkney ore demo

On the day that Orkney Island council's planning and development committee agreed to recommend the rejection of an application from the South of Scotland Electricity Board to survey for uranium, the island experienced what is believed to be its first-ever demonstration when some 400 people marched in opposition to the application. The SSEB has an agreement with some land owners and may appeal to the Secretary of State for Scotland to overrule the objections. The survey is partly financed by the EEC.

Close to the hedge



KENNETH MELLANBY

THE British landscape of small fields and hedgerows was the product of nineteenth century agriculture. Until recently, our most efficient farms were the most beautiful and provided plenty of cover for a rich selection of our native fauna and flora. British farmers consider that they are the real conservers of the countryside. This view has had official support, for most of the activities of farmers—rooting out hedges, ploughing ancient grass land, the erection or removal of all but the largest buildings—are free from planning controls. Today the whole question of rural land management and conservation needs to be re-examined.

The word 'conservation' has, unfortunately, many meanings. It can refer to the maintenance of the fertility of the soil, to preserving grass or forage as hay or silage, as well as to preserving wild animals and plants. Farmers in Britain are indeed conserving their soil and are not, as some critics suggest, destroying its structure by methods aimed at obtaining high yields today. In fact it is our most heavily cropped areas which are the most fertile; the field which gives the highest yield this year will probably give the highest next year also. Good farming is the best method of building up and maintaining the fertility of the soil.

Unfortunately, however, some recent agricultural developments, though doing wonders for food production, no longer ensure that rural Britain retains much of its beauty and diversity. In the second annual report of the Nature Conservancy Council the dangers of modern agriculture to wildlife are clearly described without any of the exaggerated overstatements which so often detract from the jeremiads of some conservationists. Large fields of clean, weed-free cereals and productive grass leys containing only one or two cultivars are of little value to wildlife. Though the willingness of many farmers to make some compromise by retaining cover on unproductive corners of their land is welcomed, it is clear that positive action by conservationists of all kinds is needed, and that much more money will have to be spent saving marshes and bogs, old grass and other habitats which have no useful place on the modern farm.

The situation is more serious than some of us, including scientists involved in these problems, may realise. Perfectly sound ecological research has suggested that some changes, particularly the removal of hedges, have done less damage to wildlife than is generally imagined. Many birds, for instance, have proved to be remarkably adaptable, and can still exist in substantial numbers when the landscape has been greatly impoverished. The somewhat theoretical 'index of diversity' may not be substantially reduced when many hedges and hedgerow trees are removed. These findings must not be allowed to make people over-optimistic. The fact is that many of the most influential conservationists are ornithologists and as long as birds are not too greatly affected, they have been apt to accept changes affecting plants and other animals. Now birds are useful as delicate indicators of pollution, but the purpose of the rest of the countryside is not only to provide them with living quarters.

Birds may tolerate the removal of many hedges and trees, but the shrubs and trees lost are themselves an important part of the native flora we wish to conserve. An oak tree is not only a roosting place for pigeons and kestrels, and the source of food for some 300 different species of insect; it is in its own right the largest chunk of wildlife to be seen on many acres of farmland. Conservation must devote more attention to preserving the common and everyday features of the countryside and must make the enjoyment of these easily available to our people in general if more public support and funds are to be used to protect the countryside. The conservation of rarities and the support for esoteric ecological studies is not enough.

news and views

Ferromanganese deposits: fast, fast, slow

from Peter J. Smith

FERROMANGANESE deposits on the ocean floor were discovered by the *Challenger* expedition more than 100 years ago and have been objects of scientific study and speculation ever since. In recent years, however, their existence (especially in the form of nodules) has become well known far beyond the scientific arena, largely because of their potential economic importance and the problems this has produced in devising a fair and workable international law governing the exploitation of the seabed. Some oceanographers have expressed resentment that this familiarity has given ferromanganese deposits a popular prestige totally unjustified by their volume in comparison with the volume of all oceanic sediments—a view that would perhaps carry more weight if the renewed interest in oceanic ferromanganese and associated metals had not drawn attention to the importance of hydrothermal processes at oceanic ridges. But nodules, slabs, grains, coatings and intrusions of oceanic ferromanganese remain a fascinating scientific issue quite independent of their economic implications.

Part of their scientific attraction undoubtedly lies in their ability to grow remarkably rapidly under suitable circumstances. On page 596 of this issue of *Nature*, for example, Burnett and Piper report the discovery of a ferromanganese crust which apparently grew at a rate in excess of 800 mm per million years. This figure may be put in perspective by the claim by Scott *et al.* (*Geophys. Res. Lett.* **1**, 355; 1974) that deep sea ferromanganese crusts and nodules generally grow at rates of 1–10 mm per million years. In addition, Burnett and Morgenstein (*Earth planet. Sci. Lett.* **33**, 208; 1976) report that in a forthcoming book Ku will conclude that "both the radiometric and nonradiometric techniques employed to assess . . . rates demonstrate conclusively that ferromanganese nodules of the deep sea grew at extremely slow rates . . . on the order of millimeters per million years."

It is not clear from this reference whether Ku's conclusion will be held to apply to all ferromanganese deposits, in which case the validity of claims for higher rates must presumably be denied, or whether it will be a more general statement applicable only to the majority of deposits. Either way, many claims for higher rates have certainly been made. One of the earliest was by Pettersson (*Medd. Oceanog. Inst. Goteborg, Ser. B* **2**, 1; 1943) who determined a growth rate of 1,000 mm per million years for a manganese nodule by measurement of its radium content. Using the same method, Von Buttlar and Houtermans (*Naturwissenchaften* **37**, 400; 1950) later found rates of 600–1,300 mm per million years for several other nodules. And more recently Scott *et al.* have reported growth rates of 130–250 mm per million years for a manganese oxide crust, and Moore and Vogt (*Earth planet. Sci. Lett.* **29**, 349; 1976) have obtained rates of 1,000–2,000 mm per million years for similar crusts.

Some of the most astonishing rates of growth, however, were discovered by Goldberg and Arrhenius (*Geochim. cosmochim. Acta* **13**, 153; 1958) who reported finds on the sea floor of an approximately 50-yr old naval shell with a Mn–Fe oxide coating almost 30 mm thick and a World War II shell with a coating about 15 mm thick, indicating growth rates of about 60,000 and 100,000 mm per million years respectively. Admittedly these deposits formed in shallow near-continental waters and may thus not be comparable to deep sea deposits. On the other hand, their ages could be inferred directly without recourse to radiometric and other physicochemical methods of dating, and so the determined growth rates are fairly certain, at least to the correct order of magnitude. Unfortunately, this is not so for older ocean floor deposits—a situation which leaves room for doubt about the validity of measured growth rates in general.

Indeed, Burnett and Piper acknowledge the possibility of doubt in showing that different methods of dating lead to quite different estimated growth rates. Specifically, the rate of 800 mm per million years was obtained by hydration-rind dating and by measuring an excess ^{230}Th exposure age; uranium-series dating gave a much lower rate of about 48 mm per million years. Burnett and Piper give apparently valid reasons for supposing the latter rate to be incorrect, thus making a case which Burnett and Morgenstein recently developed at greater length. In the previous study, of four Pacific ferromanganese deposits, two had uranium-series and hydration-rind dates in agreement whilst two produced significant discrepancy. In each of the two disagreeing cases the uranium-series date was the lower, further study suggesting that it was incorrect because of a thorium distribution controlled by processes in addition to radioactive decay.

In spite of such problems, however, it seems likely that when dating methods have been fully assessed and possible sources of error identified, many of the higher (as well as the lower) growth rates claimed for ferromanganese deposition will be substantiated In other words, there is apparently a wide variation in growth rates which must be taken into account in deciding how deposits form. Over the past 100 years many models have been proposed to explain the origin of ferromanganese deposits, including the interaction of sea water with submarine volcanic products, direct precipitation from sea water of land-derived ferromanganese, and the remobilisation of ferromanganese from oceanic sediments or underwater igneous outcrops. But although these processes may play some part in some or all circumstances (for example, direct precipitation may largely account for the high deposition rates often observed in near-continental shallow water), high rates of growth observed in samples from oceanic ridges suggest the existence of at least one other major source.

In recent years this has been identified as hydrothermal activity, which in this context means the circulation of seawater within cracks and pores of hot, newly-formed basaltic crust, the leaching of metals from that crust and the consequent metal enrichment of the resulting hydrothermal fluids. Hydrothermal activity is the most likely candidate for several reasons, not the least of which is the need to invoke it for other purposes such as to explain the distribution of heat flow in the vicinity of oceanic ridges. But more directly, by extrapolating from the East Pacific Rise, Lyle (*Geology* **4**, 733; 1976) has recently estimated the total input of hydrothermal manganese to the world's oceans to be about 9×10^8 kg yr^{-1}, or nearly four times the dissolved load of manganese carried by rivers. Unfortunately, there are no reliable figures available for the detrital input of manganese, and so the total contribution from the continents remains unknown. Nevertheless, by any standards hydrothermal activity is evidently an important source of oceanic ferromanganese. □

How does T4 turn off *E. coli*?

from Christopher G. Goff

IT has been clear for a long time (on the time scale of molecular biology) that bacteriophage T4 can turn off the expression of *E. coli* genes in its host cell, while continuing to direct synthesis of its own gene products (Benzer *Biochem. biophys. Acta* **11**, 383; 1953; Hayward and Green *Proc. natn. Acad. Sci. U.S.A.* **54**, 1675; 1965). This is true despite the fact that expression of T4 genes depends throughout infection on the *E. coli* transcription enzyme and *E. coli* protein synthesis machinery. A satisfactory explanation of this "host shutoff" has been hard to come by. We know that T4 degrades *E. coli* DNA, while protecting its own genome from self destruction by replacing its cytosine with hydroxymethylcytosine, not recognised by T4 nucleases. But host gene products stop appearing well before *E. coli* DNA is broken down. The shutoff mechanism is obviously complex; it may involve more than one of the numerous T4-specified changes which occur in both the transcription and translation apparatus of *E. coli* after infection. Nevertheless two recent papers suggest how one specific T4 protein bound to *E. coli* RNA polymerase may be a major factor in the shutdown of *E. coli* RNA synthesis after infection.

There are four T4 proteins non-covalently attached to *E. coli* RNA polymerase after T4 infection (Stevens *Proc. natn. Acad. Sci. U.S.A.* **69**, 603; 1972). Two of these, the products of T4 genes *33* and *55*, are positive control elements needed for synthesis of the major class of T4 RNA appearing late after infection (Horvitz *Nature new Biol.* **244**, 137; 1973; Ratner *J. molec. Biol.* **89**, 803; 1974). Another of these four proteins, 10,000 daltons in size but genetically undefined, apparently alters or inactivates the sigma subunit of RNA polymerase (Stevens & Rhoton *Biochemistry* **14**, 5074; 1975), at least *in vitro*. The fourth, 15,000 daltons in size, has until now been mysterious; no lethal mutations have defined its gene or its function. But Snyder's lab at Michigan State has recently reported (Sirotkin, Wei & Snyder *Nature* **265**, 28; 1977) that the *alc* mutants isolated last year by Snyder, Gold, and Kutter (*Proc. natn. Acad. Sci. U.S.A.* **73**, 3098; 1976) affect this T4 protein. These *alc* mutants were isolated in a multiply-mutant strain of T4 unable to synthesise hydroxymethylcytosine and unable to degrade normal cytosine-containing DNA. One might expect these phage, whose DNA contains cytosine, to be viable; but they are not, because (it turns out) they cannot make the 'late' class of T4 mRNA. A single additional mutation—in the *alc* gene—permits these cytosine-containing T4 to transcribe late RNA and grow. Snyder's lab now finds that many *alc*$^-$ phage fail to attach normal amounts of the 15,000 dalton protein to *E. coli* RNA polymerase. This suggests (but doesn't yet prove) that *alc* codes for the 15,000 dalton protein. Moreover, they find that several times more *E. coli*-specific RNA continues to be made after infection with *alc*$^-$ T4 than with *alc*$^+$ T4. Here again, more data are needed, but it is possible that the presence of functional *alc* protein prevents RNA polymerase from transcribing cytosine-containing DNA, whether that DNA encodes T4 genes or *E. coli* genes. This hypothesis could explain why no conditional lethal 15,000 dalton protein mutants have been found in normal T4: the protein would not be necessary for transcription of the usual hydroxymethylcytosine-containing phage DNA, and failure to shut off host RNA synthesis would not be lethal either.

How might the *alc* protein block transcription of cytosine-containing DNA? Baralle and Travers (*Molec. gen. Genet.* **147**, 291; 1976) have recently found that *E. coli* RNA polymerase purified from T4-infected cells (and containing the 15,000 dalton T4 protein in question) has a lower affinity for *E. coli* rRNA promoters than does *E. coli* RNA polymerase from uninfected cells. This is true even when both forms of the enzyme are given excess initiation-specificity subunit sigma. The difference is very likely due to the 15,000 dalton protein; the authors have evidence that Stevens' 10,000 dalton T4 protein and an ADP-ribose residue added to the α subunit of RNA polymerase (Goff *J. biol. Chem.* **249**, 6181; 1974) are not responsible. In some *in vitro* conditions which permit normal *E. coli* RNA polymerase to initiate synthesis rapidly at rRNA promoters, the enzyme from T4-infected cells is unable to use those promoters at all. In these conditions, then, the 15,000 dalton protein seems to cause essentially complete shutoff of rRNA synthesis. The big question in any such *in vitro* experiment is, of course, "What are the conditions *in vivo*?"; but certainly the 15,000 dalton (putative *alc*) protein could have a role in host shutoff. Travers has suggested before that RNA polymerase can "flip-flop" between a form active on ribosomal RNA promoters and one or more forms active on mRNA promoters, and that guanosine tetraphosphate (ppGpp), associated *in vivo* with the stringent response, forces RNA polymerase out of its rRNA-specific conformation (*Molec. gen. Genet.* **147**, 225; 1976). In their *Molecular and General Genetics* paper, Baralle and Travers show that the T4 infection has the same effect on RNA polymerase as ppGpp; the nucleotide cannot further reduce the fraction of rRNA made by the enzyme from T4-infected cells, in any *in vitro* conditions. So the *alc* protein may be an allosteric effector locking RNA polymerase in a form inactive on at least some *E. coli* promoters—and conceivably inactive on T4 promoters as well, if they contain cytosine rather than the usual hydroxymethylcytosine.

There are still a lot of questions here, even if Snyder and Travers are completely right. Baralle and Travers' *in vitro* experiments reveal no reduction in transcription of φ80 mRNA from cytosine-containing DNA when the 15,000 dalton protein is present. Would the *alc* protein alone prevent use of cytosine-containing T4 promoters *in vivo*? Mailhammer *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **72**, 4928; 1975) saw a significant reduction of *E. coli* β-galactosidase synthesis in a coupled *in vitro* protein synthesising system when they used RNA polymerase from T4-infected cells; they attributed the apparent shutoff of *E. coli* mRNA synthesis to the ADP–ribosylation of the α subunit. *In vitro*, and presumably *in vivo*, active sigma protein is required for transcription of both *E. coli* and T4 genes. Yet Stevens' 10,000 dalton T4 protein inhibits sigma function *in vitro*; this T4 protein has been largely ignored in the studies mentioned here. Possibly the *alc* protein, ADP–ribosylation of α, and the 10,000 dalton protein all play a part in shutoff of *E. coli* transcription when T4 infects the cell. □

Bacterial adherence

from a Correspondent

THE ability of many pathogenic as well as beneficial microorganisms to attach to a particular surface of their host is one obvious requirement for colonisation and in some cases invasion of that host. The initial attachment of bacteria to the nasal or intestinal mucosa, for example prevent them from being washed away or dislodged by a cough or a sneeze. But surprisingly, little is known about the initial interactions between colonising bacteria and the host tissues. Some recent work suggests, however, that the interactions may be considerably more complex and specific than previously realised and some of the surface molecules involved have been identified.

Since carbohydrate, in the form of glycoproteins or glycolipids, is an important constituent of most cell surfaces, including bacterial and mucosal surfaces, a role for these substances in bacterial adherence has been suspected for more than 20 years. Duguid and colleagues, following an earlier observation of Collier and de Miranda, were the first to show this directly by using mannose to inhibit binding of *Escherichia coli* to intestinal epithelial cells (*J. Path. Bact.* **74**, 397; 1957). A large number of other simple sugars were tested and found to be inactive. The bacterial surface component responsible for adherence appeared only in old non-growing cultures about the same time as filaments appeared. These original observations have now been taken a step further by Ofek, Mirelman and Sharon (see this issue of *Nature*, page 623). They show that in agreement with the earlier results binding of non-pathogenic K12 or B strains of *E. coli* to human cells is specifically inhibited by mannose or mannosides. Binding is also shown to be inhibited by a mannose-seeking plant lectin (concanavalin A) which presumably competes with the bacterial surface component for epithelial cell-surface mannose receptors. These receptors are destroyed by mild periodate treatment of the epithelial cells, which is consistent with the presence of mannose-like receptors, since these groups are particularly susceptible to periodate oxidation. The bacterial component (a lectin) is extracted into simple buffers without detergents and is presumably part of the filaments seen in adhesion-competent organisms, rather than being an integral part of the bacterial envelope. The soluble component, as yet unpurified, agglutinates cells at high dilution and inhibits attachment of *E. coli* to cells. It is a protein or perhaps glycoprotein which is destroyed by trypsin or heat.

The nature of the periodate-sensitive epithelial cell receptors carrying mannose and recognised by the bacterial lectin is unknown. Not surprisingly, mucins present in intestinal tract secretions, which contain little mannose, were found by Duguid and Gilles to be poor inhibitors of bacterial adherence. Other glycoproteins containing more mannose and binding concanavalin A are presumably the functional receptors. Perhaps these glycoproteins are more intimately associated with the mucosal cell surface membrane since ultimately invasion of the mucosal lining (perhaps by phagocytosis) takes place. Alternatively, these later membrane-mediated events in bacterial invasion may involve additional interactions between the epithelial cell surface and other bacterial surface components.

A wide range of *E. coli* strains show mannose-sensitive binding to host cells and to erythrocytes in haemagglutination (Jones & Rutter *J. gen. Microbiol.* **84**, 135; 1974), although not all, even some which produce enterotoxin, are pathogenic. Two *E. coli* surface components appear, however, to correlate exactly with pathogenicity in pigs and calves. These are the K88 and K99 antigens respectively (Jones & Rutter *op. cit.*; Burrows, Sellwood & Gibbons *J. gen. Microbiol.* **96**, 269; 1976). The K antigens are proteins, most probably glycoproteins, since a small amount of carbohydrate is present even in the purest preparations, and can be distinguished from the lectin-like substance by their binding to mucosal epithelial cells in the presence of mannose. Like the lectin, however, their production by bacterial strains always correlates with the appearance of fine branched filamentous projections covering the surface of the cell. Together with the mannose-binding lectin, the K antigens may form a part of the projections and if so are then favourably placed to interact with the surface of the preferred host cell.

So far analogous surface antigens on human enteropathogenic strains have not been identified unequivocally but it is reasonable to assume that such components, in addition to the lectin identified by Duguid and Ofek *et al.*, are necessary for the successful colonisation and invasion of the human intestinal tract as opposed to the normal colonisation of the colon.

Clearly, the relation of mannose-binding lectin and the K antigens in bacterially-induced neonatal diarrhoea is of great interest, since this disease is now one of the major causes of death in small children in developing countries (Sack *A. Rev. Microbiol.* **29**, 333; 1975) as well as being a severe economic burden in livestock production. In the future, more detailed identification of those surface components involved in bacterial adherence could lead to rational schemes for the preparation of broad range vaccines effective in blocking or reversing bacterial attachment. Such vaccines may have advantages over more conventional vaccines which aim to neutralise toxins which are active at a later stage in infection. □

Optical fibres in communications

from a Correspondent

ONE of the consequences of rapid growth in demand for telegraphic communications is a continuing search for more efficient ways of transmitting information over large distances (see *Nature* **261**, 371; 1976). High rates of signalling call for transmission lines with high frequency response; hence our telephone services now make use of microwave devices at very high frequencies of the order of 10^9 Hz. It was inevitable that in the search for ever higher transmission rates electromagnetic waves in the visible range would be considered. With frequencies of the order of 10^{15} Hz, light waves are potentially capable of solving line-capacity problems for the foreseeable future.

One difficulty is that light is so easily absorbed. Line-of-sight transmission through the atmosphere is too unreliable to be of use, and research has concentrated on channelling the light inside fine glass fibres which can be made at relatively low cost and have the flexibility associated with ordinary wires (see for example, Chynoweth *Phys Today* **29**(5), 28; 1976). If sufficiently transparent glasses can be found, these fibres will be the telephone wires of the future. At the recent Solid State Physics Conference in Manchester, UK, glasses having losses as low as 0.5 dB km^{-1} were reported in a review lecture given by W. A. Gambling.

Disordered materials in general and glasses in particular present some of the most difficult problems in solid state physics. Absorption of photons takes place by electrons which are thrust into unoccupied states of higher energy. In crystalline materials transparency results when there is a gap in energy between occupied and unoccupied states which is too wide for the photon energy to excite electrons across, any residual absorption is due to impurities or imperfections in the crystal. In a glass there is no well-defined energy gap and its transparency must be explained in another way; despite the absence of an energy gap there exists a range of energies in which the electronic levels are localised rather than extended over the whole of the material. Transparency in glass comes about because, although there may be empty states of the correct energy to receive an electron which has just been excited from a localised state by a photon, these empty states are almost certainly localised in a different part of the glass and so are not available to receive the electron. Thus a glass may have excellent transparency limited only by scattering from statistical irregularities in density frozen in at the solidification temperature, provided it contains no impurities which themselves can absorb light. Iron and copper are particularly troublesome contaminants and must be reduced to the level of 1 part in 10^9 for really low losses.

To achieve such purity novel methods of glass manufacture are used. In one method silicon tetrachloride gas is reacted with oxygen to deposit silica on the inside of a quartz tube. Dopants can be introduced into the gas to vary the refractive index of the deposit, which is important for controlling propagation of light in the fibre. After sufficient silica has been deposited, the tube is collapsed and the fibre-drawing process begun. Several kilometres can be pulled from a single tube.

Currently it is possible to produce optical cables with low enough losses ($\sim$4 dB km^{-1}) to allow distances of several kilometres between repeater stations, and test lines have already been installed near Ipswich in the UK by the Post Office. Developments in glass technology already in hand should assure the economic advantage of the new method of transmission in the near future. ☐

HPRT mutants

from Dallas Swallow and Sue Povey

MUTANT cells deficient in the enzyme hypoxanthine phosphoribosyl transferase (HPRT) have been isolated from cell cultures of a variety of mammalian species. These deficient cells have been selected, in many cases after mutagen treatment, in medium containing purine analogues such as 6-thioguanine which are toxic to cells containing HPRT. However, the nature of the mutations involved has been the subject of much debate. Whereas some of the mutants can most readily be explained by mutations in the X-linked structural HPRT locus, as an altered HPRT protein has been identified, many are probably regulatory. This was originally suggested by the lack of the expected relationship between cell ploidy and mutation rate (Harris *J. Cell Physiol.* **78**, 177; 1971; Chasin *J. Cell Physiol.* **82**, 299; 1973) and further, by the occasional reappearance of apparently normal rodent HPRT following somatic cell hybridisation between a rodent cell line deficient in HPRT and a normal human cell (Watson *et al. Expl Cell Res.* **75**, 401; 1972; Shin *et al., Nature new Biol.* **241**, 194; 1973; Croce *et al. Proc. natn. Acad. Sci. U.S.A.* **70**, 2590, 1973).

In a recent paper Milman and coworkers have examined HPRT in the aneuploid human cell line HeLa, using an elegant technique characterising the enzyme in terms of isoelectric point and subunit molecular size (*Proc. natn. Acad Sci. U.S.A.* **73**, 4589; 1976). The protein synthesised by these cells was labelled with ^{35}S-methionine and cell extracts subjected to isoelectric focusing followed by electrophoresis in sodium dodecyl sulphate. In the two-dimensional autoradiograph obtained, the spot corresponding to the usual HPRT was identified by several criteria including its removal by immunoadsorption using specific anti-HPRT antiserum. This spot was absent in each of 24 6-thioguanine resistant colonies isolated from HeLa after mutagen treatment. One of these $HPRT^-$ mutants, however, produced a new spot, different in isoelectric point but of the same subunit molecular size, and also cross reacting with the anti-HPRT serum. Five independent revertants of this 'missense' mutant, able to grow in MTH medium (containing methotrexate, thymidine and hypoxanthine) which selects for the presence of HPRT, were isolated. All of these, even after repeated cloning, contained spots corresponding to both the usual and the abnormal HPRT proteins. From these revertants further 6-thioguanine resistant colonies could be readily obtained and these had again lost the 'usual' HPRT spot.

If one accepts that the revertants were indeed true clones the simplest explanation of this intriguing experiment is that the loss of HPRT in the 'missense' mutant was due to a mutation at the structural locus, and that the revertants represent activation of some HPRT locus specifying an enzyme indistinguishable from the usual one, but not normally expressed. As HPRT is known to be multimeric (see, for example, Olsen & Milman *J. biol. Chem.* **249**, 4030, 4038; 1974) it would be of interest to examine these revertants using a technique which might demonstrate heteromeric isozymes. The existence of such hybrid forms would confirm that both genes are active in the same cell at the same time.

It is not entirely clear whether HeLa resembles other clonal cultures derived from female somatic cells in having only one active X chromosome. However, if this is the case, then an attractive hypothesis to explain the findings is the reactivation of the HPRT gene on the normally inactive X chromosome. Although many attempts to reactivate the inactive X chromosome in cultured somatic cells have not been successful (see for example Comings *Lancet* **ii**, 1137; 1966; Migeon *Nature* **239**, 87; 1972), good evidence for reactivation of the HPRT locus was obtained in one series of human–mouse hybrids (Kahan & DeMars, *Proc. natn. Acad. Sci U S A.* **72**, 1510, 1975). In this experiment the authors were able to identify both X chromosomes by virtue of one's being present as an X-autosome translocation and also by heterozygosity for the X-linked enzyme, glucose-6-phosphate dehydrogenase (G6PD) as well as HPRT deficiency. HPRT$^+$ clones were selected using HAT medium (hypoxanthine, aminopterin and thymidine). All the clones contained human HPRT, as identified immunologically, and the inactive X chromosome which carried the normal HPRT gene, but not the active X chromosome. The other X-linked enzymes, G6PD and phosphoglycerate kinase, were not detectable suggesting that the derepression was very localised. If reactivation of the HPRT locus on the inactive X chromosome does account for the reappearance of HPRT in the HeLa clones of Milman *et al.*, it would be interesting to test other X-linked loci in these cells.

It has been deduced from family studies that Henrietta Lacks from whom the HeLa line was derived was a heterozygote for G6PD (type BA), although the cell line HeLa is G6PD A (Hsu *et al. Science* **191**, 392; 1976). Thus it would be interesting to test G6PD in these clones to look for the derepression of the G6PD B allele on the inactive X chromosome.

Future experiments may throw some light on the mechanism of the maintenance and possible reversal of X-inactivation. It is unclear whether a similar explanation could account for some of the rodent revertants, since the X chromosome constitution and indeed the sex of origin of the various long-term rodent lines are in many cases unknown. However, it is possible that some completely different phenomenon which might have more general application to autosomal loci, will be found to explain the reappearance of HPRT in the experiments of Milman and others. □

More Luna results

from J. A. Edgington

LAST year's successful flight of Luna 24, the third Soviet spacecraft to return lunar samples to Earth, coincided with the Viking landings on Mars and attracted less attention than it deserved. Its core sample from Mare Crisium is now being examined in Moscow and Western scientists hope to receive some of this material soon. Under a US–Soviet agreement the US has provided 3 g from each of the six Apollo flights, and the Russians have reciprocated with 3 g of Luna 16 and 2 g of Luna 20 sample, out of total sample returns of 100 g and 50 g respectively. In addition, 1 g from each Luna mission was donated to French investigators, and 500 mg to British scientists.

All but about 100 mg of each UK sample was divided between eight investigating teams, and accounts of the separation procedures, together with experimental results from some of the investigators, have recently appeared in *Phil. Trans. R. Soc.* (**A284**, 131; 1977). Luna 16 landed in Mare Fecunditatis in 1970, and Luna 20 in a nearby highland area in 1972; papers by the American and French investigating consortia appeared some time ago (see *Geochim. cosmochim. Acta* and *Earth planet. Sci. Lett.* for April and September, 1973). The present articles, perhaps because of their relatively leisurely publication, provide good examples of small sample techniques and of careful data interpretation.

For example, N. N. Greenwood *et al.* (University of Leeds) have used Mossbauer spectroscopy to estimate the relative abundances of iron-bearing minerals, and their interpretation of the spectra, based on experience with Apollo samples, is somewhat different from that of the Russian workers (for example, T. V. Malysheva, *Proc. 3rd. Lunar Sci. Conf.* 105; 1972) and generally more cautious. However, one feature consistently observed in lunar fines material, a pronounced asymmetry in the pryroxene absorption spectrum, is definitely ascribed by the Leeds group to the presence of extremely small particles of metallic iron, which moreover they have shown to be concentrated in the surface layers of the fragments. At the University of Newcastle, S. K. Runcorn's group has shown that this iron is superparamagnetic and exhibits an inverse square law spectrum of grain volumes, extending to diameters much less than 13 nm.

The origin of this free iron, which is found in both mare and highland soils, is a topic of great current interest. It is non-meteoritic, being almost nickel free, and is thought to be produced by preferential sputtering by the solar wind. If so one might anticipate the presence of implanted carbon in association with it, and G. Eglinton's group at the University of Bristol has found just this. In place of the pyrolysis method, which determines only total carbon content, the Bristol group have developed an acid dissolution technique using deuterochloric acid, DCl, for their lunar sample studies. Trapped hydrocarbons release mainly CH_4 and may thus be distinguished from the acid-hydrolysable carbon, mainly the free element, which is released as CD_4. Eglinton *et al.* show that the content of hydrolysable carbon correlates strongly with iron content and magnetic susceptibility, although only for the Luna 20 samples did they note an increase in hydrolysable carbon with diminishing grain size. This may reflect the fact that Luna 16's basaltic soil is derived from a material of lower melting point than the gabbroic soil returned by Luna 20. The arguments used here are complex and will certainly be examined closely, though Eglinton's group has recently presented clear evidence for the intimate association of carbon and α-Fe in synthetic materials (Jull *et al. Nature* **262**, 566; 1976).

Like the Bristol workers, S. H. U. Bowie and colleagues (Institute of Geological Sciences) have produced very precise results from exceptionally small samples. Their measurements of oxygen isotopic ratios show an enrichment of ^{18}O (of about 0.65%), compared with terrestrial ocean water, in good agreement with previous measurements and apparently typical of the lunar regolith. This isotopic differentiation is also usually attributed to the sputtering action of the solar wind, so its value should relate to the exposure time of the material. Bowie's group find a complex variation of enrichment with grain size, and suggest that this may most reasonably be explained by the presence at one locality of impact ejecta from many distant sites, each with a different exposure history.

The last paper of the collection—by P. H. Cadogan and G. Turner (University of Sheffield)—describes the determination of ^{40}Ar–^{39}Ar ages of four samples, two each from Luna 16 and 20. The former yield an age of 3.4–3.5 Gyr for the Fecunditatis basalts, in excellent agreement with the Caltech group (*Earth planet. Sci. Lett.* **13**, 368 and 375; 1972). Apollo samples from the other major basins all show a range of ages of 0.2–0.3 Gyr, and the present lack of evidence for such an extended period in Fecunditatis cannot be regarded as significant on the basis of so few measurements. A metaclastic fragment from the Luna 20 sample, probably typical of the adjacent Crisium basin, yielded an age of 3.9 ± 0.1 Gyr.

Cadogan and Turner assign a minimum age of 4.3 ± 0.1 Gyr to their Luna 20 anorthosite fragments. There are now many highland samples dated to this period, and controversy has developed over how to interpret these ages. Are they evidence for a lunar cataclysm, comprising a few major basin-forming events, which ended 3.9 Gyr ago? Alternatively, can they be accounted for by a steadily decreasing cratering rate, resulting in a statistically-determined distribution in which individual ages reflect the latest event to reset the Ar clock? Cadogan and Turner favour the calaclysmic theory. Samples from Luna 24 should arrive at Houston in the spring and radiometric results from them are eagerly awaited. ☐

Morphogenesis of the mammary gland

from John K. Heath

UNDERSTANDING the mechanisms underlying the formation of organs poses a formidable problem to the developmental biologist. It is known that in most systems interactions between the epithelium of the organ rudiment and its adjacent mesenchyme are involved, but these interactions have proved to be complex. Two recent pieces of work which use the mouse mammary gland, present new experimental approaches which may provide an insight into this problem.

If the mammary epithelium is cultured in contact with mammary mesenchyme the tissues undergo typical mammary morphogenesis and differentiation, but if the epithelium is cultured alone its development is curtailed. If salivary gland is used as the source of mesenchyme, however, the subsequent morphogenesis of the mammary epithelium is typical of the salivary epithelium (Kratochwil *Devl Biol.* **20**, 46; 1969), but the biochemical properties of the mammary epithelium in this case, however, are similar to normal mammary glands *in situ*. Sakakura *et al.* (*Science* **194**, 1439; 1976) have now taken submandibular salivary gland mesenchyme from mouse embryos 14 days after conception and combined it with mammary epithelium from 16 day post-conception female embryos. After a brief period of culture the combined tissues were transferred to a site under the kidney capsule of adult female mice. Subsequent histological examination of the transplants revealed the typical salivary pattern of morphogenesis But if the mice carrying the grafts were mated and allowed to give birth and lactate, the ducts in the graft became distended with milk. Biochemical studies showed the transplanted tissues to be producing amounts of the B protein of lactose synthetase similar to those found in lactating mammary glands *in situ*. These findings show that although the mesenchyme plays an important part in determining the overall form, the cytodifferentiation of the gland is either already determined by 16 days or is independent of the underlying mesenchyme.

The use of heterologous mesenchyme in recombination experiments is common. But by the time experimental recombinations can be made many interactions involved in the formation of the organ may have occurred. Another problem is that although interactions can be demonstrated it is hard to tell which tissue takes the lead in determining the subsequent path of development. These difficulties have been circumvented by the exploitation of a mutant gene affecting the differentiation of the mammary gland (Kratochwil and Schwartz *Proc. natn. Acad. Sci. U.S.A.* **73**, 4041; 1976).

The mammary gland of the male can be distinguished from that of the female by the fourteenth day of gestation since it undergoes regression and either disappears completely or remains in a rudimentary state (depending on the strain of mouse used). The mesenchyme surrounds an epithelial bud and begins to condense around it. The bud then starts to undergo necrosis and the 'stalk' of the bud is cut off. This pattern of regression can be inhibited by destruction of the foetal testes and can be induced in females by administering testosterone. The involvement of exogenous substances such as hormones would seem only to complicate an already difficult situation. However Kratochwil and Schwartz have shown how the action of testosterone can be used as a starting point for unravelling the interactions involved in the process of regression.

They asked whether the hormone exerts its effect on the mesenchyme or the epithelium or both The key to the solution of this problem was the use of the X-linked mutant 'Testicular Feminisation' (Tfm), tissues of which are insensitive to testosterone (probably due to a malfunctioning hormone receptor molecule). Although a X^{Tfm}/Y mouse is genetically male it lacks male secondary sex characteristics, and in particular the mammary glands do not show the typical testosterone-induced regression. Kratochwil and Schwartz combined epithelium and mesenchyme from X^{Tfm}/Y and X/Y embryos and observed the effects of testosterone on their development. The regression response occurred only if the mesenchyme was wild type. This implies that testosterone initially acts on the mesenchyme and that the subsequent fate of the epithelium is determined by the mesenchyme. An interesting corollary of this observation is the implication that the necrosis of the epithelium is the result of killing by the mesenchyme as opposed to the cell-autonomous suicide typical of cell death in other systems.

The exploitation of appropriate mutants has proved of enormous value in other developmental problems and Kratochwil's work has opened up the possibility of their use in the study of organogenesis. In addition these experiments may lead to the use of other hormone-triggered tissue interactions for looking at epithelial/mesenchymal interactions. ☐

Hot white dwarfs and the EUV

from M. G. Edmunds

APART from the Sun, very few astronomical sources have yet been detected in the extreme ultraviolet (EUV) wavelength region 100–1,000 Å. The flight of the Apollo–Soyuz mission in July 1975 provided a platform for a grazing-incidence mirror telescope with a filter photometer, and the detection of two sources outside the Solar System has been reported. Both sources have good positional identification with white dwarf stars, and the second of these (Margon *et al. Astrophys. J. Lett.* **210**, 79, 1976) is Feige 24, a well-known spectrophotometric standard at visible wavelengths.

The EUV continuum observations have implied a considerably higher atmospheric temperature for these white dwarfs than had previously been assumed. At optical wavelengths the continuum radiation energy distribution is fairly insensitive to the atmosphere parameters, but model atmosphere calculations suggest that the fluxes in the EUV are more sensitive, especially shortward of the once-ionised helium absorption edge at 229 Å, provided that there is a significant helium abundance in the star's atmospheres. The temperature of the other white dwarf HZ43 has been inferred to be as high as 10^5 K, and it is detected as a very soft X-ray source Although high for a white dwarf, such a temperature is comparable with temperatures derived for the central stars of planetary nebulae by the Zanstra method—in which the ultraviolet flux from the star is indirectly estimated by observation of optical re-emission of the energy from the ultraviolet radiation absorbed by the nebular gas surrounding the star. Thus it is reasonable that HZ43 is a fairly young white dwarf, still very hot after passing through the planetary nebula stage, in which it shed its outer layers during its evolution from a giant.

The EUV observations and ultraviolet data from the Orbiting Astronomical Observatory 2 (Holm *Astrophys. J. Lett.* **210**, L87) imply that Feige 24 is not quite so hot, around 6 to 7×10^4 K. To predict the EUV fluxes, Margon *et al.* attempt a model atmosphere calculation for a pure hydrogen atmosphere, and they find that the low observed flux shortward of 170 Å implies that there must be at least some helium present in the atmosphere to provide enough opacity shortward of the ionised helium edge. They suggest a possible, but less probable, alternative in the presence of absorption by ionised helium in the interstellar gas. Feige 24 is known from spectroscopic evidence to be a binary pair of a white dwarf and a cool main sequence dwarf showing emission lines. By subtracting the expected infrared flux of the white dwarf from the total flux of the pair, Holm deduces the energy distribution and hence a rough classification for the main sequence star. By comparison with known main sequence stars, it is then possible to infer a distance of about 90 pc for the binary pair. For a spectral region shortward of the Lyman limit at 912 Å there is very strong absorption in the interstellar medium by bound–free transitions of neutral hydrogen. The detection of any EUV flux from Feige 24 at this distance indicates that the local interstellar hydrogen is only about 0.01 to 0.02 particles per cubic centimetre, very low compared with the mean value for the Galactic plane of about 0.6 particles per cubic centimetre. This reinforces the view that the interstellar medium is very clumpy, with strong concentrations into clouds coexisting with a tenuous intercloud medium.

It has been suggested that Feige 24 shows the spectral characteristics of old novae, in which accretion of gas from the red dwarf across onto the white dwarf has liberated radiation. If such processes are still occurring, the resulting radiation is liable to be variable, and the continued use of Feige 24 as a spectrophotometric standard might justifiably be questioned. ☐

Effects of photon momentum

from a Correspondent

THE photon dynamics resulting from light absorption by an atom are sufficient to cause an observable deflection of the excited atom. Radiation effects of this nature can now be utilised as techniques in atomic scattering experiments opening up a new and exciting area of investigation.

The advent of commercially available tunable continuous wave (CW) dye laser systems now enables atomic physicists selectively to prepare the target atom in a scattering experiment in a well defined excited atomic state. The tunable power currently available (several milliwatts at a bandwidth of 5 MHz) is sufficient to maintain the necessary excited state population required for a scattering experiment to be performed. The sodium atom with its resonance transition 3^2S–3^2P, suitably placed in the region of efficient organic dye operation is a very attractive candidate for optical pumping. Work on the scattering of state selected sodium atoms ($3^2P_{3/2}$) off neon atoms has been reported (Carter *et al.*, *Phys. Rev. Lett.* **35**, 1144; 1975) in the determination of ground and excited potentials of the NaNe molecules. Hertel *et al.* (*J. Phys. B.* **7**, 570; 1974) were the first to perform high resolution electron scattering experiments on laser-excited sodium atoms where elastic, inelastic and superelastic processes were studied.

In the work by Hertel only differential cross section $\sigma(\theta)$ measurements were made where the scattered electron was monitored over a limited angular scattering range θ. To establish a total cross section, measurement of $\sigma(\theta)$ is required over the angular range $\theta = 0$ to 180°. An alternative method for directly measuring the total cross section σ for electron atom scattering, that is, atomic beam recoil, was developed several years ago (Bederson in *Methods of Experimental Physics* (ed. Bedersen B. and Fite W. L.) **7A**, 89 (Academic, 1968) for measuring σf or the scattering of electrons off ground state atoms. In this procedure a well defined narrow atomic beam is cross fired at right angles by a beam of low energy electrons. The collimation in the apparatus after the interaction region is sufficient to enable the reduction in flux of the atomic beam to be monitored. The signal scattered out of the incident beam by the electrons $\Delta I = I_o - I_s$ (where I_o and I_s are the atomic beam current with the electron beam off and on respectively) therefore gives a direct measure of the total electron scattering cross section. The removal of atoms from the beam is the dynamical effect of the momentum transfer imparted by the scattered electron to the atoms and this is sufficient to cause atomic recoils of several degrees.

No scattering experiments so far have taken advantage of the dynamical effects of photon–atom interactions as a diagnostic method. The momentum transferred to an atom, of mass m and velocity V, by resonance absorptions, at wavelength λ, will result in a recoil through an angle α_o ($= h/m V\lambda$) with a recoil in the opposite direction for stimulated emission. Since spontaneous emission is random in direction the steady state recoil experienced by an atom passing through a laser beam will saturate at a value of $\alpha_o t / 2\tau$, where t is the time spent in the laser beam and τ is the natural life time of the atomic state being excited. In the experiment of Bhaskar *et al.* (*Phys. Rev. Lett.* **38**, 14; 1977) $\alpha_o \approx 3\times10^{-5}$ rad per photon absorption and the nett atomic beam deflection observed at 80 cm from the interaction region is several millimetres. This photon dynamical effect can now be combined with the atom recoil technique where the laser beam is perpendicular to the plane containing the atom and electron beams. This will yield the total cross section for scattering of electrons from the excited state $3^2P_{3/2}$ ($M_F = 3$) using the relation

$$\Delta I_{on} / \Delta I_{off} = f(\sigma_e / \sigma_g) - 1) + 1$$

where ΔI_{on} and ΔI_{off} are the atom scattering out signals with the laser beam on and off respectively, and σ_e and σ_g are the total cross sections for electron scattering off excited and ground state atoms respectively. Bhaskar *et al.* have measured the absolute value of σ_e at an incident electron energy of 4.4 eV and obtained a value of $(285 \pm 55)\times10^{-16}$ cm^2.

Extension of this technique to differential cross-section measurements and to experiments in which the spin state of the atom is selected will greatly increase the knowledge of fundamental processes in atomic scattering. ☐

A hundred years ago

A MEDAL to commemorate the part taken by the Institute of France in the observation of the transit of Venus has been struck at the national mint. It bears the representation of a female passing before the car of Apollo, with the motto in Latin, "Quo distent spatio, sidera juncta docent." Each member of the Institute has received a silver medal, as well as the heads of the mission; the assistants received a bronze one. A medal has been cast in gold and presented to M. Dumas, the President of the Transit Commission. The expenses were defrayed by subscription among the members of the Institute.

From *Nature* **15**, February 15, 344; 1877.

Strategy for detection of cancer hazards to man†

Sir Richard Doll*
